BAILEY & LOVE'S SHORT PRACTICE OF SURGERY

SEVENTEENTH EDITION

Revised by

A. J. HARDING RAINS AND **H. DAVID RITCHIE**

M.S. (Lond.), F.R.C.S. (Eng.)

Professor of Surgery, University of London at Charing Cross Hospital Medical School; Hon. Consultant Surgeon, Charing Cross Hospital; Member of Council, Royal College of Surgeons of England; Hon. Consultant Surgeon to the Army; Dean, Institute of Basic Medical Science, R.C.S. and British Postgraduate Medical Federation; Examiner in Surgery, Universities of London, Birmingham and Oxford (M.Ch.); Formerly Examiner in Surgery for the Universities of Belfast and Newcastle upon Tyne and Examiner for the Primary F.R.C.S. (Eng.) and Member of the Court of Examiners, Royal College of Surgeons of England.

M.A. (Camb.), Ch.M. (Ed.), F.R.C.S. (Ed.), F.R.C.S. (Eng.)

Professor of Surgery, University of London at The London Hospital Medical College; Hon. Consultant Surgeon, The London Hospital; Examiner in Surgery, the Universities of London and Liverpool and the Royal College of Surgeons of Edinburgh; Formerly Member of the Court of Examiners of the Royal College of Surgeons of England, the Worshipful Society of Apothecaries and the University of Dundee.

Specialist chapters by

GEOFFREY KNIGHT

F.R.C.S. (Eng.)

Senior Surgeon, West End Hospital for Neurology and Neuro-surgery; Neurological Surgeon, Royal Postgraduate Medical School, London, and Queen Elizabeth Hospital for Children; Surgeon in charge, S.E. Metropolitan Regional Neuro-surgical Centre; Hunterian Professor, Royal College of Surgeons.

WILLIAM P. CLELAND

F.R.C.S. (Eng.), F.R.C.P. (Lond.), F.A.C.S.

Surgeon, Brompton Chest Hospital and Director, Department of Surgery, Institute for Diseases of the Chest; Thoracic Surgeon, King's College Hospital and Royal Postgraduate Medical School, London; Consulting Thoracic Surgeon to the Royal Navy.

MICHAEL A. R. FREEMAN

M.D. (Camb.), F.R.C.S. (Eng.)

Consultant Orthopædic Surgeon, The London Hospital; Senior Lecturer in Orthopædic Surgery, London Hospital Medical College, University of London; Director Biomechanics Unit, Department of Mechanical Engineering, Imperial College, London.

PETER F. PHILIP

M.S. (Lond.), F.R.C.S. (Eng.)

Surgeon and Consultant Urologist, Charing Cross Hospital, Royal Masonic and Bolingbroke Hospitals, London; Examiner in Surgery, University of London.

PREFACE TO SEVENTEENTH EDITION

Undergraduate and postgraduate students alike increasingly feel as we do, that they may find themselves inadequately equipped to face the examination hazards with which they are confronted unless they have access to a text which has recently been updated. Seeking to supplement out-of-date textbooks by using addenda in the form of recent advances in a subject may lead to difficulties in integration, within the limited time available to the modern student. We present this latest edition of 'Bailey and Love' in the belief that the present extension of authorship in various chapters is an essential prerequisite to providing the type of up-to-date comprehensive volume which can meet their needs. On the following pages we readily acknowledge our many collaborators who are numbered amongst the experts in their respective fields.

Technological advances have necessitated further supplementation of the descriptions of investigative techniques, particularly E.R.C.P., and EMI scanning. Also we have come to terms with the change to SI Units of measurement. But we have tried to ensure that none of this be allowed to distract us from achieving such clarity and emphasis as we can in describing the basic clinical signs and symptoms which are absolutely essential to therapeutic success in the surgical field.

The authorship is in the hands of surgeons with experience in British teaching hospitals and the preparation of students for current examinations in surgery. At the same time we have not forgotten one of the original aims of this textbook which is to provide a reliable and continually up-dated account of current surgical practice for those parts of the world where medicine may be less well developed and supported than it is in Britain. Indeed we trust that Bailey and Love's 'Short Practice' will continue to fulfil its role as a reference book for surgeons who do not have ready access to information on latest trends and developments.

ACKNOWLEDGMENTS

We acknowledge in particular the help received in rewriting and revising the following sections in this edition:

Wounds. Skin and Burns. Ian F. K. Muir, *M.B.E.*, M.S., F.R.C.S., Consultant in Plastic Surgery, N.E. Regional Hospital Board, Scotland.

Bomb Blast and Terrorist Warfare. Lt.-Col. N. A. Boyd, *O.B.E.*, M.S., F.R.C.S., R.A.M.C.

Infection. William A. Gillespie, M.D., F.R.C.P.I., Professor of Bacteriology, University of Bristol.

Leprosy. Dr. R. J. W. Rees, F.R.C.Path., National Institute for Medical Research, Mill Hill.

Syphilis. Alfred E. Tinkler, M.D. (Dub.), D.P.H., Consultant Venereologist, Bristol.

Melanoma. Gerald Westbury, F.R.C.S., M.R.C.P., Consultant Surgeon, Westminster Hospital, London.

Blood Transfusion. Marian S. Edwards, M.R.C.Path. Consultant Hæmatologist, Ipswich Group of Hospitals, Ipswich, Suffolk.

Fluid and Electrolyte Balance. Surgical Nutrition. Brian E. Lane, F.R.C.S., Consultant Surgeon, Jervis Street Hospital, Dublin, Ireland.

Hodgkin's Disease. Keith W. Reynolds, M.S., F.R.C.S., Consultant Surgeon, Charing Cross Hospital, London.

Boeck's Sarcoid. David G. James, M.D., F.R.C.P., Consultant Physician and Dean, Royal Northern Hospital, London.

Arterial Surgery. Brian P. Bliss, M.S., F.R.C.S., Consultant Surgeon, Plymouth Hospitals.

Neurological Disorders Affecting the Musculo-Skeletal System. Brian McKibbin, M.Sc. (Surg. Illinois), M.D. (Leeds), F.R.C.S., Professor of Traumatic and Orthopædic Surgery, Welsh National School of Medicine, Cardiff, Wales.

Eyes. Miss E. M. Eagling, F.R.C.S., Consultant Ophthalmic Surgeon, The Midland Eye Hospital, Birmingham.

Ear, Nose and Throat. H. B. Holden, F.R.C.S., Consultant E.N.T. Surgeon, Charing Cross Hospital, London.

Salivary Glands. G. R. Seward, M.D.S., F.D.S., M.B., B.S., Professor of Oral Surgery, The London Hospital, London.

Thyroid. James S. Hilary Wade, *M.C., T.D.*, F.R.C.S., Consultant Surgeon, United Cardiff Hospitals, Wales.

Parathyroids. Ernest Morrison, F.R.C.S., Consultant Surgeon, Royal Victoria Hospital, Belfast.

Breast. Sir James Fraser, Ch.M.(Ed.), F.R.C.S.(Ed.), Professor of Surgery, The University of Southampton.

Liver. R. Shields, M.D., F.R.C.S., Professor of Surgery, The University of Liverpool and A. G. Johnson, M.Chir., F.R.C.S., Reader in Surgery, Charing Cross Hospital, London (Injection of Varices).

Colon and Rectum. C. V. Mann, M.Ch., F.R.C.S., Consultant Surgeon to The London and St. Mark's Hospitals, London.

Polyps. Ian McColl, M.S., F.R.C.S., Professor of Surgery, Guy's Hospital Medical School, London.

Transplantation. Grant B. Williams, M.Sc. (Lond.), M.S., F.R.C.S., Surgeon, Transplant Unit, Charing Cross Hospital and Consultant Urologist, Charing Cross, St. Stephen's and the Royal Marsden Hospitals, London.

The Surgical Patient. Dr. Glin Bennet, M.D., F.R.C.S., M.R.C.Psych., Consultant Psychiatrist, United Bristol Hospitals, Bristol, Senior Lecturer in Psychiatry, University of Bristol.

Biographical Data

John G. Fairer, *T.D.*, LL.B., F.F.A.R.C.S., (Barrister, Inner Temple), Honorary Archivist, Faculty of Anæsthetists, Royal College of Surgeons of England.

Both Hamilton Bailey and McNeill Love, when medical students, served as clerks to Sir Robert Hutchison, 1871–1960, who was Consulting Physician to the London Hospital and President of the Royal College of Physicians. They never tired of quoting his "Medical Litany" which is appropriate for all clinicians, and, perhaps especially, to those who are surgically minded.

"From inability to leave well alone;
From too much zeal for what is new and
contempt for what is old;
From putting knowledge before wisdom,
science before art, cleverness before
common sense;
From treating patients as cases; and
From making the cure of a disease more
grievous than its endurance,
Good Lord, deliver us."

to which may be added:

"The patient is the centre of the medical universe around which all our works revolve and towards which all our efforts trend." J. B. Murphy, 1857–1916, Professor of Surgery, Northwestern University, Chicago, U.S.A.

"To study the phenomena of disease without books is to sail an uncharted sea, while to study books without patients is not to go to sea at all." Sir William Osler, 1849–1919, Professor of Medicine, Oxford, England.

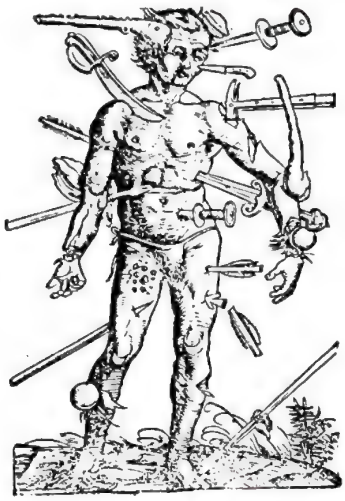
A SHORT PRACTICE OF SURGERY

CHAPTER I

WOUNDS AND SEPSIS

'Skin is the best dressing'

FROM the earliest times the healing of wounds has been the central problem in surgical practice (fig. 1). This applies equally to the wounds of warfare and human assault, to the wounds of accidents, and to the wounds which the surgeon makes deliberately in the course of surgical operations. Once made,



From a handbook for army surgeons, in the middle ages.
FIG. 1

FIG. 2.—Joseph Lister, FRCS, aged 28. 'The father of modern surgery' 'The man who made surgery safe'.

the breach in the surface of the body, the skin, exposes the deeper tissues to the danger of bacterial infection (sepsis), and this danger persists until the healing process has restored an intact surface.

A Sharp Lesson from History.—It has often been said, and truly, that the practice of surgery can be divided into surgery before Lister and surgery after Lister (fig. 2). The meaning of this statement is to be found in an understanding of certain aspects of his research, by animal and human experiments. Armed with a splendid microscope, for his father had perfected the achromatic lens, and working all hours after a day's work in hospital, he was amongst the first to describe accurately the early vascular changes of inflammation[1] due to injury, and how increased blood flow

[1] For this work he was elected F.R.S. in 1860.

Joseph Lister (Lord Lister), 1827–1912. Professor of Surgery, Glasgow, Scotland (1860–1869), Edinburgh (1869–1877), and King's College Hospital, London (1877–1892). He reported on the use of a carbolic dressing to prevent infection in a paper in the Lancet in 1867.

(hyperæmia) was followed by intravascular coagulation. Had he prolonged his 'glorious' nights and got no sleep at all, he would have antedated the discovery of the cellular component of inflammation (migration of leucocytes by Cohnheim and phagocytosis by Metchnikoff).

Lister was puzzled and perplexed by inflammation which was then running amok in patients with wounds involving the skin, especially those with compound fractures. The sepsis and fulminating putrefaction were terrible indeed. Recovery after such an injury or an operation was considered by many surgeons to be a matter of luck. There was a mortality of up to 80% after amputation, reaching almost 100% in those wounded on the battle-fields of those days.

When his attention was drawn to the work of Louis Pasteur on fermentation indicating the presence of ' microbes in the air ', Lister immediately guessed why inflammation got so out of hand in surgical patients. By incorporating carbolic acid, already known as a disinfectant of sewage, in the dressing of wounds of hitherto unfavourable cases, sepsis was overcome and prevented. This work led him, in spite of disbelief by others in Pasteur's theory and his own clinical hypothesis and application, to an enunciation of his antiseptic principle—that every procedure of surgical technique should be against sepsis, *i.e.* anti-sepsis. Extending the use of carbolic acid and other chemicals, such as mercury perchloride and iodine, he produced, in effect, sterile dressings, catgut and silk ligatures, and metallic means for the open reduction of fractures. A carbolic acid spray was employed temporarily to act as another barrier to those (then) theoretical germs.

As a result, surgery was released from the shackles of sepsis and immediately most operations commonly practised today were thought out and put into practice. Other methods, based on the use of heat (e.g. the autoclave) were introduced to prevent infection during operation. Strictly speaking, the word ' asepsis ' was an unnecessary innovation. Lister had demonstrated that safe surgery was dependent upon surgeons committing themselves and whatever techniques they devised to being anti-sepsis.

The moral of this story is obvious. If we survey the everwidening surgical scene of today it is plain that the battle against sepsis (antisepsis) must continue. In the midst of successes we see occasional grim reminders that patients can still fester and die from whole-body inflammation, namely septicæmia, vascular paralysis and a disseminated form of the intravascular coagulation which Lister had observed in his early researches.

WOUND HEALING

Healing by First Intention.—Rapid healing of the wound, particularly rapid skin cover, is the ideal objective—the first intention—of the surgeon. This is brought about by joining together the edges of the wound by sutures[1] (figs. 4, 5 and 6), by clips, or by adhesive materials, e.g., film or tape.

---

[1] Suture (Latin) = Sewing together (a stitch). A seam. Ligature (Latin) = Anything that binds together.

Julius Cohnheim, 1839–1884. Professor of Pathology, Leipzig.
Elie Metchnikoff, 1845–1916. A Russian biologist who worked in France.
Louis Pasteur, 1822–1895. Chemist and Bacteriologist. Professor of Chemistry, Sorbonne, Paris.

Alternative methods of closure used to achieve protection against infection by skin cover include *delayed primary suture*, *secondary suture*, and *skin grafting* (p. 119).

Healing by Second Intention occurs: 1. When the wound edges are not brought together. 2. When there is skin loss which cannot be repaired. 3. When the wound becomes infected and breaks open, or has to be laid open.

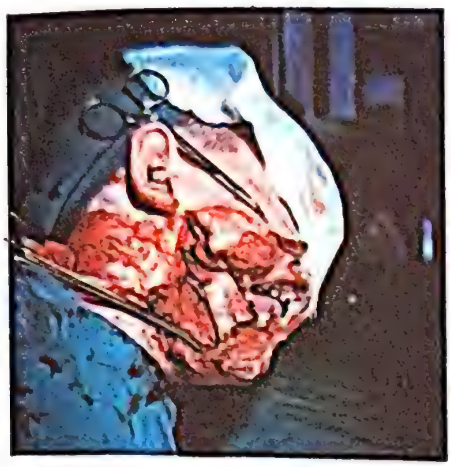


FIG. 3.—Severe facio-maxillary injury. (*Rainsford Mowlem, F.R.C.S.*)

FIG. 4.—Accurate suture and healing by first intention (fig. 5). (*Rainsford Mowlem, F.R.C.S.*)

FIG. 5.—See figs. 3 and 4. Healing by first intention.

FIG. 6.—Ulcers of the leg healing by second intention.

Healing by second intention is the normal way of healing of an ulcer (fig. 6) or of an abscess after it has been drained.

Healing by second intention is much slower than healing by first intention and invariably involves the laying down of more scar tissue (p. 14). The longer the wound remains raw, the greater will be the amount of scar tissue laid down and the greater will be the contraction and deformity.

Factors Influencing Wound Healing

General State of the Patient (including Nutritional State).—If the patient's reserves have been very depleted by a long illness, such as carcinoma of the stomach, or he has jaundice, then wound healing may be very slow.

It is important under these conditions that any deep sutures in muscle planes should either be of non-absorbable material, or deep tension sutures should be employed, and the skin stitches should be left in longer than usual. When much tissue healing is required, e.g. after an extensive burn, the patient needs a high protein, high calorie diet.

Local Factors influencing wound healing can be summarised as follows:—

Favourable	*Unfavourable*
Tissues in the wound should be healthy, with a good blood supply.	Poor blood supply, due to trauma or vascular disease.
No dead tissue should be left in the wound.	Presence of dead or damaged tissue.
No tension in tissue planes.	Tension.
No hæmatoma.	Hæmatoma formation.
Minimum of foreign material, e.g. ligatures and sutures.	Presence of large amounts of foreign material, e.g. catgut, silk.
No pathogenic bacteria.	Presence of pathogenic bacteria.

Blood Supply.—The blood supply of the wound is of great importance and it is noteworthy that wounds of the face, because of their excellent blood supply, heal well (fig. 5), even though they may communicate with the cavities of the mouth and nose, and some degree of bacterial contamination is inevitable. On the contrary, wounds of the lower leg, particularly in patients with arterio-sclerosis and diabetes, are very liable to infections.

Vitamin C.—In experimental work this has been shown to have a marked effect on wound healing.

Tissue Oxygenation.—Wound healing would be delayed if this is unsatisfactory because of anæmia or the reduction of blood supply, e.g. by obstruction of the main blood-vessels.

Completion of Healing.—Complete healing of a wound takes a long time. The collagen fibres of the uniting scar tissue undergo repeated disruption and reformation before final maturation. The tensile strength of the wound only approaches that of normal tissue after 6 months, but 100% completion may take as long as 2 years.

Examples of Wound Surgery and Closure

Incised Wounds = Primary Suture.—These as the name implies are clean wounds with minimal tissue damage sustained as the result of cuts with knives, broken glass etc. These wounds should be treated by suture of all structures (including tendons and nerves) within 6 hours of the injury (p. 198).

Lacerated Wounds = Wound Excision[1] and Primary Suture of Skin.—This group includes most wounds seen in civilian practice—road traffic accidents, industrial injuries. The wounds are due to relatively blunt objects and are associated with a certain amount of tearing so that the edges

[1] Debridement (Débridement = unleashing).—This term was introduced by Dominique Jean Larrey, 1766–1842, the famous French surgeon in Napoleon's army. He used it to describe the removal of bullets, bits of cloth, loose bits of bone and soft tissue—a much less extensive procedure than the thorough wound excision which is now practised.

and surfaces of the wound are jagged and contain moderate amounts of devitalised tissue.

These wounds may be treated by *wound excision and primary suture of the skin within 6 hours of injury*. Each layer is tackled in turn and devitalised tissue is carefully trimmed away. The object of wound excision is to convert the injury from a jagged lacerated wound into one which approximates to the incised wound. However, a certain amount of damaged but recoverable tissue remains in the wounds, and for this reason it is usually unwise to attempt complicated repairs of deep structures such as tendons and nerves in these wounds. As soon as the skin wound is soundly healed, probably in 4 to 6 weeks' time, a formal secondary repair of any divided tendons and nerves can be carried out. (Marking and suture of nerves, Chap. 26.)

Crushed and Devitalised Wounds. War Wounds = Wound Excision and Delayed Primary Suture of Skin.—Three difficulties exist in this type of wound which includes the most serious wounds due to road traffic accidents, industrial accidents and war injuries, e.g. gunshot wounds and explosions:—

1. It may be impossible with certainty to distinguish between viable and non-viable tissue.

2. Because of extensive tissue damage great swelling of the tissue may occur. If primary suture is performed, the inflammatory œdema and therefore the tissue tensions may rise to dangerously high levels resulting in local ischæmia[1] and local death in tissues which were previously viable. Dead muscle is the ideal environment for the development of gas gangrene.

3. The wound may be heavily contaminated by bacteria.

Treatment of these wounds commences by careful excision of dead tissue, layer by layer. Any dead muscle should be widely excised (gas gangrene, p. 28). The wound is not sutured but left open and dressed. The wound is re-examined 4 to 6 days later, and if it is confirmed that all remaining tissue is viable and the œdema has subsided sufficiently to allow the wound to be sutured without tension, *delayed primary suture* can be performed. This 2-stage procedure is particularly successful for war and gunshot wounds (see missile wounds p. 8). So important is it to avoid tension that it may be safer to close the wound by skin grafting even when no skin loss has taken place. When the wound has healed and the tissue tensions have returned to normal, the graft can be excised and the skin sutured in the usual way.

If there is any doubt about the advisability of suture—DON'T.

Wounds with Skin Loss (figs. 7, 8 and 9).—The patient is in danger from superadded infections until the wound has completely healed by re-epithelialisation of the skin surface. Healing of the skin layer is of importance not only in its own right but because the healing of deeper structures, such as the tendons and bones, can only take place satisfactorily in the presence of an intact skin cover. Furthermore, the longer any exposed surface remains raw the greater will be the deformity and disability. In all wounds with skin loss

[1] Ischæmia (Greek) = A lack of blood flow.

FIG. 7. FIG. 8. FIG. 9.

FIGS. 7, 8 and 9.—Wound excision and primary skin grafting.

therefore, the skin loss should be repaired as soon as is practicable and as follows:—

1. Clean incised wounds with skin loss—Primary grafting.
2. Lacerated wounds with skin loss—Wound excision and primary grafting.
3. Crushed and devitalised wounds with skin loss—Wound excision and delayed primary, or occasionally secondary grafting. For types of skin-grafting for burns wounds, see p. 119.

Secondary Suture, by freeing skin at the edge of a granulating wound is rarely used. It is easier and safer to perform secondary grafting and to carry out any reconstructive surgery later.

Management of Wounds due to Injury

It should go without saying, and yet it has to be said, that all who would deal with the wounded must understand the principles of First Aid. Members of the medical profession are often criticised for their lack of knowledge of this subject. The reader is strongly recommended to possess an up-to-date handbook. Suffice to say, in the plan of action presented here, that the following are assumed to have taken place:—(i) *First aid*—attention to the three B's—Breathing (airway), Bleeding (Chap. 5), Breaks (and Bends), (ii) *The prevention of the second accident*, namely loss of life due to lack of perseverance with first aid measures during transport and until handing over to the surgical and resuscitation teams in a hospital, and (iii) *Resuscitation*, including intravenous infusion, and as required, tracheal intubation and chest drainage. The first two of these measures may have been required at the place of injury (e.g. on a motorway).

The Practical Technique of Wound Management

1. Examine the patient. Is he shocked? (p. 77). Has he any other injuries?

2. Examine the wound. If the wound is bleeding, or the patient is in pain or frightened, it is often not possible to make a detailed examination of the wound. Nevertheless, much useful information can be obtained from a brief superficial examination.

3. Have any deep structures been divided by the injury? More complications occur simply because the observer has failed to think about what structures might have been involved than because of any technical short-comings in the operation. *Limbs*—Has a tendon been involved? Test movement. Has a nerve been involved? Test movement and sensation. Examine for fractures. *The Abdomen*—Has a viscus been involved? If so, which viscus? Examine the urine. *The Head*—Has the skull been damaged—or the brain, or the eye, or the ear? (see Head injuries, Chap. 24).

Procedure in the Operating Theatre.—Cover the wound with a dry sterile swab and wash and clean the skin around the wound, then arrange the towels in place. Leave the cleaning of the wound itself until last. The wound must now be examined and treated layer by layer. Tattered skin should be trimmed, but viable skin need not be excised. If necessary, the wound must be extended so that a good view can be obtained of the underlying tissues. If deep fascia has been injured the layer should be freely incised to open up the muscular compartment. Damaged muscle must be excised until the muscle bleeds freely and contracts when it is cut. Bone recovers well, and any fragment should be replaced in position. Foreign bodies should be located and removed. Any tendons, nerves or major blood vessels crossing the wound should be carefully examined to determine if they have been injured or not. If the abdomen or chest, or the cranium have been involved by the wound, the wound must now be suitably enlarged so that the deeper parts can be examined and any necessary repair carried out, following the rules outlined in the succeeding paragraphs on skin closure and missile injuries. Any necessary splintage should be applied: (*a*) If a fracture needs immobilising. (*b*) If the soft tissue injury is extensive even when there is no fracture.

Antibiotics in the Treatment of Wounds

The most important factor in the avoidance of infection in wounds is careful operative treatment as described above, because if only healthy, well vascularised tissues are left in the wound, the body's defences will be able to deal with all but the most virulent organisms. With extensive wounds with much tissue damage, or if there has been any delay in treatment, systemic antibiotic therapy should be administered. Systemic penicillin over a period of 5 days should be routine, further therapy being dependent upon clinical progress and on the result of bacteriological examination of wound swabs (p. 18).

Prophylaxis against tetanus is described on p. 26.

Wound Infection. On inspection there is redness in the margin of the wound and swelling. Later, small abscesses may appear in relation to the stitches. Infection may spread into the surrounding subcutaneous tissue (cellulitis, p. 22) and collections of pus may form in the layers of the wound. At this stage, the patient is usually toxic and the temperature is raised. If the infection is particularly virulent, invasion of the blood-stream (septicæmia, p. 23) may occur. (Also see sepsis, p. 15.)

Treatment

1. *Early stages*—if the infection is treated before pus formation occurs, it may be possible to halt it by systemic antibiotic therapy. Any stitches which appear to be tight or causing tension should be removed.

2. *Stitch Abscess Formation.*—Any affected stitches should be removed. If there are no deep collections of pus then the infection may subside more quickly.

3. When deeper pus formation has taken place the stitches should be removed. This may result in sufficient separation of the edges of the wound to achieve satisfactory drainage, but otherwise the patient should be returned to the operating theatre, the wound opened and drained and allowed to heal by second intention.

SPECIAL TYPES OF WOUND

Penetrating Wounds

Penetrating wounds are notoriously deceptive. A sharp object can penetrate many inches with a mere slit in the skin as the only immediately obvious sign. Impaired movement or loss of sensation indicates injury to tendons or nerves, and hæmorrhage may be obvious, e.g. ' butcher's thigh ' (p. 134).

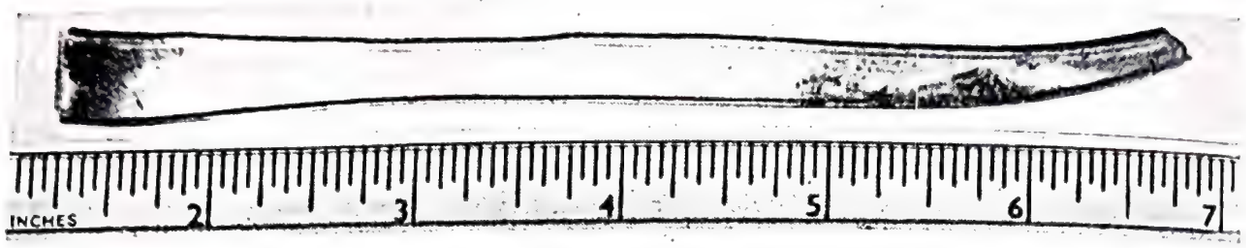

FIG. 10.—Following an air raid a man, aged fifty, walked into an adjacent hospital because of minor facial wounds. He collapsed and died a few minutes later, quite unaware that this slender piece of glass, which was just protruding through the skin, had penetrated three layers of clothing and his abdominal wall. It had severed the middle colic artery.

(*Mildmay Mission Hospital, London.*)

Penetrating wounds of the abdomen may be symptomless until internal hæmorrhage (fig. 10) or peritonitis indicates damage to blood-vessels, solid viscera or bowel; therefore the wound must be explored without delay to discover whether there is intraperitoneal injury.

MISSILE INJURIES

As Urban Terrorist Warfare becomes increasingly common throughout the world it is necessary to understand the mechanism and the management of bullet and bomb blast injuries.

Mechanism.—The amount of damage caused by missiles is dependent on the kinetic energy (KE) released by the missile as it traverses tissue. The energy can be calculated from the formula $KE = \frac{1}{2}MV^2$, where M is the mass and V the velocity of the missile.

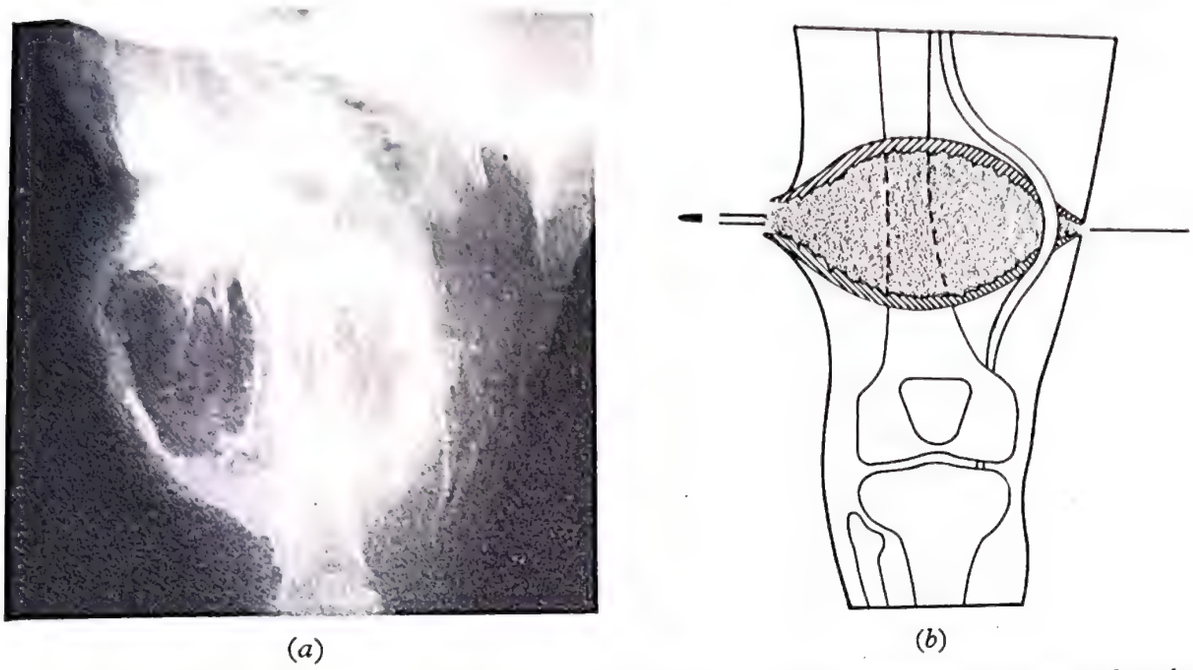
The low velocity missile, such as a bullet from a pistol, travelling below 1,500 feet per second, produces injury by its direct effect on tissue by laceration and crushing, within the narrow confines of the missile track.

The high velocity missile, the sniper's bullet, has a much greater lethal potential. Tissue necrosis occurs several centimetres on either side of the missile track due to the associated shock-wave and a phenomenon known as cavitation. The penetrating high velocity missile releases energy which is absorbed by adjacent tissue particles, imparting to them an acceleration which flings them forwards and outwards producing the temporary cavity (fig. 11).

Tissue necrosis occurs especially in muscle at some distance from the missile track and forms a perfect culture medium for pathogenic organisms sucked in from the entrance and exit wounds by the negative pressure in the cavity.

The amount of damage caused by a high velocity missile is also dependent on the density and structure of the target organ. Comparatively little damage occurs in the through and through wound of a lung, whereas the passage of such a missile through or sometimes close to the liver may completely shatter that organ.

Bombs.—Injury from bombs is not only related to the size, velocity and flight characteristics of the penetrating fragments, but is also compounded by the effect of the pressure wave that accompanies an explosion. Close to a bomb blast the positive



(*a*) (*b*)

FIG. 11.—High velocity missile injury (experimental). (*a*) X-ray taken 30 msec after the bullet had traversed the limb. The cavity is collapsing. (*b*) Cavitational destructive effect due to the energy of the high velocity missile. The arteries and nerves are often temporarily displaced by such an insult.

pressure phase of the blast wave may rise momentarily to over a thousand pounds per square inch (6895 kN/m^2). As the tympanic membrane ruptures at about twenty pounds per square inch (138kN/m^2), it is evident that the effect on the human body of such an explosion may be devastating, especially in confined areas.

(*a*) (*b*)

FIG. 12.—High velocity missile wound. (*a*) Entrance wound. (*b*) Exit wound.

Management.—All missile injuries should undergo the operation of wound debridement, which literally means to debridle or unleash. The entrance and exit wounds, frequently of only small diameter (fig. 12), do not indicate the considerable damage that may have occurred to the deeper

structures within. The higher the velocity of the missile, the greater the area of damage around the missile track, and the greater the accompanying tissue necrosis and œdema.

After cleansing with an antiseptic, the *skin is incised* using generous longitudinal incisions in order to examine thoroughly the deeper structures and facilitate subsequent extension of the exposure should this be required. A minimal amount of skin edge is excised and only that which has been contaminated. Skin, being an elastic structure, stretches easily and is capable of withstanding the short insult as the missile traverses the tissue.

Once incised, the *deep fascia is exposed*, under which is usually seen a tense bulging hæmatoma. The deep fascia must be split widely in order to decompress tissue and

(*a*) (*b*)

FIG. 13.—High velocity missile wound. (*a*) Extensive exploration of the entrance wound in the groin was required in order to adequately complete wound debridement and gain proximal control of the femoral artery should this have been damaged. The extent of the skin incision is clearly demonstrated, which was partially restored at initial operation after exploration of the large vessels. (*b*) The exit wound in the buttock is shown here at the end of wound debridement prior to delayed primary closure.

allow adequate inspection of the necrotic area. It is one of the most important facets of wound debridement (fig. 13).

Before further proceeding with the operation, *identification of the neurovascular bundles* is imperative and can be difficult in the necrotic tissue. A tourniquet may be used to aid identification, but once the structures are seen it must be released in order to confirm viability of tissue. Dead muscle, muscle that does not bleed, does not contract and has an unhealthy colour, should be excised. It can sometimes be difficult, however, to distinguish bruised muscle from dead muscle.

Foreign matter should be removed from the wound and pieces of clothing especially looked for both in the missile track and in the tissue planes on either side. It is not necessary, however, to go after every piece of metal seen on X-ray, especially in mine injuries, for their particular retrieval would probably only cause further morbidity.

The ends of *severed tendons* are trimmed. Primary suture is not performed at initial operation.

Severed nerves should be tacked together lightly using two stitches in order to preserve nerve length. No formal repair is carried out. It is important to record in the operation note the type of nerve injury, for postoperatively a neurological deficit is frequently found in spite of the presence of an intact nerve seen at operation.

Bone is invariably shattered into many fragments following a high velocity missile injury. At debridement the majority of fragments are found to have some attachment either through periosteum or muscle. On no account should bone be discarded from such a wound, for loss of bone will result in subsequent loss of limb length or non-union. Contaminated bone is cleaned as best as possible using a curette and retained within the wound. Internal fixation of bone is never used at the time of initial surgery. The only exception to this is in some cases of multiple fractures in the hand or foot or to protect an arterial anastomosis. The very nature of the comminuted fracture does not anyway lend itself readily to internal fixation.

At the end of operation the wound should be irrigated thoroughly with an antiseptic solution to remove any remaining debris. Hæmostasis is secured as best as possible. The wound is then left open without closure of either fascial layer or skin, even in the presence of exposed bone. A lightly fluffed gauze dressing is placed over the wound to allow free drainage. Plugs of paraffin gauze or tight packing of the wound must be avoided as they prevent drainage which inevitably occurs in this type of injury. Immobilization in a padded plaster aids rest to the soft tissues whether or not there is an accompanying fracture. Antibiotic cover, *e.g.* a combination of ampicillin and cloxacillin, is usually reserved for those high velocity missile injuries that have involved bone.[1]

Delayed Primary Closure.—All wounds treated by wound debridement and left open are inspected under a general anæsthetic on about the 4th to 6th day after injury. Provided the wound looks healthy delayed primary suture is performed.

In certain wounds especially in the swollen limb, split skin grafting may be used to effect wound closure in order to avoid skin tension. If, at the time of delayed primary closure dead muscle is found, perhaps having been retained due to doubt at the first operation, the muscle is excised and the wound left open for a further period before closure.

SUMMARY—DO'S AND DON'TS OF MISSILE INJURIES

DO	*DON'T*
INCISE THE SKIN GENEROUSLY	EXCISE TOO MUCH SKIN FROM WOUND MARGIN
INCISE THE DEEP FASCIA WIDELY	PRACTISE KEYHOLE SURGERY
IDENTIFY NEUROVASCULAR BUNDLES	STITCH TENDONS OR NERVES
EXCISE ALL DEAD MUSCLE	REMOVE BONE
REMOVE ALL INDRIVEN CLOTHING	CLOSE THE WOUND
RECORD THE EXTENT OF DAMAGE IN OPERATION NOTES	PACK THE WOUND TIGHTLY BUT ALLOW FREE DRAINAGE: USING LIGHTLY FLUFFED GAUZE
LEAVE WOUND OPEN AT END OF OPERATION	

Gunshot Wounds of the Abdomen

Every gunshot wound of the abdomen requires exploration. Blood loss can be considerable in this type of injury and adequate fluid replacement therapy must be available. Longitudinal incisions are made in order to facilitate their extension.

The passage of a high velocity missile close to bowel or a solid organ may result in considerable damage to that structure due to the associated shock wave and cavitation effect of the missile. Deep rents may be found in the liver substance following the passage of a high velocity missile either above or below the organ. The lethal potential of bruised bowel wall may go unrecognised. If it is returned to the abdominal cavity it may subsequently become gangrenous and give way 24 to 48 hours after injury.

Gunshot wounds of the colon and rectum require a colostomy of some description. If the damaged section of large bowel is resected and a primary anastomosis performed, a proximal colostomy must be carried out in order to defunction the distal bowel. Alternatively the injured bowel may be resected and both ends brought out to the surface, one as a colostomy and the other as a mucous fistula. In the very ill, exteriorization of a loop of damaged bowel is permissible with subsequent fashioning of the colostomy at a later stage. Primary anastomosis without a drainage procedure only courts disaster, with intra-abdominal sepsis and fistula formation.

---

[1] The combination of penicillin and tetracycline is not advised.

Injuries to the kidney should be treated by conservative surgery. Immediate nephrectomy is seldom indicated. The closure of a damaged calyx, with nephrostomy, along with the control of hæmorrhage from the renal cortex by a free muscle graft, will often suffice. Distortion of the renal architecture, by trying to close the capsule of the organ, is probably undesirable.

Injuries of the pelvis are commonly lethal, death frequently being due to secondary hæmorrhage following sepsis. It is essential at the time of initial surgery to provide adequate perineal drainage with excision of the coccyx if necessary.

Gunshot Wounds of the Chest (see also Chap. 38).

Penetrating wounds of the pleura and lung may require adequate ' venting ' of the chest to prevent or deal with the embarrassment of respiration caused by rapid accumulation of air under tension and blood. It may be necessary to insert chest drains before the availability of a chest x-ray. Once pulmonary function is stabilised, operation with wound debridement is carried out as described on p. 4.

Gunshot Wounds of Head

The penetrating high velocity missile wound of the brain is lethal. The management of the low velocity penetrating missile and tangential wound depends initially on the maintenance of a satisfactory air way and restoration of blood volume in order to maintain adequate oxygenation of the brain. Good x-rays are mandatory to localise indriven bone fragments. Wound debridement is carried out using gentle irrigation and suction to remove necrotic brain and bony fragments. Every effort, including the use of a piece of temporalis fascia, is made to close the dura.

It has been shown that the application of intermittent positive pressure ventilation (PCO_2 4-4·7 kPa) assists in the reduction of intra-cranial pressure by reducing brain swelling. More maimed brains have been caused by the lack of oxygen than by the bullet.

Foreign Bodies in the Tissues

In every case of suspected foreign body which is opaque to x-rays, a radiograph must be taken in at least two planes. When removal is attempted, a good light, ample time, proper anæsthesia and a bloodless field are all invaluable together with the use of x-rays in the localisation of the object by means of metal skin markers, needles and in particular an x-ray image intensifier with a T.V. display screen.

Hypodermic needles may break at the neck. The most difficult needle to recover is one situated in the internal pterygoid muscle, which has broken when a dental surgeon has attempted a mandibular block. The glistening tendinous intersections in the muscle continually raise the surgeon's hopes, but patience is usually rewarded.

Domestic needles commonly become impacted between the small bones of the hand or foot. The patient may be entirely unaware of their entry. Unless a small fragment is lodged deeply, removal is advisable, as infection may otherwise develop, and startling cases are on record in which a needle has entered the venous circulation and become embedded in the heart muscle, or travelled to some distant part of the body.

Sewing-machine needles occasionally transfix the terminal phalanx and nail, and then break. The finger should be forcibly pressed on to a hard surface, so that the fragment retraces its path. The end then projects through the nail and is removed with forceps.

Fish hooks, and similar articles which possess barbs, are removed by pushing the hook in such a direction that it emerges through the skin at the nearest point. The barb is nipped off, and the hook withdrawn.

Gravel is not uncommonly driven into the subcutaneous tissues of the face, hands, or knees. Ugly scars are the penalty for incomplete removal—a particularly distressing sequel if occurring on the face—' tattoo marks '. In all but minor cases an anæsthetic and meticulous removal are indicated. Brisk rubbing with a nail-brush is sometimes helpful.

Glass splinters from windows usually contain sufficient lead to make them radio-opaque. In fact, contrary to popular belief, most glass is radio-opaque in soft tissues. Every lacerated or punctured wound caused by glass must be examined radiographically, as it is surprising how often fragments of glass are otherwise missed. In the majority of cases removal is indicated.

Surgical operations in which metallic sutures are used occasionally lead to trouble. Thus, **wire sutures** in the abdominal wall sometimes break within a few days of their insertion, and the fragments may then cause a pricking pain in the wound. It is remarkable that even stout wire undergoes ' metal fatigue ' in time and breaks into small pieces. The fragments in some situations cause serious trouble.

Pieces of clothing may be found in gunshot wounds (see Missile Injuries, page 8).

Bites and Stings

Insect bites in the United Kingdom are usually inflicted by wasps or bees. Anaphylaxis can follow a bee or wasp sting in sensitised people (p. 27), especially if the venom is injected directly into a vein, e.g. in the dorsum of the hand. Wasps are fond of alcoholic drinks, and picnickers especially should keep an eye on their beer, lest, after drinking, they suddenly develop œdema of the glottis. Most bees, as distinct from wasps, suffer avulsion of their sting and poison gland, which is left protruding from the wound. Pressure on the gland squeezes poison into the tissues, so the gland and sting should be removed by scraping. *Bee venom is acid*, and should be neutralised by the application of ammonia, soda, or methylene-blue. On the contrary, the *venom of the wasp is alkaline*, and requires an acid, such as vinegar or lemon juice, for its neutralisation.[1] Antihistamine drugs are given orally, and local application is of value in allaying local irritation. If an anaphylactic reaction occurs, adrenaline (1:1000) 0·5 ml., is injected intramuscularly every 10 minutes until the patient recovers.

Bites of animals such as the horse, cat, and dog require the usual treatment of wounds. Where there is the slightest suspicion that the animal is suffering from rabies, the bite should be freely excised. If possible, the responsible animal should be kept under observation, or, if it has been killed, Negri bodies should be sought in the brain. Prophylactic treatment can be obtained only at a special institute.

Snake Bites.—In England the only poisonous reptile is the adder, or viper (*Vipera berus*), but a fatal result is unlikely. First-aid measures consist of the application of a tourniquet, and within the first few minutes sucking the wound may remove some of the venom. Antihistamine drugs are given. Drastic measures such as excision of the wound and the application of permanganate of potash cause unnecessary trauma or necrosis of tissue. Antivenom serum is not used in England because of the risk of serum anaphylaxis and serum sickness.

Scorpion stings, well known in the deserts, cause intense pain for many hours and constitutional upset. The patients respond well to emetine injected locally, 65 mg. for adults, and proportionately less for children (Dodge). Hydrocortisone is perhaps a more readily available alternative.

Human bites are discussed on p. 197.

INCISIONS AND SCARS

Incisions.—The object of a surgical incision is to expose the part to be operated on to best advantage, and this should be combined with a desire to finish with a scar which is as good and as inconspicuous as possible. The creases and wrinkles in the skin are parallel with the lines of skin tension and it is in accordance with these lines that incisions should be made.[2]

---

[1] Bicarbonate for Bee, Vinegar for Vasp!

[2] Confusion has arisen in the past because of the interpretation of the significance of Langer's lines. These lines which were worked out by Langer in 1862 are associated with the distribution of the collagen and elastic fibres in the skin, and are not of importance with regard to skin incisions.

Adelchi Negri, 1876–1912. Professor of Bacteriology, Pavia, Italy. Discovered deeply staining inclusion bodies in the cells of the central nervous system in cases of Rabies in 1903.

Jeffery Samuel Dodge, Contemporary. Senior Medical Officer in Epidemiology, Health Department, Bradford, Yorkshire.

Karl Langer, 1819–1887. Professor of Anatomy, Vienna.

Incisions should not be made directly across skin creases unless there is some over-riding reason as the resulting scar will become hypertrophic. In no circumstances should an incision be made directly across the crease in the flexor surface of a joint. Adequate exposure can be obtained by making incisions 'S' or 'Z' shaped if a single straight incision will not suffice.

Scars.—Because of the final effect on function and appearance, it is the surgeon's aim to achieve a scar which is of good colour, narrow, soft and not contracted. All scars pass through a natural sequence of stages:—

Stage 1. 0–4 weeks. The scar is fine, soft, not contracted, not strong.
Stage 2. 4–12 weeks. The scar becomes red, hard, thick and strong. It tends to contract.
Stage 3. 12–40 weeks. The scar gradually becomes soft, supple, white and tends to relax.

The rate and extent to which these changes occur vary with (*a*) the position of the scar on the body, (*b*) the direction of the scar with regard to the lines of skin tension, (*c*) the age of the patient, (*d*) the race.

(*a*) *Position on the Body.*—The worst position on the body for scars is over the sternum. Scars in this area very regularly become severely hypertrophic and even truly keloidal (fig. 14). The region over the shoulder is also a poor one for making scars, as is the back.

(*b*) *Direction with regard to lines of skin tension.*—Scars are better when they are in the lines of skin tension, i.e. lying in or parallel with the skin folds. Scars which directly cross skin folds, e.g. particularly the flexion creases of the joints should be avoided.

(*c*) *Age.*—The age of the patient makes a considerable difference in the reaction of scars. The best scars are obtained in very old people with fine wrinkled skin. The skin scars in these people very quickly settle down and 9 months later may be almost invisible. There is another favourable age in very early infancy, that is in the first year of life, but after that the tendency to scar formation becomes more marked, and the worst period for making scars likely to contract is in older children.

(*d*) *Race.*—The more highly pigmented the person the worse the scars will be.

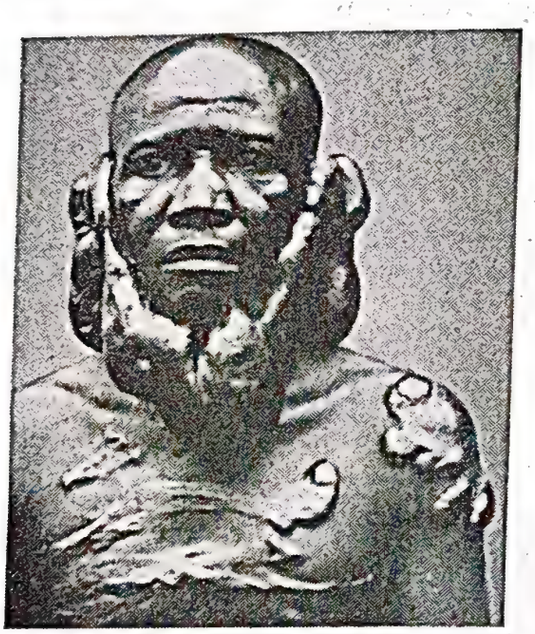


FIG. 14.—Extensive keloid in a West African. (*C. Bowesman, F.R.C.S., Kumasi, Ghana.*)

Hypertrophic Scars.—This type of scar is common in young people and particularly after injuries such as burns. It is so common as to be considered the normal pattern of scar formation. Both the intensity and the duration of the active phase of scar formation are increased. However, even in cases where severe hypertrophy occurs the scar does not become worse after 12 weeks. By this time, the scar is very thick, red and often itchy, and this condition then persists in this severe state for a further 3 to 6 months. After this time, it gradually regresses and will continue to improve for a year and a half, and even then gradually for 2 to 3 years.

Keloid[1] (figs. 14 and 15).—True keloid in white-skinned people is a rare condition, and the only common site is over the sternum. It is said that the true keloid spreads into normal tissue not affected by the original injury or operation. However, in many scars this is difficult to determine, and the certain distinction between the true keloid and the hypertrophic scar is found not in the appearance, but in the time scale. The hypertrophic scar never gets worse after 6 months, but a true keloid continues to get worse even after a year, and some may even progress for 5 to 10 years. It would appear that the maturation and stabilisation of the collagen fibrils is inhibited (p. 4). Treatment is extremely difficult. Excision and resuture are certain to be followed by recurrence and although x-ray treatment was used in the hope that this would prevent recurrence the results of this are uncertain. Improved results have been obtained by shaving away the excess tissue, taking care not to carry the incision into normal tissue at any point and then resurfacing the area by a thin skin graft. Some excellent results have also been obtained by the injection of steroid preparations.

FIG. 15.—An unusual keloid, ten years after a laparotomy.

SEPSIS

Infection is the invasion of the body by pathogenic micro-organisms. For this to happen, a sufficient number of pathogens must enter the tissues, and the resistance of the patient must be low enough to allow them to multiply and invade. General factors which lower resistance include uncontrolled diabetes, steroid therapy, agranulocytosis, and hypogammaglobulinæmia. Local factors of importance are hæmatoma formation, crushing of tissues in injury or at operation, fractures and foreign bodies (page 5).

Pneumococci are Gram-positive diplococci which cause lobar pneumonia, otitis media, sinusitis, meningitis and, together with other organisms, bronchopneumonia. In young girls they occasionally cause acute peritonitis, perhaps entering via the Fallopian tube (Chapter 46). Pneumococci are sensitive to penicillin.

Hæmophilus influenzæ is a small Gram-negative bacillus. Although often present in the healthy upper respiratory tract, *H. influenzæ* is the commonest pathogen in purulent bronchitis, and, as such, frequently predominates in the sputum of elderly patients with post-operative chest infection. It does *not* cause influenza. *H. influenzæ* is resistant to penicillin, but usually sensitive to tetracycline and ampicillin.

Gram-Negative Bacilli (pathogenic in intestine)

Salmonella typhi and **S. paratyphi** cause typhoid fever in which the blood-stream is invaded. Following this the organisms may persist in the gall bladder, the intestinal lymph nodes, the kidneys or the bone marrow, and the patient is then a ' carrier '. Salmonellæ may cause septicæmia, osteitis and other suppurative lesions (p. 137).

Many other salmonellæ cause gastro-enteritis (food poisoning). **Shigellæ** cause bacillary dysentery.

ANTIBACTERIAL THERAPY

Antibacterial drugs damage bacteria without harming the tissues. They consist of (1) **synthetic drugs** such as the sulphonamides and (2) **antibiotics**, which are the

---

[1] Keloid = Like a claw.

Hans Christian Joachim Gram, 1853–1938. Professor of Pharmacology (1891–1900) and Professor of Medicine (1900–1923), Copenhagen. Described his method of staining bacteria in 1884 while engaged in post-graduate study in Berlin.

Daniel Elmer Salmon, 1850–1914. American Pathologist who isolated the first member of the group of organisms, now bearing his name, in 1886.

products of other microbes. For many years attempts were made to produce a therapeutically useful antibiotic, but it was not till 1941 that Florey produced a reliable preparation of penicillin. (Penicillin was discovered by Fleming in 1928.)

PRINCIPAL ORGANISMS OF SEPSIS

These are the *Staphylococci, Streptococci, Escherichia coli, Proteus,* and *Pseudomonas æruginosa.*

GRAM-POSITIVE COCCI: *Staphylococci, Streptococci*

	Habitat and Spread	*Principal Infections*	*Antibiotic Sensitivity*
Staphylococcus aureus Gram-positive cocci in clusters; golden colonies; forms coagulase which clots plasma.  FIG. 16	Lives in nostrils of 30 per cent. of population (nasal carriers), and sometimes in skin. Present in infected discharges. **Spread.** By direct contact, on hands, etc. Airborne spread also by garment dust and skin squames.	Boils, styes, carbuncles, septic hands, breast abscess, wound infection. Ac. osteomyelitis, septicæmia, post-operative pneumonia, and entero-colitis. Mainly local infections. Some strains cause food poisoning.	(a) **Outside Hospital.** Most strains now form penicillinase and are penicillin-resistant. (b) **In Hospital.** In addition to being Pencillin-resistant many are resistant also to several other drugs. Most are still sensitive, however, to flucloxacillin and methicillin.
Streptococcus (fig. 17) Gram-positive cocci in chains. Many varieties; some are hæmolytic. Group A hæmolytic streptococci (*Str. pyogenes*) are highly pathogenic. *Str. fæcalis* and anaerobic streptococci live in the large bowel and cause sepsis in abdominal tissues.	Group A strep. live in pharynx of 5–10 per cent. of population. **Spread.** By indirect contact, respiratory droplets from the naso-pharynx and wound discharges.	Group A strep. cause—tonsillitis, otitis, sinusitis, scarlet fever. Dangerous in wounds, puerperal sepsis, cellulitis, erysipelas. Infections tend to spread along cellular planes.	**Group A** strep. are penicillin sensitive; many are resistant to tetracycline.  FIG. 17

SYNTHETIC AGENTS

Sulphonamides inhibit the growth of many bacteria, but are partially neutralised by substances present in pus, blood, and the tissues. Sulphonamides therefore are most useful in infections where tissue inhibitors are absent—e.g. infections of the urinary tract. The most useful is sulphadimidine; it gives good blood and urine levels and few toxic effects. Treatment of urinary infection should continue for at least a week. Alternatively, long acting sulphonamides may be used for urine infection, requiring dosage only once a day or once a week. *Succinylsulphathiazole* or *phthalylsulphathiazole* are used mainly in an attempt to reduce the bowel bacteria before surgery. The most important toxic effect is sensitisation appearing as a skin rash with or without fever. Trimethoprim potentiates sulphonamides. Cotrimoxazole (' Septrin ', ' Bactrim ') contains trimethoprim and sulphamethoxazole.

Nitrofurantoin (' Furadantin ', etc.) is given orally for *Esch. coli* urinary infection.

Nalidixic acid (' Negram ') is used similarly, though resistance readily develops.

Isonicotinic acid and **Para-amino-salicylic acid** (p. 32).

ANTIBIOTICS

Some antibiotics, notably penicillin and aminoglycosides, are *bactericidal*, and kill susceptible bacteria. Others, e.g. tetracycline, chloramphenicol are *bacteriostatic* and merely inhibit the growth of bacteria. When leucocytes can enter the lesion they complete the destruction of the microbes.

Howard Walter Florey (Lord Florey), 1898–1968. Professor of Pathology, Oxford, England (1935–1962).

GRAM-NEGATIVE BACILLI (*normal in intestine; pathogenic elsewhere*) (*fig. 18*)

	Habitat and Spread	*Principal Infections*	*Antibiotic Sensitivity*
Escherichia coli aerobic FIG. 18	Normal inhabitant of large bowel.	Wounds, especially abdominal (in peritonitis and intestinal strangulation); contain endotoxins which cause pyrexia, rigors and shock if bacteræmia ensues. The commonest cause of urinary infection.	All are penicillin resistant—some are sensitive to ampicillin (not *Pseudomonas*). Resistance to other drugs varies—hospital cross-infecting strains become resistant to nearly all drugs.
Pseudomonas æruginosa (formerly *pyocyanea*) aerobic	Large bowel. Likes to colonise moist superficial lesions which form its principal habitat. *Spread.* From lesions, by indirect contact; also from contaminated ward lotions, sinks, etc.	Contains endotoxins. An opportunist which attacks damaged tissues and moist surfaces such as burns, ears, urinary tract, tracheostomy wounds. In severely ill patients it may be fatal.	
Proteus aerobic	Large bowel.	Wounds, urine. Contains endotoxins. Splits urea into NH_3 making urine alkaline so that phosphatic deposits occur.	
Bacteroides anaerobic	The predominant organism of the colon; greatly outnumbers all others.	Often accompany (and outnumber) *Esch. coli*, etc. in peritonitis and other abdominal sepsis.	Resistant to penicillin, ampicillin gentamicin; usually sensitive to chloramphenicol erythromycin, clindamycin, metronidazole.

Penicillin, unlike sulphonamides, retains its activity in pus and blood. It acts best on multiplying organisms and hence may be antagonised by simultaneously-administered bacteriostatic agents. Penicillin is especially valuable in infections by Gram positive organisms, e.g. *Str. pyogenes*, pneumococci, non-penicillinase-producing staphylococci, *B. anthracis*, and clostridia of gas-gangrene. It is the treatment of choice for actinomycosis, syphilis, and gonorrhoea. Penicillin-sensitive bacteria rarely acquire resistance, though they may be replaced by resistant strains. However, some gonococci have now become relatively penicillin-resistant.

Many modifications of penicillin are now available. *Benzyl penicillin* (penicillin G), administered by injection, is still the most potent, but is destroyed by penicillinase and hence is ineffective against many staphylococci. Other modifications (also destroyed by penicillinase) include *Penicillin V*, which is acid stable and given orally for mild infections; *Ampicillin* and *Amoxycillin* (a better absorbed form) which act on some Gram negative bacilli (*Esch. coli*, *Hæmophilus*) as well as Gram positive organisms; *Carbenicillin* which in high concentrations acts also on some Pseudomonas

strains. *Methicillin* and *Flucloxacillin* are forms of penicillin that are *insensitive* to penicillinase and hence valuable in infections by penicillin-resistant staphylococci. This is their only valid use.

The main disadvantage of the penicillins is their tendency to provoke allergic reactions such as skin rashes, and occasionally anaphylaxis (p. 27).

Aminoglycosides include streptomycin (now used mainly for tuberculosis), gentamicin and tobramycin. Given by injection, and excreted by the kidneys, they are bactericidal against many bacteria (but not anærobes). All are toxic to the eighth cranial nerve, if the blood level is maintained too high. In order to avoid the dangers of inadequate treatment on the one hand, and of toxicity on the other, dosage must be related to weight and age, and blood levels estimated during treatment. Particular care is needed in renal insufficiency and in the elderly.

The **tetracyclines** are broad-spectrum antibiotics, with almost identical actions. They are generally active against staphylococci and streptococci, Gram-negative cocci, coliform bacilli, *H. influenzæ*, actinomyces, and lymphogranuloma venereum. Many staphylococci, streptococci, and coliforms have now acquired resistance. Administration of these drugs disturbs the intestinal flora and may cause digestive upset. Tetracyclines are contraindicated in late pregnancy, and are *dangerous* in patients with renal insufficiency.

Chloramphenicol is the drug of choice in typhoid fever. It is sometimes valuable in peritonitis due to mixed bowel organisms. Owing to risk of blood dyscrasia it should rarely be given otherwise.

Erythromycin is a valuable non-toxic antibiotic mainly active against Gram-positive bacteria. Staphylococci readily become resistant to it. **Clindamycin** and **lincomycin** act similarly and fewer organisms are yet resistant.

USE AND SELECTION OF ANTIBACTERIAL DRUGS

All these drugs have disadvantages or dangers and should be used with discretion and only when the clinical state of the patient requires them. They should *not* be used for localised infections that respond to surgical treatment, e.g. superficial abscesses, uncomplicated appendicitis, septic discharging wounds without cellulitis. If possible, chemotherapy should be deferred until an aetiological diagnosis has been made and sensitivity determined; but if treatment of a serious or acute infection has to be started without delay, relevant specimens should be taken and the bacteriologist's advice should be sought. New drugs should be used with caution,[1] so as to reduce the selection of resistant strains. In general, if there is no improvement in a few days, the treatment should be stopped or changed. Treatment of more than a few weeks is usually only needed in special circumstances, e.g. tuberculosis.

The drugs should *not* be used for routine prophylaxis, e.g. to prevent infection in traumatic or surgical wounds. Prophylactic chemotherapy however is justified to prevent dangerous infections by specific organisms, e.g. penicillin to prevent tetanus; and to prevent gas gangrene after thigh amputation in arterial disease (pp. 28 and 157).

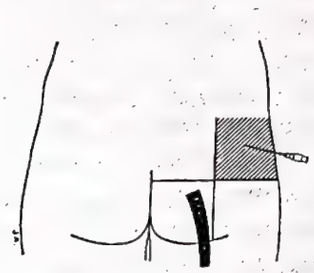

FIG. 19. — 'Safe' area for intramuscular injection to avoid the sciatic nerve.

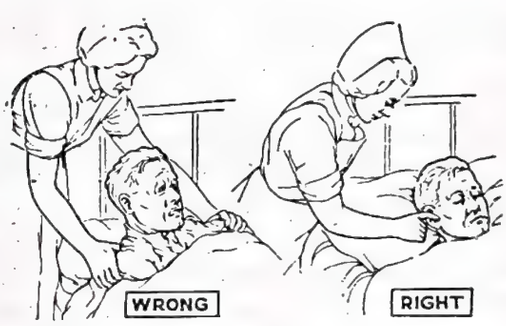

FIG. 20.—Wakening a sleeping person. (*As used by North American Indians for centuries.*)

[1] Sir Robert Hutchison, 1871–1960, Physician, London Hospital, used to warn that 'It is always well, before handing the cup of knowledge to the young, to wait until the froth has settled'.

ADMINISTRATION OF ANTIBIOTICS

Care must be taken with intramuscular injections or damage may be done to deep structures. The best site is the upper and outer quadrant of the buttock (fig. 19), or the antero-lateral aspect of the thigh.

If it is necessary to arouse a patient for therapy or other causes, gradually increasing pressure on the tragus should be applied, until the patient wakens, often with a smile! Shaking the patient awakens him with a 'jump', and the resulting irritability is not conducive to an immediate return to sleep (fig. 20).

HOSPITAL INFECTION

Resistant pathogenic organisms can be lurking in hospital wards and theatres. Superficial and deep wounds may become infected by organisms from the patient (self-infection) or by cross-infection from other patients or from members of staff. A symptomless carrier may be responsible; but persons with septic lesions are especially dangerous sources and should not enter the operating room. The most important hospital organisms are *Staph. aureus* and Gram-negative bacilli.

Staphylococci do not always cause sepsis; they may merely colonise an already discharging wound. Wound discharges containing staphylococci are sources of cross-infection. Other important sources are infections of urine, skin, lung, and the noses of carriers among patients and staff. Superficial lesions such as varicose ulcers, eczema, and bed sores may also become sources, if colonised by staphylococci. Ward staphylococci may be conveyed to the theatre and there cause infection. Staphylococci may cause many post-operative complications—e.g. wound infection, bronchopneumonia, urinary infection, furunculosis and enterocolitis.

Staphylococcal enterocolitis is fortunately uncommon. It is a severe 'super-infection' of the gut by drug-resistant staphylococci usually following the administration of a broad spectrum antibiotic for bowel surgery. The sudden onset of profuse cholera-like diarrhœa with dehydration and prostration is the usual feature, and it may be rapidly fatal. A smear of fæces will probably show clusters of staphylococci and culture will yield enormous numbers. (Normal fæces often contain a few staphylococci.) Treatment is urgent and consists of replacement of fluid and electrolytes. The antibiotic should be changed to one effective against the causative staphylococcus (e.g. flucloxacillin or chloramphenicol if appropriate).

Gram-negative Bacilli.—Hospital infections by *Esch. coli*, *Proteus* and *Ps. æruginosa* have been increasing recently because some other organisms have been diminished by antibiotics. Tracheostomy wounds are peculiarly liable to infection by *Ps. æruginosa* and hence this opportunistic pathogen has become a problem in intensive-care wards, just as it has long been in urological wards and burns units. Gram-negative bacilli commonly cause sepsis in abdominal wounds. They infect the urinary tract after catheterisation and operation; the organisms may be introduced by inadequately disinfected cystoscopes, inexpert catheterisation, and open draining indwelling catheters.

Tetanus and Gas-gangrene (p. 24).—Tetanus spores are often present in soil, dust and unbleached wool. They are very resistant. Tetanus is the principal danger from faulty heat sterilisers. Gas gangrene may be caused by the patient's own intestinal clostridia after lower limb amputations when resistance is reduced by diabetes or arteriosclerosis.

PREVENTION OF HOSPITAL INFECTION

Prevention mainly consists of reducing the *sources* of pathogens and restricting their spread. The breeding of resistant strains should be minimised by avoiding unnecessary antibiotics. No single precaution will succeed on its own. Sources are

reduced by isolating patients with drug-resistant staphylococcal infections and by careful dressing of wounds.

Newborn infants may be dusted or bathed with dilute hexachlorophene preparations to restrict staphylococcal colonisation of umbilicus and skin (Chap. 51) and so diminish the incidence of pustules in infants and breast abscesses in mothers. Recently it has been shown that grossly excessive use of hexachlorophene may cause absorption of toxic quantities but it is safe if correctly used. The abandonment of hexachlorophene, through fears of toxicity, has already increased the sepsis rate in some maternity hospitals.

The spread of pathogens is diminished by general hygienic measures, including avoidance of overcrowding and good ventilation. Hands should be washed with soap and dried with disposable paper towels (*wet hands are dangerous*). When patients leave hospital, or more often if necessary, bedding may be disinfected by a suitable laundering process. Bath tubs should be disinfected with hypochlorite.

Infected discharges must be disposed of safely. In urological units, urinals should be disinfected after use; drainage vessels for indwelling catheters should contain disinfectant or incorporate a non-return valve (Chap. 55).

Special care must be taken to exclude bacteria from susceptible tissues. Post-operative wounds should be left untouched as far as possible. When it is necessary to remove stitches or a tube, a meticulous non-touch technique must be followed. Before removal of stitches the skin and the external portion of the stitch must be disinfected with an adequate skin antiseptic such as 70% alcohol.

The correct *heat-sterilisation* of instruments and dressings is sufficiently complicated to deserve skilled supervision in central sterile supply departments and operating theatres. Unbleached cotton-wool, sometimes used to pad splints, may contain tetanus spores and should never be used unless satisfactorily sterilised. Instruments which are damaged at high temperatures present special problems. Non-boilable cystoscopes may usually be 'pasteurised' at 80°C in steam at subatmospheric pressure in a special autoclave. This kills non-sporing organisms. A chemical (glutaraldehyde) may also be used.

At operation, the risk of self-infection is minimised by efficient disinfection of the patient's skin with 1% iodine or 0·5% chlorhexidine in 70% alcohol; the latter is less likely to cause sensitisation. The risk of infection from the surgeon's skin is reduced by hand-washing with liquid soap or detergent containing hexachlorophene, Povidone, iodine or chlorhexidine and by rejection of pricked gloves.

Staff with septic lesions should not enter the theatre. Air contamination is minimised by restricting unnecessary movement of staff, entry of unnecessary visitors, and by ensuring that outer clothes are replaced by freshly-laundered theatre garments and overshoes. Masks must be changed at the end of the session or more often, and should *never* be handled while worn. Airborne bacteria may be further reduced by air-conditioning systems giving frequent changes of suitably humidified, filtered air at a positive pressure.

Finally, since even the best precautions cannot exclude all bacteria from wounds, it is most important not to reduce the resistance of tissues by rough handling, unnecessary drainage, and inadequate hæmostasis (p. 15).

CHAPTER 2

ACUTE INFECTIONS

ACUTE ABSCESS

An abscess is a collection of pus. Bacteria which cause pus formation (pyogenic organisms) reach the infected area by one of three routes:

(i) Direct infection from without, e.g. penetrating wounds.
(ii) Local extension from some adjacent focus of infection.
(iii) Blood-stream (hæmatogenous) or lymphatic vessels.

In the case of (iii) hæmatogenous infection, some predisposing factor may be present. For example, a bruised muscle causes an extravasation of blood which forms a suitable nidus for pyogenic organisms. Acute osteomyelitis may occur after a minor injury to a limb.

The bacteria, having entered the tissues, multiply and cause inflammation. The area is surrounded by a painful zone, infiltrated with leucocytes and bacteria.

Pus.—Polymorphonuclear leucocytes contain a proteolytic enzyme which causes liquefaction of the tissues into pus, which is composed of dead leucocytes and bacteria. The tension in the abscess rises owing to the exudation of plasma and it may spread along the paths of least resistance to the surface of the body, or to a hollow viscus where the pus is eventually discharged.

Symptoms.—The patient feels ill, the degree depending upon the size of the abscess, the virulence of the organism, and the tension within the cavity. Throbbing pain is characteristic of suppuration, the pain becoming more severe if the affected part is dependent, e.g. an infected finger.

Signs.—(*a*) GENERAL.—The temperature is elevated. In severe cases rigors may occur.

(*b*) LOCAL.—The five classical[1] local signs of inflammation are due to hyperæmia and inflammatory exudate:

1. *Heat*—the inflamed area feels warmer than the surrounding tissues.

2. *Redness* of the skin over the inflamed area. Both this sign and the previous one are due to hyperæmia.

3. *Tenderness*, due to the pressure of exudate on the surrounding nerves. If the exudate is under tension, e.g. a furuncle (boil) of the ear, pain is severe, whereas lax tissues (e.g. scrotum) may swell enormously with little discomfort.

4. *Swelling*.

[1] Aulus Aurelius Cornelius Celsus, 25 B.C.–A.D. 50. A Roman medical writer described the first four of these signs as Calor (heat), Rubor (redness), Dolor (pain), and Tumor (swelling). The fifth sign Functio Læsa (loss of function) was added by Galen, A.D. 130–200, Roman Physician.

5. *Loss of function*—an inflamed tissue does not perform its physiological function.

The degree to which these signs are evident depends on the extent of the inflammation and its proximity to the surface. The swelling is at first brawny and œdematous; later softening and fluctuation are manifest (fig. 21). In some cases increasing œdema is characteristic of deep pus, as in acute mastitis.

If untreated, an abscess tends to point; the skin or membrane covering it gives way and the contents are discharged, usually with relief.

FIG. 21.—An abscess. The arrows indicate fluctuation in two planes.

Prevention.—An abscess can sometimes be aborted by antibiotics, e.g. tetracycline, co-trimoxazole (Septrin), rest and, if possible, elevation of the affected part.

Treatment.—As soon as pus is diagnosed, the abscess must be incised and dependent drainage instituted. In regions where incisions are fraught with danger to important anatomical structures, as in the neck or axilla, a modification of Hilton's method should be used. This consists of incising the skin and superficial fascia, and opening the abscess by thrusting a pair of sinus forceps or a hæmostat into the cavity. By separating the blades, a sufficiently large opening can be made to insert, if necessary, a finger in order to convert loculi into a single cavity, followed by a drainage tube.

Pus from an abscess must be cultured so as to determine the sensitivity of the organisms.

Errors in treatment.—1. Once pus has formed antibiotics alone will not suffice. Indeed, the inflammation continues to smoulder and a hard, lump forms, called an 'antibioma'. In certain areas, e.g. the breast, it becomes difficult clinically to decide whether such a lump is malignant or inflammatory.

2. Incising an aneurysm in mistake for an abscess. It has been done on many occasions!

CELLULITIS

Cellulitis is the term given to a spreading inflammatory exudate along subcutaneous and fascial planes. Gangrene may follow and widespread sloughing of tissues occasionally results (p. 154). The condition was formerly known as 'hospital gangrene', which then often progressed to a fatal issue.

Streptococcus pyogenes is the commonest cause of severe cellulitis, but other organisms of sepsis may cause it. Organisms may enter the tissues through an accidental wound, trivial in nature, such as a graze or scratch, or possibly as the result of an operation. If the general resistance of the patient is undermined by such conditions as diabetes, cellulitis is likely to spread rapidly and may lead to septicæmia.

The clinical condition depends upon the virulence of the organism and the extent of infection. Redness and itching or stiffness commence at the site of inoculation, to be followed by tenderness and swelling. The skin becomes

John Hilton, 1804–1878. Surgeon, Guy's Hospital, London.

shiny in appearance. The appearance of fine creases or wrinkles in the skin heralds the resolution of the condition.

Treatment consists of rest, elevation of the part, and above all the use of the appropriate antibiotic. Diabetes, if present, should be treated.

CELLULITIS IN SPECIAL SITUATIONS

Scalp.—This is due to infection of the sub-aponeurotic layer of areolar tissue. Pus may extend to the attachment of the epicranial aponeurosis, so that the whole scalp is lifted off the calvarium. Necrosis of bone, or thrombosis of emissary veins spreading to intracranial sinuses, may follow. Early incisions, parallel to the arteries, are necessary when pus is suspected. The condition may present as a Pott's puffy tumour (Chap. 24).

Orbit.—This follows wounds or spread of infection from air sinuses in the vicinity (Chap. 28). Proptosis and impairment of ocular movements follow, and infection may spread to the meninges, or thrombosis extend along the ophthalmic veins to the cavernous sinus (Chap. 28). The eyeball itself occasionally becomes infected (panophthalmitis). Owing to the risk of cellulitis, all wounds of the orbit demand careful attention. If infection supervenes, drainage is provided by incisions in the eyelids or conjunctival fornix. Panophthalmitis is treated by evisceration of the eye; this procedure is safer than excision, which is liable to be followed by meningitis from infection extending along the open sheath of the optic nerve.

Neck.—A complication of wounds, tonsillitis, or mastoiditis. Ludwig's angina is a term applied to submaxillary cellulitis (Chap. 32). The two main dangers of cervical cellulitis are œdema of the glottis with possible asphyxia, and mediastinitis.

Pelvic Cellular Tissue.—The common cause is a lateral tear of the cervix during parturition. Inflammation may extend upwards in the broad ligament so that an indurated swelling appears above the inguinal (Poupart's) ligament (parametritis, Chap. 49). Ultra short-wave therapy and the appropriate antibiotic will usually give relief. If the swelling appears above Poupart's ligament and deep œdema or softening is detected, the abscess is incised and drained extraperitoneally.

BACTERÆMIA AND SEPTICÆMIA

Bacteræmia and Septicæmia are terms used to describe the presence of organisms in the blood as diagnosed by blood culture.

The clinical features are those of severe infection and shock (p. 77), sometimes preceded by a rigor. The pyrexia is commonly intermittent, and rigors may continue. Jaundice is due to liver damage. Acute tubular necrosis of the kidneys may occur. Peripheral circulatory paralysis of vasomotor tone and disseminated intravascular coagulation of blood forebode a fatal outcome.

Treatment must be prompt and aggressive. The causative focus must be found and treated, surgically if necessary. A blood culture is taken and adequate doses of broad spectrum antibiotics given, these being changed if

François Poupart, 1661–1708. Surgeon, Hôtel Dieu, Paris.

necessary when the sensitivity of the organism is known. Transfusion with blood and other plasma expanders, and the injection of hydrocortisone are usually mandatory.

PYÆMIA

Pyæmia is due to the circulation in the blood-stream of infective emboli composed of masses of organisms, vegetations or infected clot.

Clinically, pyæmia is characterised by rigors, an intermittent fever and the formation of abscesses. Abscesses occur in any part of the body. Joints are occasionally affected, and may become quietly disorganised. Death may follow abscess formation in vital structures, e.g. heart or brain.

The *treatment* of pyæmia consists in endeavouring to prevent further emboli from reaching the blood-stream. Thus, if the condition is caused by thrombosis of the lateral intracranial venous sinus, then ligation and division of the internal jugular vein may interrupt the stream of emboli. Otherwise, abscesses are dealt with as they occur, and general treatment is instituted as for septicæmia. Portal pyæmia is discussed in Chap. 43.

ACUTE SPECIFIC[1] INFECTIONS

TETANUS

About 200 to 300 cases of tetanus occur annually in the United Kingdom, with a mortality of about 40%. This number is unlikely to diminish, as the majority follow a trivial or forgotten abrasion. Eradication can only follow universal active immunisation. Tetanus is relatively more common in other parts of the world.

The causal organism, *Cl. tetani*, is a Gram positive rod which forms a terminal spore giving a drum-stick appearance. It is an anaerobe; the growth requirements depend on other organisms in the wound, and on foreign bodies or dead tissue; and when it grows it forms a very powerful toxin. Although the organism is common, especially in manure and soil, the complex conditions for growth and toxigenesis can only occasionally co-exist and thus the disease is uncommon, but seems to occur when least expected (J. Macrae).

Tetanus is a wound infection; any wound will serve, but deep, contused, soil-contaminated injuries infected with pyogenic organisms and containing foreign bodies are most likely sources of tetanus toxæmia. The disease is wholly produced by the exotoxin. The organism itself does not damage tissues. The toxin travels along nerves to the central nervous system where it has a dual action: (1) it interferes with the acetyl-choline/cholinesterase balance at the peripheral motor end plates so that a continuous excess of acetyl-choline remains, producing clinically a sustained state of tonic muscular spasm, and (2) it causes extreme hyper-excitability of motor-neurones in the anterior horn cells which can result in explosive and widespread reflex spasm of muscle in response to even minor sensory stimuli. The toxin producing such effects is fixed in the tissues and cannot then be neutralised by antitoxin. Only free toxin can be neutralised. There is also a concomitant sympathetic overactivity.

---

[1] A specific disease is one which is produced by a single type of micro-organism.

James Macrae, Contemporary. Physician, Ham Green Hospital, nr. Bristol, England.

Clinical Features.—Generally a short incubation period implies a serious attack, but an incubation period measured from the time of wounding until the first symptom is often fallacious since we cannot know when the organism started to grow or to produce toxin. Indeed, it is known that wounds containing tetanus organisms have healed and been forgotten for years and then some local change produced the correct combination of factors allowing the organism to multiply and produce toxin (latent tetanus). This should be remembered when re-opening an old accident or war wound.

FIG. 22.—Risus sardonicus.

A better prognostic index is the ' period of onset '. This is the time between the first symptom and the first reflex spasm. If this period has been less than forty-eight hours, death is very likely. As the period of onset lengthens so does the prognosis improve.[1]

The first symptoms are difficulty in swallowing and stiffness of the jaw, succeeded by pain in the neck, back, and abdomen. Then tonic muscle spasm develops, often sparing the limbs relatively. The sardonic smile of tetanus is evidence of this stage of the disease (fig. 22), and there is considerable difficulty in swallowing and reduction in breathing capacity. Thereafter, reflex convulsions can occur affecting all the muscles, causing great pain, opisthotonus and sometimes muscle rupture (psoas, rectus abdominis, pectoral) (fig. 23). These spasms are spontaneous or may be induced by even trivial stimuli of noise, injury, or movement. If severe, they stop respiration and the patient becomes cyanosed. A cyanotic tetanic convulsion threatens life. Tonic muscular spasm remains between the reflex attacks, thus distinguishing tetanus from strychnine poisoning.

FIG. 23.—A torn rectus abdominis muscle from a case of tetanus, which followed a trivial wound of a toe. (*R.C.S. Museum.*)

The temperature is usually a little elevated and the pulse is rapid. Without appropriate treatment, death occurs in a few days, usually from pneumonia, or from respiratory failure during a cyanotic attack.

Patients older than forty-five years fare badly with tetanus. In the newborn the infection enters the raw stump of the umbilical cord (tetanus neonatorum) and the disease tends to be rapidly fatal. It is unfortunately still common in certain parts of the world.

At an early stage, tetanus might be mistaken for tonsillitis, back strain, an

[1] Hippocrates, *circa* 460–377 B.C., is believed to have been the first to recognise this fact.

acute abdominal condition, or hysteria (the latter, especially if dysphagia is the presenting symptom).

Treatment.—Prophylactic.—*Active immunity* is conferred by injections of absorbed toxoid; it is 100% safe but it takes time to develop. One ml. is administered and repeated at intervals of six weeks and six months, and followed by a 'booster' dose every five years. If such an active immunity is present, another dose of toxoid should be given at the time of injury.[1] Long acting depot penicillin (e.g. Penidural) should also be included in the prophylactic treatment.

Antitetanus Sera.—The inherent disadvantages of equine antiserum (A.T.S.) (see Serum reactions, p. 27), can be avoided if human antitetanus globulin (A.T.G.) is available. This is an homologous antitoxin and its protective value is one hundred times that of the heterologous equine type. A dose of 250 units of A.T.G. will give adequate cover during the period needed to establish active immunity. A.T.G. can be obtained in Great Britain, but supplies are small.

It is essential that every patient who has had antitetanic serum should be immunised at once with toxoid.

Treatment of Established Case.—All cases should be isolated in quietness and comfort. It is not necessary to attempt excision of the wound. If pus is present it should be drained but, in general, ordinary wound toilet will suffice. 100,000 I.U. of antitetanic serum are given at once, half intravenously and half intramuscularly, to limit the further fixation of toxin. If available, human antitetanus globulin (A.T.G.) is preferable to A.T.S.—only one dose is ever needed. In treatment, as in prophylaxis, tetanus antibody material, whether heterologous or homologous, is the only substance capable of neutralising the toxin which causes this serious disease. Further treatment resolves itself into three stages, dependent on the development of the disease.

Stage 1.—*A mild case* is one where there is tonic rigidity but neither swallowing nor respiration is noticeably affected. Initial sedation should be by intramuscular promazine (Sparine) (100 to 150 mg.) and intramuscular amylobarbitone (200 mg.). These drugs will probably need to be continued six-hourly.

Stage 2.—*A seriously ill* case is one where there is swallowing difficulty. There may be some reflex spasm but no major cyanotic episodes. A naso-gastric tube is passed and sedation continued as above. A liquid balanced diet containing 2000 Calories (approx. 8400 kJ)[2] and 50 g of protein is given by the tube, unless the blood urea rises, when protein must be temporarily discontinued. If the patient has difficulty in breathing, he will require a tracheostomy in order to maintain a clear airway. The operation can often be done under local anæsthesia and a cuffed tracheal tube must be inserted. Nursing must now include meticulous care of tracheostomy tube—posture, suction, and humidification (Chap. 37). Sedation must be maintained as before.

Stage 3.—*Dangerously ill.*—Should the patient have a major cyanotic convulsion, the third stage of treatment is necessary. Curare, in doses of 25 to 40 mg. is given intravenously initially and afterwards intramuscularly to maintain complete relaxation. Simultaneously, intermittent positive pressure respiration must be provided until such time as no further muscle spasms occur (usually twelve to thirty days). Sedation as given in Stages I and II is stopped. This last stage of treatment makes such demands on medical and nursing services that it can only be used safely in a special, experienced respiratory unit. Such a case requires over 350 individual acts of nursing

---

[1] Tetanus toxoid practically eliminated tetanus during the 1939–1945 war.

[2] The International Union of Nutritional Sciences accepted in 1969 the recommendation that the medical or kilo calorie be replaced by the Joule in nutritional sciences. (1 medical calorie = 4186·8J!)

service each day, and a special nurse continually, while the monitoring requirements of artificial respiration need special equipment and skill.

The plight of the '*dangerously ill*' case is often worsened by the development of complications made possible by the unnatural preservation of life brought about by artificial respiration. Such patients may develop severe negative nitrogen balance, myocarditis, vascular failure associated with extremes of blood pressure and pulse-rates, and severe damage to motor neurones in the cord and brain leading to major paralysis. These are all due to toxin. Thus, even if treatment prevents death by spasm or pneumonia, patients may still die from a lethal dose of toxin.

Although the major therapeutic effort is exerted in the control of spasm and respiration, the general care of the patient must not be forgotten. Antibiotics are used judiciously to prevent infection. The eyes must be protected while curare is used, or conjunctivitis develops. The curarised patient is unresponsive, but is conscious and sensitive: this must never be forgotten.

The treatment described, if available, can reduce the tetanus death rate to about 15%, but application of such treatment is difficult and obviously not possible except in specially equipped hospitals.

SERUM REACTIONS

Patients who have had previous serum injections or who are prone to asthma or allergic diseases may have a local or general reaction when serum or other antigen is injected. Anaphylaxis is the term given to describe this reaction.

Prevention.—Utmost care must be taken before any intravenous or subcutaneous injection is given. The older test by intradermal injection of small amounts has now been abandoned because skin sensitivity bears no constant relation to general sensitivity and death has occurred following an intramuscular injection of serum after a negative intradermal test. *When using serum, the best procedure is to dilute it ten times in normal saline and to inject it subcutaneously in small amounts.* If anaphylaxis develops it will be mild and respond easily to treatment. If trouble is anticipated, intravenous Piriton (chlorphenitamine) 10 mg. should be given ten minutes beforehand. With antitetanic serum 35 per cent. of patients get some sort of reaction. The usual routine is to give 0·2 ml. of the serum, to wait half an hour, then give the remaining 0·8 ml. and to wait for a further half-hour. Adrenaline (1:1 000) must be immediately available.

Acute Anaphylaxis.—The symptoms may appear within a few minutes. They are most alarming and may rapidly lead to death. In general the treatment is to give adrenalin (1:1 000) 1 ml. subcutaneously or Piriton 10 mg. intravenously, and to apply a tourniquet. There are four main types of acute reaction.

(1) *Respiratory distress* with urticaria, bronchospasm, and œdema of the glottis. Treatment is to introduce a large needle through the crico-thyroid membrane in order to give endotracheal oxygen. Calcium gluconate 20 ml. of 10 per cent. intravenously will help. If pulmonary œdema occurs, hydrocortisone succinate 100 mg. intravenously must be given.

(2) *Generalised Convulsions.*—This requires 50 mg. 2·5% thiopentone intravenously repeated in five minutes if necessary.

(3) *Peripheral Vascular Failure.*—This requires phenylephrine 1 mg. intravenously and intravenous hydrocortisone. If this fails, a noradrenaline drip should be started.

(4) *Sudden Cardiac Arrest.*—This requires immediate cardiac massage: the heart must be restarted within three minutes (Chapter 39). The help of an anæsthetist is invaluable and all cases will require oxygen.

Local anaphylaxis is occasionally seen if further injections are given at the same site after the interval of a week. An acute inflammatory reaction occurs, which in rare cases progresses to sloughing of tissues.

Serum sickness is the commonest serum reaction and may occur in any patient. Urticaria, œdema, pains or effusions in joints, and elevated temperature are usual features, which frequently occur seven to ten days after the injection. Cold applications applied locally, minimise the discomfort. Oral anti-histamines must be given until the condition responds.

INFECTIVE GANGRENE

Gas Gangrene

Gas gangrene (clostridial myositis), although uncommon, is a regular contributory cause of death in the case of accidents. It may complicate thigh amputations in patients with arterial disease.

Clostridia are introduced into the wound from clothing more commonly than by soil, hence wounds of the thighs and buttocks are especially liable to infection owing to fæcal contamination.

The causative organisms present in the normal intestine and in soil are *Clostridium welchii* (*Cl. perfringens*) and, less common, *Cl. septicum* and *Cl. œdematiens*. They invade and multiply in damaged muscle, form gas bubbles and produce toxins.

Clostridia are often found in wounds without causing disease.

The diagnosis of true gas gangrene, i.e. gas in the tissues combined with gangrene, is essentially clinical. Pain, swelling, œdema, and toxæmia, usually develop within forty-eight hours. There is a rapid increase in the pulse-rate, a slight rise, or, in severe cases, a fall of temperature, and vomiting. The mental condition usually remains clear, and death occurs suddenly. (We have seen a patient die while engaged in completing a football forecast.) On examination of the wound, stitches are seen to be under tension, and, through the pouting edges, thin brownish fluid exudes, which possesses a sickly foul odour. The limb is tense and swollen, and palpation often reveals crepitus. An X-ray will demonstrate the presence of gas in intramuscular planes, and is very useful in the diagnosis of early cases. Gas and foul fluid form in the cellular spaces; contractability of the muscles is soon lost, and their colour changes successively from dull red to green and then black. If septicæmia occurs, gas is produced in many organs, notably the liver, which at necropsy drips with frothy blood, and is well named a ' foaming liver '.

Treatment.—Prevention.—The essential prophylactic measure is early and meticulous excision of dead and dying tissue. Partial suturing is sufficient, and secondary suture can be undertaken at a later date (p. 6). Prophylactic *penicillin* should be administered.

Treatment of Established Disease.—The patient's life depends upon:

(i) Preparation for immediate operation, with blood transfusion (or plasma if necessary).

(ii) Injection of 8 mega units of penicillin immediately, followed by at least 4 mega units four-hourly for 4–8 days. Streptomycin (1–2 g.) daily may be used in addition to the large doses of penicillin.

(iii) Adequate excision of all affected groups of muscles, through *long* incisions in the limb (on both sides if necessary). If total clearance is not possible, amputation must be performed (e.g disarticulation through the hip-joint for gas gangrene in an above-knee amputation stump).

(iv) Anti-gas gangrene serum (3 ampoules of polyvalent serum immediately, and repeated six-hourly i.v.).

(v) If available, oxygen drenching in a pressure chamber (hyperbaric

William Henry Welch, 1850–1934. Professor of Pathology, Johns Hopkins University, Baltimore, Maryland, U.S.A. Discovered the causative organism of gas gangrene in 1892.

oxygen, p. 80) reduces the amount of toxin produced by the organisms, and when the condition is under control, surgery is then confined to the excision of sloughs and skin grafting.

Gas Infections

In less severe forms of infection gas bubbles occasionally are formed:

(i) *Local Type.*—Invasion is sometimes limited to a single muscle, which becomes necrotic while adjacent muscles escape.

(ii) A *gas abscess* frequently occurs if a contaminated foreign body is present in a wound (fig. 24). It subsides when the abscess is adequately opened ('uncapped'), and the foreign body removed.

FIG. 24.—Comminuted fracture of humerus due to a fragment of a high-explosive missile; three days after injury at Dunkirk (1941). Bubbles of gas are present under the triceps muscle (shown here as rounded 'white' areas).

(iii) *Subcutaneous infection* is sometimes seen spreading for a considerable distance around a wound. Crepitus is easily palpable, and the skin becomes khaki-coloured as a result of hæmolysis. *Unless this condition is recognised a needless amputation may be performed.* The surgical treatment required is thorough drainage of the wound by multiple incisions into the affected subcutaneous tissues, down to, but not including, the deep fascia, otherwise infection may be carried into the underlying fascial planes or muscles. Removal of subcutaneous necrotic fat and connective tissue is carried out. Penicillin must be given and, if available, hyperbaric oxygen can be most helpful.

Cancrum oris et noma is discussed in Chap. 30.

Carbuncles and boils are considered on p. 102.

ERYSIPELAS

Erysipelas is a spreading inflammation of the skin and subcutaneous tissues due, to an infection by *Str. pyogenes.* The general health of the patient is usually below par, and debilitating conditions and the extremes of life are predisposing causes.

Symptoms.—The skin in the vicinity of a scratch or abrasion becomes irritable and feels stiff. After a few hours symptoms of toxæmia supervene, which rapidly increase in severity.

Signs.—If the infection commences in a wound, a rose-pink rash extends over the adjacent skin. The edge of the rash is raised, a feature which is often more easily appreciated with the finger than the eye. The colour of the rash and its obvious edge distinguish erysipelas from cellulitis. As the rash extends, vesicles appear, which burst and discharge serum. Considerable œdema occurs when lax tissues are involved, particularly the orbit and the scrotum. The rash gradually fades, and for some weeks a brown discoloration of the skin remains, due to pigment set free as a result of destruction of red corpuscles.

FIG. 25.—Erysipelas with lymphatic œdema of face and eyelids. The patient was unable to open his eyes.

Complications.—*Gangrene.*—Sloughing of skin and subcutaneous tissues occasionally occurs, particularly of lax tissues in patients with poor resistance.

Lymphatic Obstruction.—A severe attack of erysipelas is sometimes followed by fibrosis of the lymphatic vessels and nodes, so that lymphatic drainage is impaired. The eyelids are not uncommonly affected, greatly to the detriment of the patient's appearance and comfort (fig. 25).

Treatment.—Fortunately it is a relatively uncommon disease and is completely controlled by penicillin.

ANTHRAX

B. anthracis is a large Gram-positive aerobic spore-forming rod. It is very resistant to heat and antiseptics. The disease occurs in domestic animals in some parts of the world and is likely to appear in men who handle imported carcases, wool, hides, hair, and bone-meal.

The **cutaneous type** is the commonest human variety; the incubation period is from three to four days. The lesion usually commences on an exposed portion of the body, such as the hands, forearms, or face (fig. 26). An itching papule occurs, around which a patch of induration soon becomes evident. The papule suppurates and is replaced by a black slough, and a ring of vesicles appears on the surrounding indurated area. This stage comprises the typical 'malignant pustule'. A brawny, congested area of induration develops around the site of infection. The regional lymph nodes are involved. Toxæmia is always in evidence. A smear of vesicle fluid is used to confirm the diagnosis by culture and animal inoculation.

FIG. 26.—Anthrax pustule. (*A. E. Hodgson, Liverpool.*)

Treatment.—Penicillin is the treatment of choice.

Prevention.—Very careful precautions are taken to sterilise potentially infected animal products and wool from countries where the disease is endemic, such as Asia Minor and Pakistan.

Differential Diagnosis.—The two conditions easily mistaken for it are a severe furuncle (Chap. 28) and accidental vaccinia (fig. 27). (The recently vaccinated child with the vaccinia pustule on its arm in full activity, while being carried by the mother or nurse, places the vaccinated area against her cheek.)

Other forms of anthrax are rarely, if ever, now seen, e.g. **Woolsorter's Disease**, a pneumonia due to inhalation of spores and an **Alimentary Type**, following ingestion of spores.

FIG. 27. — The commonest cause of accidental vaccinia.

CANDIDIASIS

Candida albicans (formerly called **monilia**) is a yeast, frequently present in small numbers in the healthy mouth and bowel. It may cause primary infection in the newborn, or superinfection when flora are disturbed by antibiotic treatment. In **Thrush** (candidal stomatitis) white patches are seen in the mouth; it may occur in infants, in post-operative patients, and with ill-fitting dental plates. **Vaginitis** is common in pregnancy and diabetes. Candida may infect most skin under breasts, and the nail folds.

FIG. 28 —Candida in sputum.

Administration of broad-spectrum antibiotics often results in proliferation of candida in the respiratory tract and bowel, and may be responsible for digestive upsets. Systemic candidiasis with invasion of lung and blood-stream is a complication of immuno-suppression in transplantation surgery and in the chemotherapy of malignant disease.

Candida infections are treated by the antibiotic nystatin.

CHAPTER 3

CHRONIC SPECIFIC INFECTIONS[1]

(TUBERCULOSIS, ACTINOMYCOSIS, LEPROSY, SYPHILIS)

TUBERCULOSIS

THIS disease derives its name from the characteristic lesion called a tubercle (a collection of inflammatory cells surrounding the organism, and later progressing to caseation) which is the response of the body to invasion by tubercle bacilli. These are mycobacteria and were first described by Koch in 1882. When stained they are difficult to decolorise with acid (hence the term 'acid-fast bacilli'). *Myco. tuberculosis* (fig. 29) may be human or bovine in type and is spread by airborne infection by the human type from open tuberculous cases, and by milk from infected cows in the case of the bovine bacillus. There are three main routes of primary infection. (1) By far the most common is by direct spread to the lungs where a primary focus occurs and thence by lymphatics to the hilar lymph nodes. With this primary infection, there is nearly always some hæmatogenous spread to other organs where the bacilli may lie dormant for many years. (2) Via the tonsils to the lymph nodes of the neck. (3) Via the lower ileum, probably in Peyer's patches, to the lymph nodes of the ileocæcal angle where they later show as calcified areas on X-ray.

Fig. 29.—*Mycobacterium tuberculosis* in human sputum.

Tuberculosis of the various organs is described in the appropriate chapters of this book.

Guidelines of Treatment.—The second half of this century has witnessed dramatic advances in the treatment of this notorious and age-old disease. Previously recovery depended upon waiting for the requisite level of immunity to be built up within the patient. This meant bed rest, prolonged for 3–4 years, and adequate nutrition in a decent environment free from overcrowding (*i.e.* in a sanatorium). Surgery, designed to aid rest and healing, was used only when the patient became well enough to withstand operative trauma, examples being extra-articular arthrodesis of joints using bone grafts, and extrapleural compression of the apices of the lungs by selective filleting of ribs (thoracoplasty). By 1950 recovery and supportive surgery was hastened by the introduction and use of streptomycin (1 g i.m. daily), para-amino-salicylic acid—PAS 1 (12–15 g daily), and iso-nicotinic acid—Isoniazid—(300 mg daily). These drugs are bacteriostatic, and the first and last bactericidal as well. Isoniazid has a small molecule, pene-

[1] A chronic specific disease can be recognised by clinical and pathological features specifically caused by a particular organism.

Robert Koch, 1843–1910. Professor of Hygiene and Bacteriology, Berlin (1885–1910). Discovered Mycobacterium Tuberculosis whilst working in the Imperial Health Office, Berlin.
Johann Conrad Peyer, 1653–1712. Professor of Logic, Rhetoric and Medicine, Schaffhausen, Switzerland. Described the Lymph Follicles in the Intestine in 1677.

trates macrophages and destroys bacilli in the middle of a tubercle. It has been usual to give the 3 drugs together for the first 3 months of treatment to avoid development of drug resistance. By then the sensitivity of the organism has been determined, and then the streptomycin may be omitted. The whole course may last for 2 years.

Today, new drugs have been introduced and shorter courses (e.g. 9 months) are being advocated. The front-line drugs include rifampicin, which is given for 4–8 weeks, and ethambutol (dosages being related to body weight). These have to be given in conjunction with INAH. Streptomycin is kept as the heavy artillery.

All these drugs must be given under careful supervision. Streptomycin has toxic effects on the vestibular branch of the auditory nerve, and on the kidneys. INAH causes peripheral neuritis, ethambutol visual impairment, and rifampicin is hepatotoxic.

It should be remembered that it is nigh impossible to eradicate every tubercle bacillus from the body. Lying dormant and enveloped in fibrous tissue any remaining bacilli are still able to cause a flare of the disease, particularly after trauma, after gastrointestinal operations resulting in nutritional deficiency, and in old age.

Amyloid Disease may be seen in cases of chronic osteomyelitis, bronchiectasis, tuberculosis, rheumatoid arthritis and multiple myelomatosis. Abnormal protein is deposited in the walls of the arterioles and later in the larger vessels. Microscopically, congo-red stains the infiltrated tissues. The kidneys, intestine, liver, and spleen are specially affected. Polyuria occurs due to infiltration of the glomeruli of the kidneys. Diarrhœa ensues owing to infiltration of the mucosal villi. The spleen and liver become enlarged and palpable. It is most important to bear in mind that this disease is a possibility in anyone who has prolonged suppuration from whatever cause. The diagnosis can be made on rectal biopsy—this method is simple, safe, and reliable. If the source of the infection can be eradicated, early amyloid disease will resolve.

FIG. 30.—Enlargement of the liver and spleen due to amyloid disease. Amputation was performed through the left hip joint for osteomyelitis of the upper end of the femur, but sinuses persisted. He succumbed six months later.

ACTINOMYCOSIS

This disease is caused by *Actinomyces israelii*, an anaerobic Gram-positive branching filamentous organism (fig. 31) which sometimes lives as a harmless parasite in the tonsillar crypts and dental cavities of the otherwise normal mouth. It is popularly supposed that it occurs in corn and grasses, but the pathogenic organism does not do so. If the organism invades tissue, it causes a subacute pyogenic inflammation with considerable induration and sinus formation. Trauma and the presence of carious teeth are important predisposing factors in the development of lesions in the mouth.

James Israel, 1848–1926. Urologist, Germany. Discovered Actinomyces Bovis in man in 1878.

Diagnosis depends on finding the organism in pus or in tissue section. Pus should be collected in a sterile tube (a swab is usually insufficient) and inspected in a good light for the presence of pin-head sized 'sulphur granules'. On microscopy the granules are seen to consist of Gram-positive mycelia. The peripheral filaments radiate[1] from the central part of the granule and may be surrounded by Gram-negative tissue clubs. The identity of the organisms may be confirmed by culture but the presence of secondary organisms often makes this difficult.

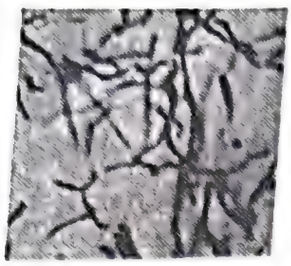

FIG. 31.—*Actinomyces israelii* in tissue section.

Actinomycotic lesions are characterised by the formation of a firm, indurated mass, the edges of which are indefinite, and infection spreads by direct invasion of adjacent tissues. Lymph nodes are not affected, but if a vein is invaded, pyæmic infection is likely to follow.

There are four main clinical forms of actinomycosis:

(i) *Facio-cervical* is the commonest form. The lower jaw is more frequently affected, often adjacent to a carious tooth. The gum becomes so indurated that it simulates a bony swelling. As extension occurs, nodules appear, which soften and burst. The overlying skin of the face and neck is indurated and bluish in colour, softening occurs in patches, and eventually abscesses burst through the skin (fig. 32). The characteristic features of the condition are chronicity, dense induration and sinuses surrounded by bluish skin.

FIG. 32.—Actinomycosis. Indurated sinuses extend from the neck to the orbit.

(ii) *Thorax.*—The lungs and pleura are infected either by aspiration of the fungus or, occasionally, by direct spread downwards from the pharynx or neck, or upwards through the diaphragm.

FIG. 33.—Actinomycosis of the lung involving the chest wall.

The disease extends through the lungs to the pleura and chest wall, which, in the late stages, is riddled with sinuses (fig. 33). An empyema is not uncommon, and the infection sometimes spreads through the diaphragm to the liver or subphrenic spaces. Clinically, the condition resembles tuberculosis, and in the early stages is only distinguished by the discovery of the organism in the sputum and confirmation by culture.

(iii) *Right iliac fossa* (Chap. 47).

(iv) *Liver* (Chap. 43).

Treatment.—Actinomyces is usually sensi-

[1] Actinomyces = Ray fungus.

tive to penicillin, tetracycline and some other antibiotics (e.g. Lincomycin), but the sensitivity should be checked in the laboratory. A prolonged intensive course of penicillin (10 mega units reducing to 4 mega units daily) is usually the best treatment until all signs of the disease have disappeared.

LEPROSY (HANSEN'S DISEASE[1])

There are probably from ten to fifteen million leprosy sufferers in the world today

Leprosy is an infectious disease widely spread throughout the tropical and subtropical areas of the world. It is caused by *Mycobacterium lepræ*, an acid-fast bacillus morphologically like the tubercle bacillus. It is mainly, but not entirely, contracted in childhood and late adolescence. While the mode of transmission regarding the portal of entry of *M. lepræ* is not known, recent studies have established that the source of infection is mainly from nasal secretions of leprosy patients and not from their skin. Leprosy is no longer endemic in Northern Europe, as it was in the middle ages and in Norway until the late 19th century; neither is it now spread by immigrants in Europe. These facts suggest that leprosy requires for its transmission some factors associated with poverty or lack of hygiene that is common in the areas where it is still endemic. A vast change in the outlook for this disease has occurred in the last 30 years. The condition was formerly regarded as hopeless, but in spite of the fact that it is now curable only 25% of the cases of this widely spread disease are under treatment. It is probably true to say that leprosy causes more paralysis, deformity, and misery than any other disease, but that in many cases these could now be prevented by modern therapy, given an adequate medical service for early diagnosis.

Although leprosy is a systemic infection, it presents predominantly as an infection of the skin, upper respiratory tract and dermal and peripheral nerves. Leprosy must always be considered in a patient presenting with a combination of skin *and* neural disorder, particularly because of the variation in the preponderance of these two manifestations and the tremendous variation in the appearance and histopathology of the dermal lesions, among individual patients with leprosy. These diverse manifestations led to a plethora of classification systems until Ridley and Jopling found that

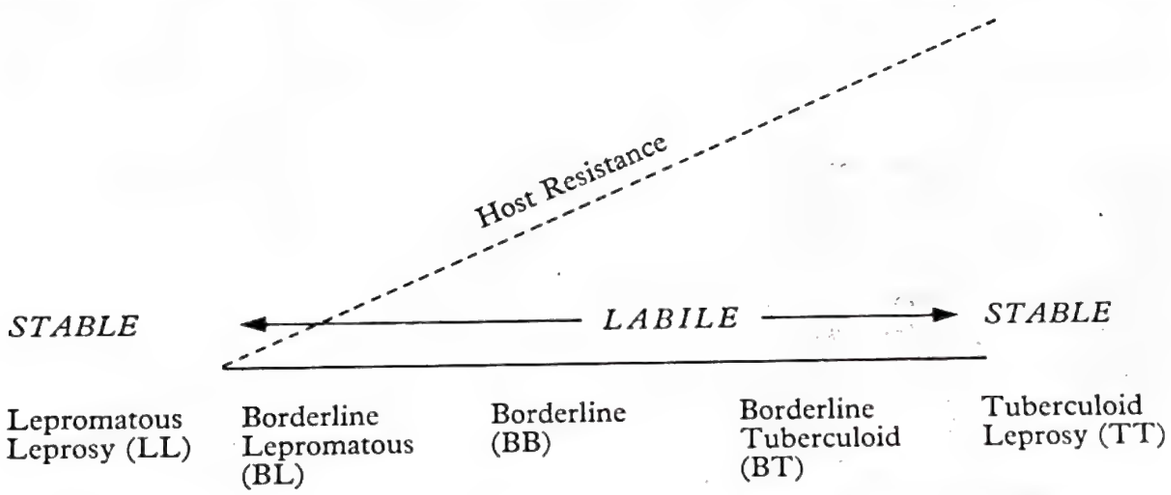

FIG. 34.—Ridley-Jopling classification of leprosy based on immunity of host.

there was a spectrum of disease in leprosy determined by the resistance of the host (fig. 34). The spectrum ranges from polar lepromatous (LL) to polar tuberculoid (TT) leprosy, denoting patients with minimal and maximal irreversible capacities to mount an immunological response against *M. lepræ*. The majority of patients are more labile in having some residual immunological capacity against *M. lepræ*, and thus are represented as borderline (BB), or borderline-lepromatous (BL) or borderline-tuberculoid (BT), if they veer more towards lepromatous or tuberculoid leprosy.

[1] Owing to the stigma attached to the word 'leper', Dr. R. G. Cochrane strongly recommends that it should never be used and similarly others have suggested that the best name for leprosy is 'Hansen's Disease'.

Gerhard Henrik Armauer Hansen, 1841–1912. Physician in Charge of a Leper Hospital near Bergen, Norway.
Robert Greenhill Cochrane, Contemporary. Formerly Medical Superintendent, Kola Ndoto Leprosarium, Shinyange, Tanzania.
William Henry Jopling, Contemporary. Consultant Leprologist, Hospital for Tropical Diseases, London.
Dennis Snow Ridley, Contemporary. Consultant Pathologist, Hospital for Tropical Diseases, London.

If left untreated, patients anywhere within the borderline spectrum can deteriorate towards lepromatous leprosy, whereas under treatment they will shift towards polar tuberculoid leprosy.

Lepromatous Leprosy

There is little or no resistance, the bacilli multiply with little cellular response, until the subcutaneous tissues may be loaded with masses of bacilli, many of them distending macrophages as large ' globi '. The cellular infiltrate is mainly of macrophages with a few lymphocytes.

Tuberculoid Leprosy

There is a strong tissue response, the bacilli are not numerous and are seldom seen except by special concentration methods. The histology consists of an epitheloid granuloma, many lymphocytes and a few giant cells.

Characteristically *tuberculoid* leprosy causes sharply localised lesions often affecting only one part of the body, while *lepromatous* leprosy is symmetrical and extensive. Since the damage in leprosy is mainly due to the response of the host cells, *tuberculoid* leprosy causes early, severe but localised deformity, while *lepromatous* leprosy causes deformity late, and more mildly and widely spread. The most severely deformed patients are those affected by some of the border-line forms where the disease may be both widespread through the body and also rather violent in its reactions.

A unique feature of the disease is not only its predilection for the surface of the body, but also for the cool parts of the surface. Warm areas like the axilla and gluteal cleft are spared, while the parts of the upper respiratory tract, like the lining of the nose, are severely involved. The testis is affected, while the ovary, and other deeply placed glands and organs, are unaffected. Since leprosy does not affect the vital organs of the body, it rarely causes death, and patients do not even feel ill for most of the time they have the disease.

During treatment, many patients manifest acute episodes which are referred to as ' reactions ' of which there are two distinct types:

The ' lepra or Type 1 reaction ' occurs in the borderline form of leprosy (BT, BB and BL), in which the skin lesions become erythematous, warm to touch and may break down, and the nerves swell and become painful and tender to touch. It is usually caused by a rapid increase in cell-mediated immunity by the host with an outpouring of lymphocytes into the lesions giving rise to acute inflammation with associated œdema. For this reason, the lesions have been referred to as ' reversal reactions ', advantageous by resulting in destruction of *M. lepræ*, but causing irreversible destruction of axons when the inflammation and œdema occur in nerves.

The other type of reaction is referred to as erythema nodosum leprosum (ENL or Type 2 reaction), usually occurring during treatment but confined to patients with lepromatous type leprosy (BL, LL). Here there are no changes in the established leprosy lesions, but new crops of very small erythematous lesions in the skin appear associated with systemic symptoms such as malaise, fever and nerve and joint pain. Occasionally, rhinitis, acute iridocyclitis, swollen and tender lymph glands, acute epididymo-orchitis and proteinuria occur. This is an Arthus type reaction, due to the deposition of immune complexes in and around blood vessels, locally or generalised throughout the body, and more akin to chronic serum sickness. This reaction may come and go or be persistent, and can in its severest form be fatal.

One of the most characteristic features of leprosy is its effect on nerves (fig. 35). Histologically, the cellular infiltrate may be seen localised around nerve fibres in and under the skin and, on clinical examination, superficial nerves such as the ulnar and posterior auricular may be observed to be swollen and tender. The anæsthesia that results from nerve involvement is an important point in diagnosis, and is also a cause of secondary damage and deformity. Much of the loss and disfigurement of hands and feet which has always been associated with leprosy is now known to be due not to leprosy itself, but to the damage and misuse which follows loss of pain sensation.

Medical Treatment.—Diaminodiphenylsulphone (Dapsone, DDS) (50–100 mg/daily) is now the standard treatment for all forms of leprosy. It is a bacteriostatic drug and experience has shown that in leprosy it has to be given for a long time—at least 3 years for all forms of tuberculoid leprosy and probably for life for all forms of lepromatous leprosy—for even when it is given to lepromatous patients until they

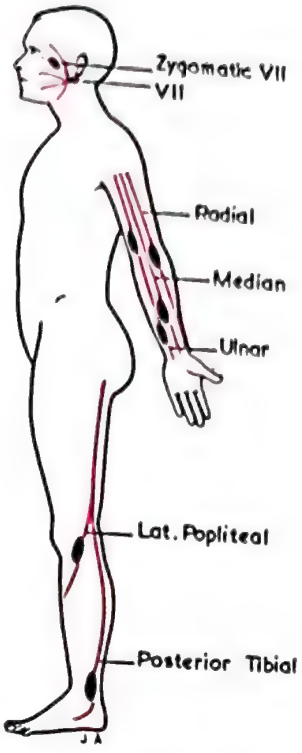

FIG. 35.—Sites of motor paralysis in leprosy.

(2) Median nerve just above wrist joint.
(3) Lateral popliteal at knee joint.
(4) Posterior tibial above ankle joint.
(5) Facial nerve in the bony canal or the zygomatic branch.
(6) Radial nerve at the elbow (rarely).

(*After Paul Brand, F.R.C.S.*)

become bacteriologically negative (5–10 years), they can still relapse when treatment is stopped. For many years it was considered that reactional episodes occurred more commonly when the full dose of DDS was given at the beginning of treatment and that reactions, once developed, persisted if dapsone treatment was continued. Both these ideas have now been proved to be fallacious. It has now been established that DDS resistance is a serious problem among patients with lepromatous leprosy, and that it occurs much more frequently in those patients who have received smaller doses of DDS in the past or have had their treatment interrupted. Since DDS resistance occurs only among patients with lepromatous type leprosy, it is strongly recommended that new patients with lepromatous leprosy should be initiated with DDS plus another drug. The other antileprosy drugs of proven value are thiambutosine, thiacetazone and clofazimine. Rifampicin, the first bactericidal drug against *M. lepræ*, has been shown to act more rapidly than any of the other antileprosy drugs. It is too early to assess the use of rifampicin in the treatment of leprosy. It is probably too expensive for regular use in the countries where leprosy is endemic.

For reactions, symptomatic treatment should be given for the milder cases, including analgesics and tranquillisers. For the more severe reactions various proprietary antimonial drugs, such as Stibophen and Fouadin, etc., have proved beneficial as has Chloroquine. For a still more persistent and severe lepra and ENL reactions it may be absolutely essential to give steroids to tide the patients over and particularly to protect the nerves. For patients with the most severe ENL reactions, but not lepra reactions, thalidomide has proved to be as beneficial as steroids. If thalidomide is available it must be confined to male patients or females outside the child-bearing age. Clofazimine in high doses can suppress all but the most severe ENL reactions.

Surgery.—The Deformities of Leprosy are divided into *primary*—those which are caused directly by leprosy and its reactions, and *secondary*—those which result from anæsthesia and consequent misuse. The stigma of leprosy is the stigma of deformity, and a wide-open field awaits the plastic surgeon in this disease.

The Face.—*Primary deformity:* the skin of the face becomes thickened and sometimes nodular in lepromatous leprosy (fig. 36); the forehead, cheeks, nose, and ears are especially affected. The result in the acute phase is referred to as ' leonine facies '. This infiltration subsides under medical treatment, but may leave the skin wrinkled and without its normal support, producing, in a young person, a caricature of old age. The hair of the eyebrows falls out and the lateral cartilages and septum of the nose may be destroyed leaving collapse of the centre of the nose and lifting of the tip towards

the bridge (fig. 37). The upper branches of the facial nerve may be paralysed, giving rise to lagophthalmos; the lower branches are sometimes partially paralysed.

The patient with the above deformities usually finds it quite impossible to return to normal social relationships even though his leprosy may be cured. Plastic surgery can completely transform such a face using a post-nasal inlay to the nose (fig. 37),

FIG. 36.—Nodular lepromatous leprosy.

and an 'island flap' for the eyebrows. A temporalis muscle segment reactivates the eyelids and a face-lift may restore more normal contours to the skin.

FIG. 37.—(*Left*) Extreme case of nasal collapse. (*Right*) After post-nasal epithelial inlay. (*N. H. Antia, F.R.C.S.*) (*By permission from the Annals of the Royal College of Surgeons of England.*)

Eyes.—Some of the blindness of leprosy is simply due to exposure following paralysis of the eyelids. This is correctable by plastic surgery. Other causes of loss of vision are lepromatous infiltration of the anterior segment of the eye and acute allergic changes of the tissues associated with reaction. Acute plastic irido-cyclitis is one of the commonest manifestations of this allergic reaction. Any redness of the eye or loss of visual acuity in leprosy demands full examination and prompt treatment if the sight is to be saved.

FIG. 38.—Clawed left hand in leprosy. Note that the thumb lies completely unopposed. (*Dr. R. G. Cochrane, London.*)

Hands[1].—*Primary Deformity.*—In the upper limbs, leprosy causes paralysis frequently in the ulnar nerve at the elbow and in the median nerve at the wrist (fig. 35) but rarely in the motor part of the radial nerve (1%). Thus the patient commonly loses the use of all the small muscles of the hand but very few forearm muscles (fig. 38). The fingers are clawed and the thumb lies beside the palm, unable to oppose the fingers.

Treatment. — The extensor carpi radialis brevis muscle is extended into the hand with free grafts which run along the lines of the lumbrical tendons to correct the clawing of the fingers. The flexor sublimis tendon to the ring finger is withdrawn in the forearm and rerouted to oppose the thumb along the line of the abductor brevis. In this way

[1] The work on reconstruction of the hand in Hansen's disease was started by Professor Paul Brand at the instigation of Dr. R. G. Cochrane (p. 29).

Paul Wilson Brand, Contemporary. Chief of the Rehabilitation Branch, U.S. Public Health Service Hospital, Carville, Louisiana, U.S.A.

the fingers and thumb may be balanced and function almost normally. Before attempting operation it is important to make sure that the fingers are made mobile by massage and exercise.

Secondary Deformity.—Since the hand is often totally anæsthetic the patient frequently burns himself, or damages himself by the uninhibited strength which he uses through his fingertips. His hands become scarred and progressively absorbed until only stumps remain. It takes patience and perseverance to teach every patient that his hands can be preserved only by constant alertness to foresee possible dangers, and constant gentleness to his own tissues which are not protected by pain. Once he is convinced that it is not leprosy that is destroying his fingers he may be willing to accept the discipline of caring for himself.

Feet.—*Primary Deformity.*—In the lower limbs the posterior tibial nerve is often involved at the ankle, giving rise to ' clawing ' of the toes and anæsthesia of the sole of the foot. The lateral popliteal nerve may also be destroyed, giving rise to foot-drop. The medial popliteal nerve is never involved, so the tibialis posterior muscle can be safely used to correct foot-drop.

Secondary Deformity.—The anæsthesia of the sole of the foot is very serious because almost every patient with insensitive feet sooner or later develops trophic ulceration. If he then continues to walk on his ulcers, the condition progresses and the infection spreads until, after a few years, the foot is contracted and distorted, and destroyed to the point where amputation must be advised.

It is important for the patient to understand the pathology of his ulcers and to realise that they are not due directly to leprosy. These ulcers heal readily with rest in a plaster cast and their recurrence can be prevented by the regular use of special footwear designed to spread the weight evenly over the whole foot.

SYPHILIS[1]

For a detailed description of venereal syphilis reference should be made to a text book on venereal disease.

Acquired syphilis is a venereal infection caused by *Treponema pallidum* (fig. 39), a delicate spiral organism (spirochæte), 6–15 μm in length. A dramatic decline in incidence after the introduction of penicillin has been followed by a gradual but significant increase throughout the world.

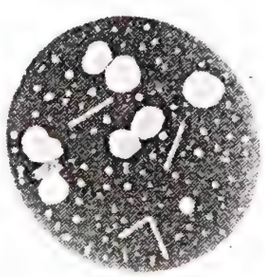

FIG. 39.—*Treponema pallidum* in the exudate from a chancre.

Transmission is by direct contact with a surface lesion containing treponemes which penetrate the skin or mucosa at the point of contact. Since treponemes are present only in the surface lesions of EARLY Syphilis, *i.e.* primary, secondary and occasionally the first year or two of latency, syphilis is only infective in its early stages. After 2–5 years acquired syphilis is rarely communicable and the ulcerative cutaneous lesions of tertiary syphilis are not regarded as infective as they contain few, if any, treponemes. The organism dies rapidly on drying, hence infective early lesions are predominantly sited in moist areas, *e.g.* genitals and mouth, and infection almost always takes place by sexual contact.

Clinical Features.—The disease is divided into 4 stages.

---

[1] Syphilis derives its name from a poem by a Physician, Girolamo Fracastoro (1478–1553), published in Venice in 1530. The poem tells of the shepherd, Syphilus, who was struck down by the disease as a punishment for insulting Apollo.

On his return from Haiti in 1493, Christopher Columbus (1451–1506) brought back syphilis, parrots and rare plants. The King and Queen of Spain received him with the highest honours.

Primary Syphilis.—A primary sore or chancre (figs. 40 and 41) develops at the site of entry of the treponemes in about 3–4 weeks. It may resolve at any stage of its development and thus be quite atypical. Starting as an indurated papule, it becomes eroded and when fully developed will present the following signs of a classical Hunterian chancre:—a shallow, indurated,

FIG. 40.—Penile primary chancres.

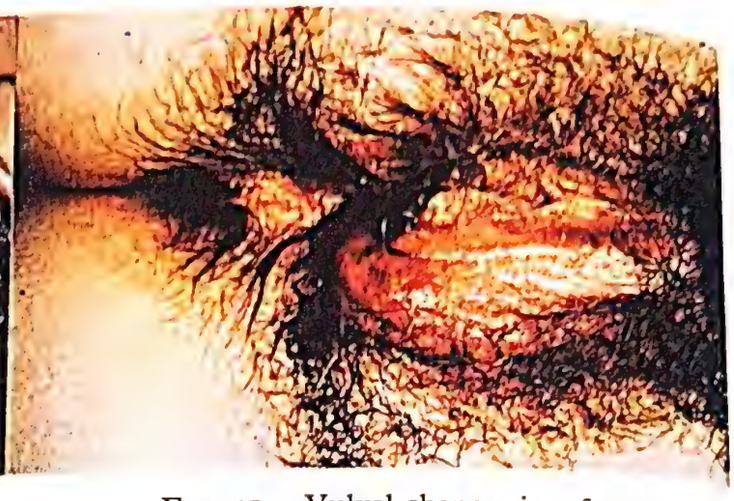

FIG. 41.—Vulval chancre in a female.

painless, non-bleeding ulcer, usually single, oval or round, with a raised hyperæmic margin. A painless enlargement of the associated lymph nodes occurs. There are no constitutional symptoms and a female patient will be unaware of the presence of an intravaginal chancre. Extragenital chancres of the lip,[1] tongue, nipple, *etc.* are now rare, but rectal and perianal primaries occur in homosexuals and are usually atypical.

Diagnosis is by finding *Treponema pallidum* in the clear exudate from the lesion by dark-field microscopy. The serum tests do not become positive for a week or two after the appearance of the chancre, hence initial negative serology must never be interpreted as excluding primary syphilis. The tests should be repeated for up to three months where doubt persists. Chancres must be distinguished from traumatic ulcers, chancroid (p. 44), herpes, granuloma inguinale (Chap. 57), early carcinoma or any genital lesion following risk.

Secondary Syphilis

Signs usually appear in 6–12 weeks as a reaction to spirochætæmia. The commonest sign is a dull red or coppery rash, generalised, symmetrical, indolent and non-irritant. Often inconspicuous, the rash is characteristically pleomorphic, being roseolar or macular at first, with papular, papulo-squamous, or other elements appearing later. Papules on contiguous moist sites, e.g. vulva, perineum may enlarge to form condylomata lata, fleshy, wart-like growths teeming with treponemes. Small, round, superficial

[1] Primary sores on the lips usually result from kissing, and a case is recorded in which a gentleman with secondary ulceration of the mouth infected five young ladies at a dance, each of whom developed a chancre on the lip.

John Hunter, 1728–1793. Surgeon, St. George's Hospital, London. To further his knowledge of venereal disease he is said to have inoculated himself with syphilis in 1767.

erosions may occur in the mouth where they may coalesce to form the so-called snail-track ulcers. A generalised, painless lymphadenopathy often occurs and less common signs include sore throat, hoarseness, ' moth-eaten ' alopecia, iritis and bone and joint pains. Constitutional symptoms, malaise, headache, pyrexia, if present, are usually mild.

Latent Syphilis

Follows the untreated secondary stage and lasts from 2 years to a life-time. There are no signs but the serum tests are positive.

Late Syphilis (*Syn.* Tertiary Syphilis).—Syphilis in all its stages is essentially a vascular disease. Following spirochætæmia, treponemes cause inflammatory reactions in the perivascular lymphatics of terminal vessels with subsequent obliterative endarteritis, tissue necrosis and fibrosis. Since almost any structure may be involved, the signs can be extraordinarily variable and will be referrable to the site or system involved. Only about 40% of untreated syphilitics will develop signs of tertiary syphilis about 5–15 years after infection, 8–10% will develop neurosyphilis, 10–12% cardiovascular syphilis and 15–20% late benign syphilis, where less vital structures are involved. The three types are not mutually exclusive. The characteristic lesion of late syphilis is the localised *gumma* or diffuse gummatous infiltration.

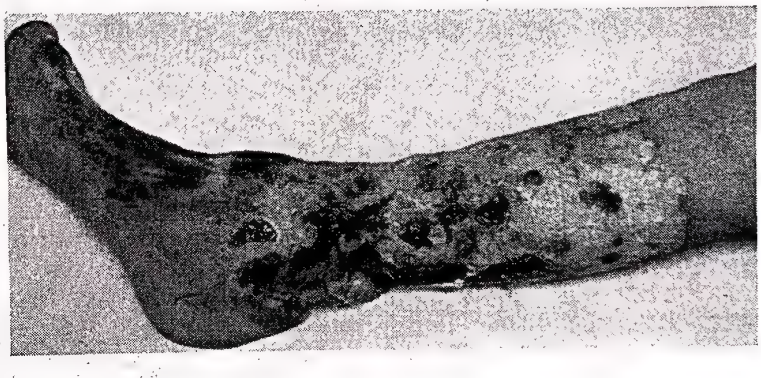

FIG. 42. — Gummatous ulcers, circular and serpiginous, with tissue paper scars. (*Case salvaged from a varicose vein clinic.*)

The gumma is a syphilitic hypersensitivity reaction consisting of granulation tissue with central necrosis. Sloughing of a subcutaneous gumma may produce the typical, painless, punched-out gummatous ulcer with ' wash-leather ' base. On healing it leaves a silvery, ' tissue-paper ' scar (fig. 42). Alternatively the gummatous process may be nodular or infiltrative without ulceration and slow peripheral spread occurs with central healing. The individual lesions are round and indurated and grouped lesions are circinate in outline with sharply defined, hyperpigmented margins.

Serological Tests for Treponemal Diseases are of two types :

1. *Non-specific* (*syn. Reagin, Non-treponemal, Lipoidal antigen tests.*)

Examples are Cardiolipin Wassermann (C/WR), Kahn, Ven. Dis. Ref. Lab. slide test (V.D.R.L.). These tests detect the presence of an antibody *reagin* in the serum of patients with treponemal infections, but *false positives* may occur since reagin may be present temporarily in some non-treponemal conditions; e.g. malaria, vaccinia, glandular fever, typhus, Weil's Disease. Stronger and more persistent false positives may occur in leprosy and collagen diseases. A diagnosis of syphilis is never justified

on serological grounds alone without confirmation from one or more of the specific tests—

2. *Specific Tests.*—(*syn. Treponemal antigen tests*)

Examples are Reiter's Protein Complement Fixation Test (R.P.C.F.T.)
Treponemal Hæmagglutination Assay (T.P.H.A.)
Absorbed Fluorescent Antibody Test (F.T.A.Abs.)
Treponema Pallidum Immobilisation Test (T.P.I.)

After curative treatment for early syphilis the reagin tests should become negative within a year but the specific tests may remain weakly positive for life, giving rise to doubts as to the continued activity of the disease. This problem can be resolved by performing the tests on the IgM fraction of the patient's serum since antibodies associated with the IgM fraction cease to be produced within a few months of curative treatment whereas the production of IgG class antibodies may continue for life. Thus, negative tests on the IgM fraction indicates arrest or cure.

Treatment.—No local treatment should be applied to a suspected chancre until dark-field examinations have proved negative on 3 successive days and no treponemicidal antibiotics should be prescribed until syphilis is confirmed or excluded. Penicillin has supplanted all other forms of treatment. A high cure rate is achieved in early syphilis with intramuscular Procaine Penicillin G, one mega unit daily for 10–14 days. This dosage is prolonged to 14–21 days for latent and late syphilis. Clinical and serological observation should be continued for two years after treatment. For penicillin sensitive patients tetracycline, erythromycin, cephaloridine and chloramphenicol are all treponemicidal but experience with them is limited.

Herxheimer Reaction.—About 6 hours after the first injection 40% of early syphilitics will develop pyrexia, malaise and possibly rigors lasting a few hours only. The reaction is infrequent in late syphilis, but may be more serious.

Prognosis is excellent after standard treatment for early syphilis. In late syphilis, particularly of the cardiovascular system, cure of the underlying disease may not significantly improve the condition of the patient.

Congenital Syphilis

Transmission.—Infection occurs when treponemes from an infected expectant mother cross the placental barrier to the fœtal circulation. The more recent the mother's infection, the more likely is this to occur and the more serious the effects on the child. The results of fœtal infection vary from death in late fœtal life or early infancy to the birth and normal development of an apparently healthy child whose only abnormality is positive serology.

Early Congenital Syphilis

Signs in the newborn, which may be delayed for a few weeks, include a generalised rash and mucous erosions as in secondary syphilis. The 'snuffles'—a syphilitic rhinitis with nasal discharge which interferes with suckling causing loss of weight; epiphysitis, periostitis, osteochondritis, hepatosplenomegaly and basal meningitis. Signs may be so slight as to escape notice or so severe as to cause death in early infancy.

Late Congenital Syphilis

The extraordinary variety of clinical manifestations which can occur in acquired tertiary syphilis can also occur in childhood or puberty in late congenital syphilis; *e.g.* congenital neurosyphilis, cutaneous, visceral or skeletal gummata, but congenital cardiovascular syphilis is very rare. In addition some manifestations, the *Stigmata*, occur in congenital, but never in acquired syphilis.

The *stigmata* of late congenital syphilis—Hutchinson's classical triad consists of:

1. *Interstitial Keratitis.*—The most frequent of the stigmata, is a syphilitic hypersensitivity reaction with onset between 5–15 years. The cornea becomes inflamed causing pain, lacrimation and photophobia. It tends to be bilateral and recurrent. Prolonged, severe recurrent attacks result in a hazy 'ground-glass' appearance of the cornea, with yellowish-red corneal patches in severe cases (salmon patches).[1] It is

[1] Not to be confused with the salmon-patch birthmark.

Karl Herxheimer, 1861–1944. Dermatologist, Frankfurt, Germany.

uninfluenced by anti-syphilitic treatment but can be controlled by local cortisone treatment.

2. *8th Nerve Deafness.* A progressive, bilateral, perceptive deafness, onset about puberty, uninfluenced by treatment.

3. *Hutchinson's Teeth.* A peg-shaped deformity of the upper central incisors, second dentition. *Moon's Molars* (mulberry molars), the 6-year molars erupt with dwarfed cusps. Other classical signs include saddle nose (fig. 43), perforation of the palate (fig. 44); sabre tibia and Clutton's joints (painless effusions, commonly in the knee joint).

Prevention and Treatment.—One mega unit of Procaine Penicillin G given to the mother for 14–21 days as early as possible in pregnancy will not only protect her from the ravages of late syphilis but will prevent infection of the fœtus, or even cure

FIG. 43.—Saddle nose of congenital syphilis.

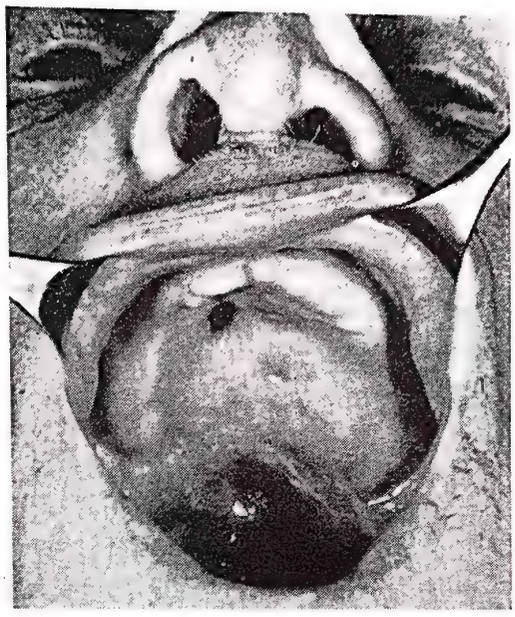

FIG. 44.—Perforation of palate.

it *in utero*, if already infected. An infected neonate whose mother received no treatment during pregnancy should be treated as for late acquired syphilis with the dosage adjusted to weight.

Neonatal Serology.—An expectant mother who has received treatment during pregnancy, or who is an untreated latent syphilitic may produce a child free from syphilis but seropositive due to passive transfer of maternal IgG antibodies. This serological problem can be solved by performing tests on the IgG and IgM fractions of the infant's serum. In the case of passive transfer the IgG tests will be positive and the IgM tests negative. Positive IgM tests indicate active disease in the child since the IgM fraction of the maternal serum proteins does not cross the barrier of the normal placenta. In all cases careful clinical and serological follow-up of mother and child is essential.

YAWS[1] (FRAMBŒSIA)

An endemic disease of rural areas in tropical countries of high humidity. The causative organisms, *Treponema pertenue*, appears indistinguishable from *Tr. pallidum* and produces identical serological reactions. Direct contact with an early lesion is the usual mode of transmission, but a vector may sometimes be responsible. It is not sexually transmitted. The primary lesion is most frequently seen on the legs of children. About one month after infection a papule appears at the site of entry of the treponemes, this ulcerates giving the lesion a pink, raised, raspberry like (frambœsia[2]) appearance. Secondary lesions, usually papillomatous, appear some weeks

[1] The possible answer to ' What's Yaws? ' is ' Syphilis '. [2] Framboise (Fr.) = Raspberry.

Sir Jonathan Hutchinson, 1828–1913. Surgeon, The London Hospital (1859–1883). Described Hutchinson's Teeth and the triad in 1858.

Henry Moon, 1845–1892. Dental Surgeon, Guy's Hospital, London (1870–1887). Described Moon's Molars in 1876.

Henry Hugh Clutton, 1850–1909. Surgeon, St. Thomas's Hospital, London, described these joints in 1886.

later. After 5 or more years of latency a minority of patients develop late gummatous-like lesions of soft tissue or bone similar to those of tertiary syphilis. The cardio-vascular and nervous systems are not involved and congenital yaws does not occur. Treatment as for syphilis.

CHANCROID (SOFT SORE)

This venereal disease is rare in western countries.

It is caused by the strepto-bacillus Ducrey (*Hæmophillus ducreyi*)*. Two to five days after infection, vesicles, often multiple, appear on the genitals. They become pustular and ulcerate, forming rounded, painful, soft, readily bleeding ulcers with undermined edges. Inguinal adenitis follows, the swollen nodes being hard and tender causing a feeling of stiffness in the groin. Resolution may occur at this stage, but suppuration may follow, the nodes becoming matted together forming a fluctuant unilocular abscess (bubo) with red overlying skin, in one or both groins. The bubo should never be incised since healing is very slow. Evacuation of the abscess by repeated aspirations is preferable. Phagedæna[1] sometimes occurs.

Treatment.—Any antibiotic which may prevent the identification of *T. pallidum* in a case of concomitant syphilitic infection, or when the ætiology of the lesion is in doubt, is contraindicated. Sulphonamides 4 g daily for 7–10 days is the treatment of choice.

Gonorrhœa.—This venereal disease is an acute specific disease and is discussed in relation to the Genitourinary system, Chapters 57 and 58.

Lympho-granuloma Inguinale is described in Chapter 57.

Granuloma Inguinale is described in Chapter 57.

PARASITIC DISEASES

Filariasis is a disease widely spread through tropical and sub-tropical countries. It is due to a nematode worm, *Filaria sanguinis hominis* which is transmitted by a mosquito (*Culex fatigans*). Once in the human body, the female worm finds its way to the lymphatics and lymph nodes (especially the inguinal group). It attains sexual maturity in six to eighteen months and produces vast numbers of microfilariæ, so that there may be 50 millions in the blood at one time. Obstruction of the lymph vessels ensues and this is manifested in (1) varicosities of the lymphatic vessels producing chylous ascites and hydroceles and, sometimes, chyluria, and (2) solid œdema (elephantiasis) often affecting the legs, scrotum, and arms, though it may occur anywhere. The best method of treatment known at present is Hetrazan (diethylcarbamazine-citrate), which appears to sterilise or kill the adult female worm. Prevention by anti-mosquito measures is, of course, vitally important. Elephantiasis may require surgery (p. 175).

Hydatid disease is discussed in Chapters 38 and 43.
Bilharziasis is discussed in Chapter 55.
Amœbiasis is discussed in Chapter 43.

CHAPTER 4

TUMOURS. CYSTS. ULCERS. SINUSES

THIS chapter concerns the general surgical pathology of tumours. Tumours arising in the various organs are considered in their appropriate chapters.

A tumour is a new formation of cells of independent growth usually arranged atypically, which fulfils no useful function and has no typical termination. The term ' tumour ' should be reserved for new-growths; its loose application to inflammatory swellings, such as Pott's puffy ' tumour ' (Chap. 24), or to enlargement of an organ due to hypertrophy, should be abandoned.

Causation

Over 300 years ago it was stated that ' any kind of external irritation, whether from motion, heat, or acrimony, may cause cancer '. Natives of Kashmir are prone to cancer of the skin of the thighs and lower abdomen (McNeill Love). This is due to their habit of keeping warm by squatting and hugging earthenware pots containing glowing charcoal (the pot being termed a *kangri*), with the result that the adjacent skin is irritated by heat and fumes. It is common knowledge that women can swallow in comfort fluids at a considerably higher temperature than men can tolerate, which fact may explain the greater incidence of post-cricoid carcinoma in females. ' Chimney-sweeps' ' cancer (Chapter 58), and ' countryman's lip ' (Chap. 28), and tar workers' cancer (fig. 45) are other examples of carcinoma due to chronic irritation.

FIG. 45.—Squamous-celled carcinoma on the back of the hand of a tar worker.

FIG. 46. — Squamous-celled carcinoma in a varicose ulcer (note everted edge).

Regeneration of tissue, with possibly the awakening of erstwhile dormant embryonic cells, may encourage malignant changes. Primary carcinoma of the liver is sometimes seen in cases of cirrhosis, and arises from the liver cells which are endeavouring to regenerate. Similarly, squamous-celled carcinoma occasionally occurs in a chronic ulcer (fig. 46), also Marjolin's ulcer, p. 109), and a fibrosarcoma arising in a scar is not uncommon. Viruses cause cell instability and are therefore implicated. A wart is the commonest example of a virus causing a tumour (see also Burkitt's tumour, p. 184).

Carcinoma is not hereditary. However experience shows that it appears to ' run in families '.

Tumours reproduce cells which are similar to those from which they arise, although if the tumour grows rapidly the resemblance becomes less obvious (*anaplasia*). It

sometimes happens that the epithelium from which the tumour grows has already changed its characteristics. The gall-bladder is normally lined by columnar epithelium, but the presence of gall-stones may result in the epithelium undergoing squamous-celled *metaplasia.*

CLASSIFICATION

The classification of tumours is fraught with difficulty owing to their varied and sometimes atypical appearances.

Teratomas.—These tumours may arise from 'totipotent' cells, containing representative cells from all three embryonic layers: ectoderm, endoderm, and mesoderm. Teratomatous 'dermoids', for example, contain hair, teeth, muscle, gland tissue.

Blastomas develop from unipotent cells, and arise from any one of the three embryonic layers (e.g. neuroblastoma, p. 51).

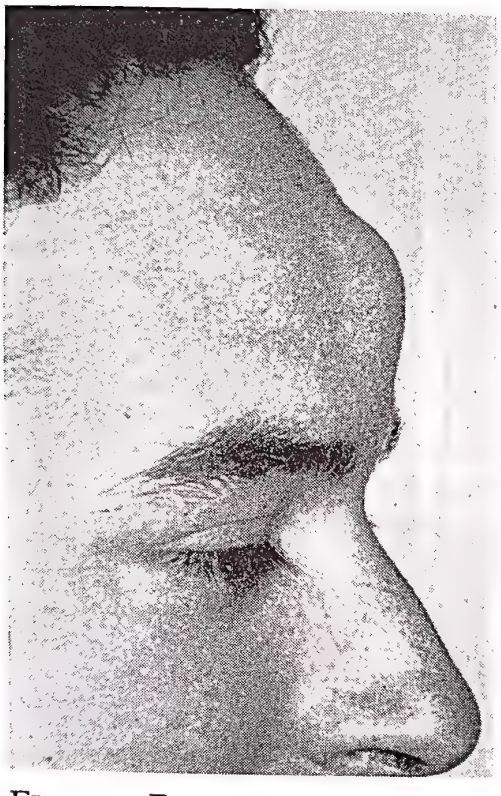

FIG. 47.—Dermoid cyst of forehead.

Dermoid Cysts.—'Dermoid' is a loose term given to cysts lined by squamous epithelium occurring in various parts of the body. Sebaceous cysts are lined by superficial squamous cells and should more accurately be called 'epidermoids'.

(i) *Teratomatous dermoids* (see above) are found in the ovary, testis, retroperitoneum, superior mediastinum, and the presacral area. Malignant change occurs not infrequently in these tumours and it is wise to regard them all as liable to carcinomatous or sarcomatous change.

(ii) *Sequestration dermoids* (p. 57) are not teratomas but are formed by the inclusion of epithelium beneath the surface at places where lines of developing skin meet and join (forehead (fig. 47), external angular process, Chap. 29, root of nose, Chap. 29, branchial cysts, Chap. 32).

(iii) *Implantation dermoids* (p. 58) may follow puncture wounds, commonly of the fingers.

INNOCENT OR MALIGNANT

An **innocent or benign tumour** is usually encapsulated, and does not disseminate nor recur after removal. Growth is uniform throughout the whole mass and symptoms, which can be dangerous, are due to its size, position, and pressure (except in certain adenomas which secrete a *hormone* which may affect bodily functions). Frequently innocent tumours are multiple.

Malignant Tumours.—The characteristics of malignancy are: (*a*) Invasion of surrounding tissues, (*b*) Pleomorphism (variable shapes) of cells, (*c*) Rapid growth, (*d*) the tendency to metastasise to other parts of the body by the lymphatics and the blood-stream, (*e*) general weight loss and a rapid downhill path.

It has been suggested that the division of tumours into these two major groups imposes a concept which is too rigid (Walter). A third group of intermediate tumours exists which includes carcinoid tumours, 'adenoma' of the bronchus, 'mixed' salivary tumours, basal cell carcinoma, etc.

John B. Walter, Contemporary. Associate Professor of Pathology, University of Toronto, Canada.

METHODS OF SPREAD OF MALIGNANT TUMOURS

(i) **Local Extension** (direct spread).—This feature is the most reliable evidence of malignancy when the tumour is examined microscopically. Invasion takes place most readily along connective-tissue planes, whereas fascia or aponeurosis forms a temporary barrier. An avascular structure, such as articular cartilage, resists invasion to a remarkable extent.

(ii) **Blood-stream.**—This is the most common method of dissemination of a *sarcoma*, as the venous clefts, so typical of a sarcoma, readily permit malignant cells to enter the blood-stream. These malignant emboli are liable to be arrested in the lungs, where they form secondary deposits. Large veins are sometimes extensively invaded by sarcoma (fig. 48).

FIG. 48.—Intravenous spread of sarcoma.

Carcinoma disseminates less commonly by the blood-stream, although a carcinoma of the kidney may invade the renal vein and inferior vena cava. Cancer cells may be detected in the venous blood draining the region of a malignant tumour. Warren Cole found that during operation on a cancer of the breast, for instance, a shower of cancer cells pass into the axillary vein.

(iii) **Lymphatics.**—The spread of *carcinoma* along lymphatics occurs both by permeation and by embolism.

Permeation.—The malignant cells grow along the lymphatic vessels from the primary growth; this may even occur in a retrograde direction. The presence of malignant cells stimulates perilymphatic fibrosis, but this does not stop the progress of metastases further along the lymphatic chain.

In some instances, notably malignant melanoma (p. 112), groups of cells may so overcome the surrounding fibrosis, as to give rise to intermediate deposits between the primary growth and the lymph nodes (fig. 49).

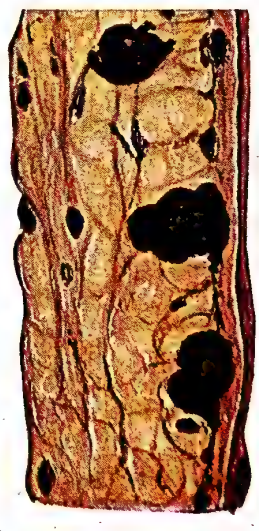

FIG. 49. — Melanomatous deposits in subcutaneous lymphatics of the abdominal wall. (*R.C.S. Museum.*)

Embolism.—Cancer cells invade a lymphatic vessel and are carried by the lymph circulation to a regional node, so that nodes comparatively distant from the tumour may be involved in the early stages.

(iv) **Seeding.**—Implantation of carcinoma has been observed in situations where skin or mucous membrane is closely in contact with a primary growth. Examples of this 'kiss cancer' are carcinoma of the lower lip affecting the upper, and carcinoma of the labium majus giving rise to a similar growth on the opposite side of the vulva. Recurrence after operation is occasionally due to implantation of malignant cells in the wound. Examples of this

Warren Henry Cole, Contemporary. Emeritus Professor of Surgery, University of Illinois, Chicago, U.S.A.

mischance are the appearance of a malignant deposit in the bladder scar after suprapubic removal of a primary growth, and nodules of carcinoma in the scar of the incision after mastectomy. When the peritoneum is involved, cells from a carcinoma may spread like snowflakes all over its serous surface. This transcœlomic spread is specially notable when cells from a colloid carcinoma of the stomach gravitate on to an active ovary and give rise to malignant ovarian tumours (Krukenberg's tumour, Chapter 41), which may be the first manifestation of gastric malignancy.

GRADING AND STAGING OF MALIGNANT TUMOURS

Grading and staging are used to assess the degree of malignancy of the tumour as an indication of the prognosis, and may be used as a guide to determine the type and the extent of the treatment which is required.

Broders' Grading of Malignant Tumours.—Tumours are divided into four categories, according to the degree of differentiation shown by component cells as viewed through the microscope. Squamous-celled carcinoma best illustrates these points, which include the degree of anaplasia, the absence or presence of prickle cells, and the number of mitotic figures.

Grade I. This is the least malignant, and not more than 25 per cent. of cells are lacking in well-marked differentiation. The remainder show keratinisation and obvious differentiation.

Grade II. From 25 per cent. to 50 per cent. are undifferentiated.

Grade III. From 50 per cent. to 75 per cent. are undifferentiated.

Grade IV. Over 75 per cent. of cells are undifferentiated, i.e. anaplastic and with mitotic figures, and are the most malignant.

This grading must not be taken too literally in estimating treatment or prognosis, e.g. different parts of the same tumour may show varying grades, and Grade I neoplasms may have disseminated widely, whereas a Grade IV tumour may still be localised.

Anaplastic tumours are usually radio-sensitive, but commonly recur, whereas highly differentiated tumours tend to be radio-resistant.

Dukes' Staging.—This is a method of classifying the spread of carcinoma of the rectum and is described in Chapter 50.

TNM Classification.[1]—This is a detailed clinical staging which is arrived at simply by the clinician ascertaining the following points during his examination of the patient: What is the extent of the primary **T**umour? Are any lymph **N**odes affected? Are there any **M**etastases? The information so obtained is scored, *for example in carcinoma of the breast*, as follows:—

Tumour	**N**odes	**M**etastasis
T_1 = 2 cm. or less. No skin fixation.	N_0 = No nodes.	M_0 = No metastasis.
T_2 = More than 2 cm., but less than 5 cm. Skin tethered or dimpled. No pectoral fixation.	N_1 = Axillary nodes movable (a) not significant, (b) significant.	M_1 = Metastases are present including involvement of skin beyond breast, and contralateral nodes.
T_3 = More than 5 cm., but less than 10 cm. Skin infiltrated or ulcerated. Pectoral fixation.	N_2 = Axillary nodes fixed.	
T_4 = More than 10 cm. Skin involved but not beyond breast. Chest-wall fixation.	N_3 = Supraclavicular nodes. Œdema of arm.	

[1] Adopted by the International Union against Cancer. TNM Classification has been extended to many sites of cancer.

Albert Compton Broders, 1885–1964. Consultant, Surgical Pathology, Mayo Clinic, Rochester, Minnesota, U.S.A.
Cuthbert Esquire Dukes, 1890–1977. Consulting Pathologist, St. Mark's Hospital, London.

Thus, for example, one patient may have a carcinoma which is $T_1N_0M_0$, while in another the extent of the disease may be $T_3N_2M_1$.

This scoring can be applied quite easily to the commonly used method of *clinical stage grouping* of carcinoma of the breast (described in Chap. 35), by the use of fig. 50. Metastases present is equivalent to Stage IV.

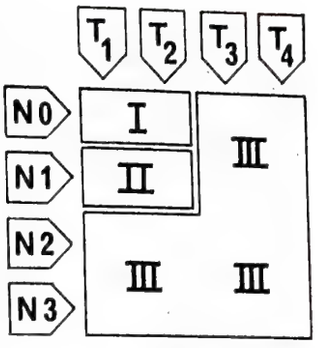

FIG. 50.—TNM scoring related to clinical stage grouping of breast cancer when there are no metastases.

BENIGN TUMOURS

There are many types of benign tumours and in this section only the main groups will be considered.

Papilloma.—A papilloma consists of a central axis of connective tissue, blood-vessels, and lymphatics; the surface is covered by epithelium, either squamous, transitional, cuboidal or columnar, according to the site of the tumour. The surface may be merely roughened, or composed of innumerable delicate villous processes, as in the case of those occurring in the kidney, bladder and rectum. In these situations papillomas resemble malignant tumours, as secondary growths arise by implantation, and, sooner or later, the tumour becomes frankly malignant (Chapter 55). Other common sites for papillomas are the skin, the colon, the tongue and lip, the vocal cords and the walls of cysts, particularly those in connection with the breast and ovary.

Fibroma.—A true fibroma (containing only fibrous connective tissue) is rare. Most fibromas are combined with other mesodermal tissues such as muscle (fibromyoma), fat (fibrolipoma), and nerve sheaths (neurofibroma), etc. Multiple tumours are not uncommon, as, for example, in neurofibromatosis (von Recklinghausen's disease, p. 52).

Fibromas are either *hard* or *soft*, depending on the proportion of fibrous to the other cellular tissue. Soft fibromas are common in the subcutaneous tissue of the face, and appear as soft brown swellings.[1]

Desmoid.—This unusual type of fibroma occurs in the abdominal wall (Chap. 51).
Keloid (p. 15).

Lipoma.—A lipoma is a slowly growing tumour composed of fat cells of adult type. Lipomas may be encapsulated or diffuse.

Encapsulated lipomas are among the commonest of tumours. The characteristic features are the presence of a definite edge and lobulation. A sense of fluctuation may be obtained. These tumours can occur in any part of the body where fat is found. As would be expected, a lipoma deeply situated is liable to be mistaken for other swellings. Most lipomas are painless, but some give rise to an aching sensation which may radiate.

Multiple lipomas are not uncommon. The tumours remain small or moderate in size, and are sometimes painful, in which case the condition is probably one of *neurolipomatosis*. *Dercum's disease* (*adiposis dolorosa*),

[1] Oliver Cromwell (1599–1658), Lord Protector of England from 1653 until his death, was disfigured by one of these tumours which he called a wart. He insisted that his portraits should show him 'wart and all'.

Francis Xavier Dercum, 1856–1931. Neurologist, Jefferson Medical College, Philadelphia, Pennsylvania, U.S.A. Described Adiposis Dolorosa in 1888.

characterised by tender deposits of fat, especially on the trunk, is an associated condition.

Should the lipoma contain an excessive amount of fibrous tissue it is termed a *fibrolipoma*. In other cases considerable vascularity is present, often with telangiectasis of the overlying skin, in which case the tumour is a *nævolipoma*. A retroperitoneal lipoma, or one in the thigh (fig. 51), occasionally undergoes sarcomatous changes.

FIG. 51. — Liposarcoma of thigh which had been present for over twenty years. The scar indicates a previous attempt at removal.

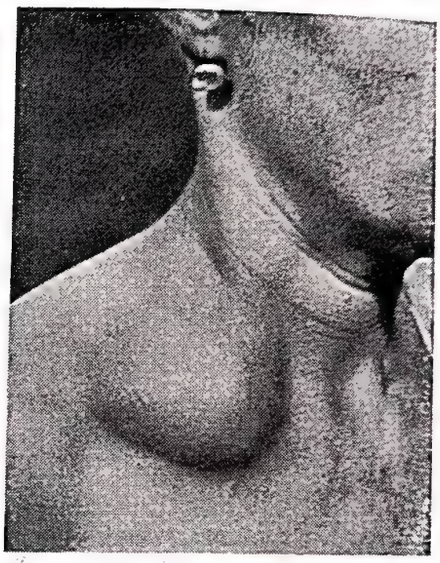

FIG. 52. — A lobulated, subcutaneous lipoma.

Myxomatous degeneration, saponification and calcification sometimes occur in lipomas of long duration.

Clinically, circumscribed lipomas are classified according to their situation:

(i) *Subcutaneous* are most commonly found on the shoulders (fig. 52) or back, although no part of the body is immune. It must be remembered that a lipoma is occasionally present over the site of a spina bifida. A careful examination should distinguish such conditions as a tuberculous abscess or a sebaceous cyst, which may superficially resemble a lipoma. Subcutaneous lipomas occasionally become pedunculated, or the influence of gravity may cause the tumour gradually to change its position.

FIG. 53.—Erosion of the skull due to a subaponeurotic lipoma.

(ii) *Subfascial.*—Lipomas occurring under the palmar or plantar fascia are liable to be mistaken for tuberculous tenosynovitis, as the tough, overlying fascia masks the definite edge and lobulation of the tumour. However, the swelling is circumscribed, and wasting of muscles is negligible. Difficulty is encountered in complete removal as pressure encourages the tumour to ramify. Subfascial lipomas also occur in the areolar layer under the epicranial aponeurosis, and if of long duration they erode the underlying bone, so that a depression is palpable on pushing the tumour to one side (fig. 53).

(iii) *Subsynovial* arise from the fatty padding around joints, especially the knee. They are apt to be mistaken for Baker's cysts (Chap. 18) but are easily distinguished as, in distinction to a cyst or bursa, their consistency is constant whether the joint is in extension or flexion.

(iv) *Intra-articular.*

(v) *Intermuscular.*—These occur particularly in the thigh or around the shoulder. Owing to transmitted pressure the tumour becomes firmer when the adjacent muscles are contracted. Weakness or aching results, owing to mechanical interference with muscular action. The condition is often difficult to distinguish from a fibrosarcoma, and exploration may be necessary.

(vi) *Parosteal* occasionally occur under the periosteum of a bone.

(vii) *Subserous* are not common, but are sometimes found beneath the pleura, where they constitute one variety of innocent thoracic tumour. A retroperitoneal lipoma may grow to enormous dimensions, and simulate a hydronephrosis or pancreatic cyst. A lipomatous mass is frequently found at the fundus of the sac of a femoral hernia, but this is a condensation of extra-peritoneal fat.

(viii) *Submucous* occur under the mucous membrane of the respiratory or alimentary tracts. Very rarely a submucous lipoma in the larynx causes respiratory obstruction. A submucous lipoma occasionally occurs in the tongue (fig. 592). One situated in the intestine is likely to cause an intussusception, which is the first indication of its presence.

(ix) *Extradural.*—A lipoma is a rare variety of spinal tumour. Owing to the absence of fat within the skull intracranial lipomas do not occur.

(x) *Intraglandular.*—Lipomas have been found occasionally in the pancreas, under the renal capsule and in the breast (see Chapter 35).

As will be noted, lipomas are very widely distributed in the body. The 'universal tumour' or the 'ubiquitous tumour' are appropriate terms, which should be remembered when a swelling causes diagnostic difficulty.

Treatment.—If a lipoma is causing trouble on account of its site, size, appearance, or the presence of pain, removal is indicated.

During operation, any finger-like projections of the tumour into the surrounding tissue must also be removed. Although the tumour is relatively avascular, care is needed to obtain complete hæmostasis in the resulting cavity—drainage often is necessary—otherwise a hæmatoma is common, which may be followed by infection and delay in wound healing.

Diffuse lipoma occasionally occurs in the subcutaneous tissue of the neck, from which it spreads on to the preauricular region of the face. The tumour is not obviously encapsulated, and gives rise to no trouble beyond being unsightly.

Adenoma.—Adenoma arise in secretory glands, and resemble the structure from which they arise. They are encapsulated, and sometimes they profoundly influence metabolism, as in the case of the thyroid, parathyroid and pancreas. Occasionally an adenoma contains a large proportion of fibrous tissue, e.g. the hard fibro-adenoma in the breast, while in other situations, notably the pancreas and thyroid gland, cystic degeneration is common. Those arising from secretory glands of mucous membrane are liable to pedunculation, as in the case of rectal 'polypus'.

Neuroma.—True neuromas are rare tumours, and occur in connection with the sympathetic system. They comprise the following types:

(*a*) *Ganglioneuroma* (Chap. 34) which consists of ganglion cells and nerve fibres. It arises in connection with the sympathetic cord, and therefore is found in the retroperitoneal tissue, or in the neck or thorax.

(*b*) *Neuroblastoma*, which is less differentiated than the ganglioneuroma, the cells being of an embryonic type (p. 46). The tumour somewhat resembles a round-celled sarcoma, and disseminates by the blood-stream. It occurs in infants and young children. It may occasionally undergo spontaneous remission.

(*c*) *Myelinic neuroma*, is very rare, being composed only of nerve fibres, as the ganglion cells are absent. They arise in connection with the spinal cord or pia mater.

Neurilemmoma (*syn.* Schwannoma).—These lobulated and encapsulated tumours arise from the neurilemmal cells. They are soft and whitish in appearance. They displace the nerve from which they arise and can be removed (fig. 54).

Neurofibroma.—False neuromas arise from the connective tissue of the nerve sheath and are really neurofibromas. The following varieties are described.

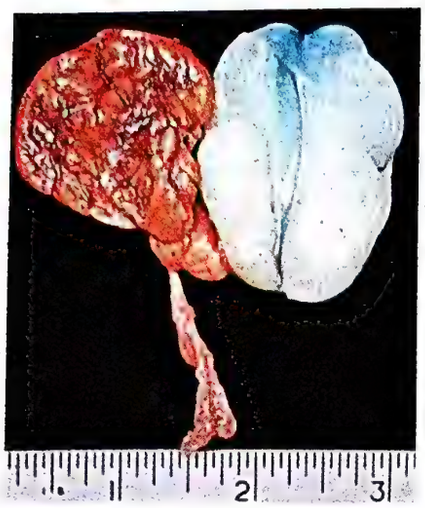

FIG. 54.—Neurilemmoma of the lingual nerve attached to submandibular salivary gland.

Local.—A single neurofibroma is usually found in the subcutaneous tissue. The 'painful subcutaneous nodule' forms a smooth firm swelling which may be moved in a lateral direction, but is otherwise fixed by the nerve from which it arises. Paræsthesia or pain is likely to occur from pressure of the tumour on the nerve fibres which are spread over its surface. Cystic degeneration or sarcomatous changes occasionally occur.

Neurofibromas may also grow from the sheath of a peripheral nerve or a cranial nerve (e.g. the acoustic tumour, Chap. 24). As the nerve fibres are 'part and parcel' of the tumour they are difficult to remove without removal of the nerve itself. In major nerves recurrence is known, also malignant (sarcomatous) change.

Generalised Neurofibromatosis (*syn.* von Recklinghausen's Disease of Nerves).—In this inherited (autosomal dominant) disease, cranial, spinal and peripheral nerves may all be diffusely or nodularly thickened (fig. 55). The overgrowth occurs in connection with the endoneurium. Associated pigmentation of the skin is common, and sarcomatous changes may occur.

FIG. 55.—Neurofibromatosis.

FIG. 56.—Plexiform Neurofibromatosis of the 5th cranial nerve. (*Dr. N. G. Nayar, Kerala*)

Friedrich Daniel von Recklinghausen, 1833–1910. Professor of Pathology, Strasbourg, France (1872–1906). Described Generalised Neurofibromatosis in 1882.

Plexiform Neurofibromatosis.—This rare condition usually occurs in connection with branches of the fifth cranial nerve (figs. 56 and 57), although it may occur in the extremities (fig. 58). The affected nerves become enormously thickened as a result of myxofibromatous degeneration of the endoneurium. If occurring in the scalp, the underlying skull may be eroded, and in other situations the involved skin sometimes hangs down in pendulous folds with grotesque effects (figs. 56, 57 and 58). Plexiform neurofibromatosis is sometimes associated with the generalised type of neurofibromatosis. Sarcoma rarely develops.

Elephantiasis Neuromatosa is a rare and congenital condition. The skin is coarse, dry, and thickened, resembling an elephant's hide, and the subcutaneous tissues become greatly thickened. If a leg is affected, the patient finds walking increasingly difficult.

AMPUTATION 'NEUROMAS'. — Fusiform swellings occur at the ends of divided nerves after amputation of a limb. These swellings consist of fibrous tissue and coiled nerve fibres (p. 158).

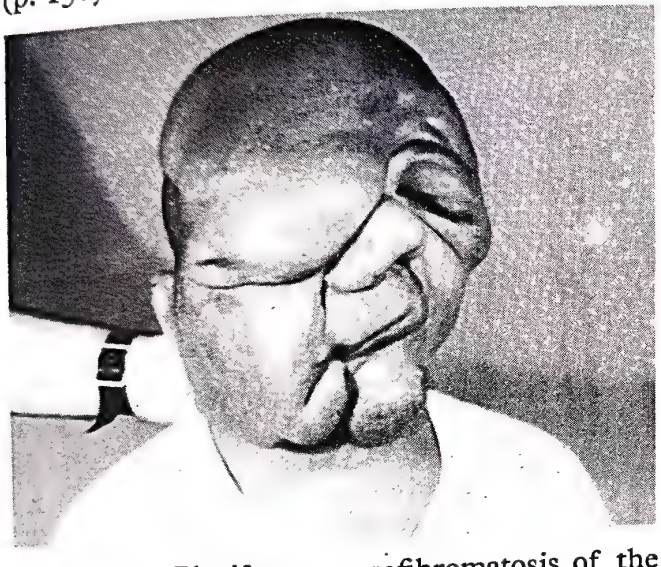

FIG. 57.—Plexiform neurofibromatosis of the 5th cranial nerve. (*Dr. P. Nayak, M.S., Bombay.*)

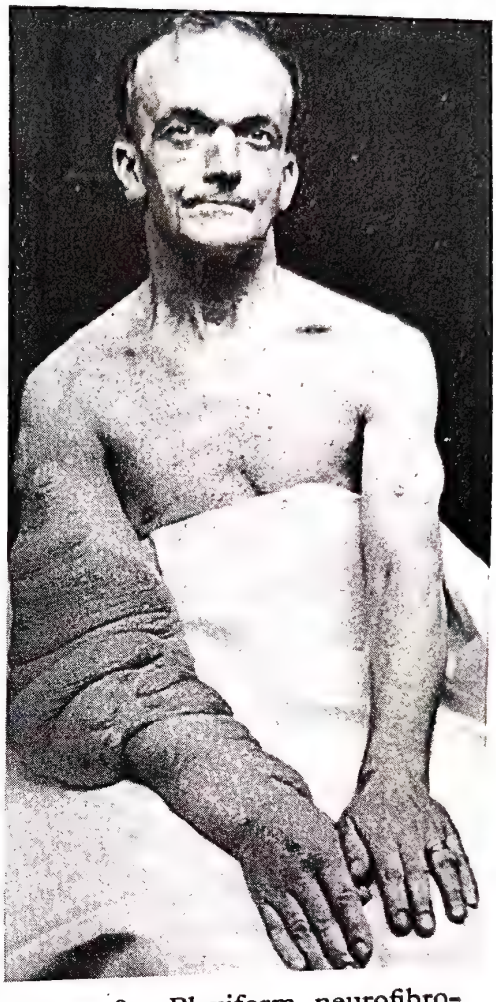

FIG. 58.—Plexiform neurofibromatosis affecting the right arm.

Hæmangiomas are described in Chapter 7 on p. 106.

Glomangioma (*syn.* Glomus Tumour).—These tumours arise from a cutaneous glomus composed of a tortuous arteriole which communicates directly with a venule, the vessels being surrounded with a network of small nerves. These specialised organs regulate the temperature of the skin, and are found in the limbs, especially the nail-beds. The tumour is compressible. The associated pain is out of all proportion to the size of the tumour, which may be only a few millimetres in diameter. The pain is burning in nature and radiates peripherally, and is often more noticeable when the limb is exposed to sudden changes of temperature.

On section the tumour consists of a mixture of blood spaces, nerve tissue and muscle fibres derived from the wall of the arteriole (angiomyoneuroma). Large cuboidal cells are frequently seen (glomal cells). Glomal tumours grow very slowly, and do not become malignant. They should be excised.

Hamartoma.—The term hamartoma is roughly translated from the Greek[1] as a 'fault' or 'misfire' or 'error' tumour, and its original meaning was 'missing the mark in spear throwing'. It is a developmental malformation consisting of a tumour-like overgrowth of tissue or tissues proper to the part. The possible range therefore is very wide, and the lesions are often multiple. Common lesions that are

[1] Hamartano (Greek) = I miss.

hamartomas are benign pigmented moles, and the majority of angiomas and neurofibromas. On rare occasions a malignant change occurs in a hamartoma, but for practical purposes the lesion is benign (Peters).

MALIGNANT TUMOURS

CARCINOMA

Carcinomas are conveniently classified according to the type of cell from which they arise, i.e. glandular, squamous, or basal-celled.

(i) GLANDULAR commonly occurs in the alimentary tract, breast and uterus, and less frequently in the kidney, prostate, gall-bladder, and thyroid. The three types of glandular carcinoma are as follows:—

(*a*) *Carcinoma simplex*, in which the cells are arranged in circumscribed groups, no glandular structure being recognisable. This type commonly occurs in the breast, and the majority of cells are spheroidal in shape.

(*b*) *Adenocarcinoma*, so called from the tendency of the cells to form acini, which resemble those of the gland from which they are derived. The alveoli are ductless, and the walls are composed of layers of cells which invade the surrounding tissues. This type is common in the stomach and colon. The cells of the primary growth, and even of the metastases, sometimes retain secretory powers.

(*c*) *Colloid* (mucoid) is a degenerative process which develops in tumours arising from mucin-secreting cells. The mucin permeates the stoma of the growth, which appears as a gelatinous mass and is typically seen in the colon and stomach.

Glandular carcinoma is also subdivided into various types, e.g. encephaloid, scirrhus and atrophic scirrhus. These distinctions depend clinically on their rate of growth, and pathologically on the relative proportions of fibrous tissue and gland elements. Examples occur in the breast (Chap. 35).

(ii) SQUAMOUS—which arise either from surfaces covered by squamous epithelium, or as a result of *metaplasia*. Thus, prolonged irritation of the renal pelvis by stones causes the normal transitional epithelium to revert to a less differentiated type, so that squamous-celled carcinoma develops.

Squamous-celled carcinoma is particularly liable to occur as a result of chronic irritation (p. 45). The regional lymph nodes are likely to be invaded, and may also be infected from the sepsis attendant upon the primary growth. Blood-borne metastases occur, but rarely from skin carcinoma.

Macroscopically, squamous-celled carcinomas are either papilliferous or ulcerative. On section solid masses of polyhedral cells are seen, which invade the deeper structures. ' Cell-nests ' are usually apparent in slowly growing cases, and are due to deeper cells becoming flattened and undergoing keratinisation. ' Prickle ' cells are characteristic, and resemble the prickle cells present in the epidermis.

(iii) BASAL-CELLED (*syn.* Rodent Ulcer, p. 109).

SARCOMA[1]

Sarcomas occur in connection with structures of mesoblastic origin. They differ from carcinomas, not only in their derivation, but also in their

[1] Sarkos (Greek) = Flesh.

Philip Michael Peters, Contemporary. Pathologist, Royal Northern Hospital, London.

age incidence, as sarcomas are most common during the first and second decades. Sarcomas often grow with rapidity, and dissemination occurs mainly by the blood-stream.

The macroscopic appearance of a sarcoma varies considerably. As the word implies, most tumours appear as a fleshy mass, but their consistency depends on the relative proportion of fibrous and vascular tissue. Hæmorrhage commonly occurs owing to the very thin walls of the veins, which in some places are represented merely by venous spaces.

Sarcomatous cells may reproduce tissue similar to that from which the tumour originated, e.g. osteosarcoma or chondrosarcoma. In some cases a sarcoma develops in pre-existing benign tumours, such as a fibroma or a uterine fibroid, and also in bones which are affected by osteitis deformans (p. 270).

Sarcomas of separate organs are considered in their appropriate chapters.

Fibrosarcoma.—This tumour occurs in scars, muscle sheaths (fig. 50) and as a fibrous epulis (Chap. 29). A fibrosarcoma of a muscle sheath presents

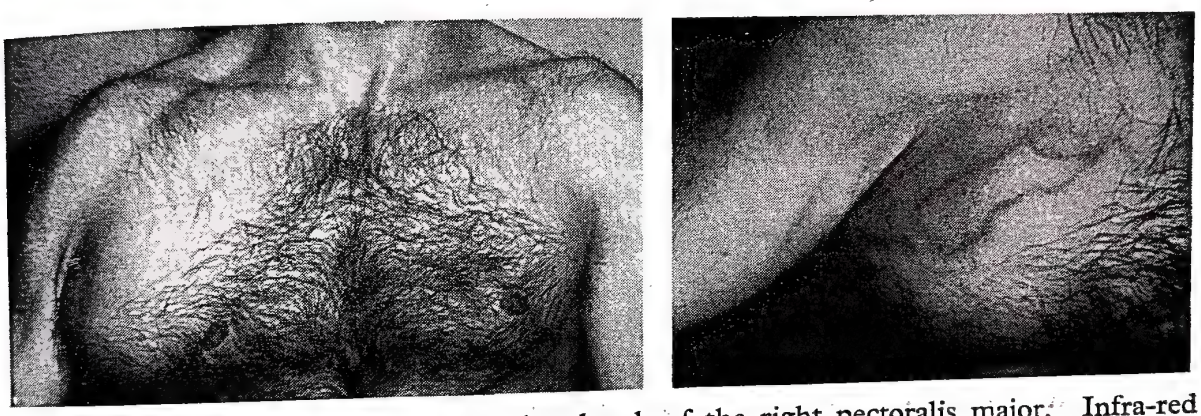

FIG. 59.—Fibrosarcoma arising from the sheath of the right pectoralis major. Infra-red photography reveals dilated veins over the tumour.

as an elastic or firm and slowly growing swelling. It either commences as a true fibroma, and gradually becomes sarcomatous, or is actually of low-grade malignancy from the beginning. Dilated veins over the tumour suggest malignancy, and if not obvious they may be demonstrated by infra-red photography (fig. 59). On palpation the tumour often feels warm and pulsation may even be detected.

These tumours are composed of spindle cells of varying lengths. In many cases it is difficult to distinguish with certainty, even microscopically, between a fibroma and a fibrosarcoma of low-grade malignancy.

Recurrent Fibroid.—Fibrosarcomas not uncommonly arise in scar tissue, sometimes many years after the scar developed.[1]

Treatment of Fibrosarcoma.—Malignant changes are hastened by incomplete efforts at removal. *The moral is that wide excision with surrounding healthy tissues should be practised in all cases.* This may mean amputation in the case of a limb. If untreated, or if wide local excision is unsuccessful,

[1] Sir James Paget, 1814–1899, Surgeon, St. Bartholomew's Hospital, London, described this type as a 'recurrent fibroid'.

a fibrosarcoma eventually fungates through the skin (fig. 60). Metastases are widely scattered, and, unfortunately, radiotherapy has but little effect on either the primary growth or on the secondary deposits.

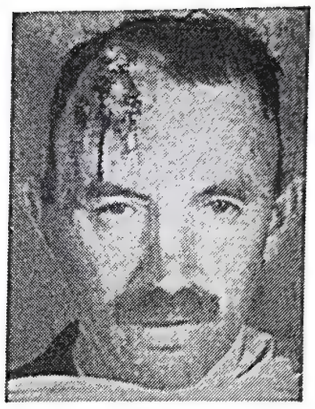

FIG. 60.—Fungating fibrosarcoma of the scalp. (*T. A. Bouchier-Hayes, F.R.C.S.I., Dublin.*)

Reticulosarcoma (*syn.* lymphosarcoma) arises in lymph nodes, tonsils, Peyer's patches or lymph nodules in the intestines. Lymph nodes of the neck or mediastinum are most commonly affected (p. 179).

Synovioma.—This rather uncommon tumour may arise in any synovial joint or tendon sheath, especially those of the hand. It appears as a soft, painless swelling, and sarcomatous changes may develop. Diagnosis can only be established by extirpation and biopsy of the tumour.

Nævus and Melanoma are described in Chapter 7.

Endothelioma. Mesothelioma.—The endothelial linings of blood-vessels, lymphatic spaces and serous membranes occasionally give rise to neoplasms. They can be malignant. They arise from the pleura (Chapter 38) and rarely from the pericardium or peritoneum. The original cells are flattened, but they become spheroidal or cuboidal when neoplastic changes occur. The 'endothelioma' (meningioma) of the dura mater is thought to arise from the arachnoid membrane, which is *not* an endothelial structure (Chap. 24).'

Peritheliomas are tumours arising in the endothelial lining of small blood-vessels or lymphatics. Carotid body tumours are probably of this nature (Chapter 32).

BENIGN ⟶ MALIGNANT

Certain innocent neoplasms are prone to undergo malignant changes, and it is important, both for treatment and prognosis, to realise when this occurs. Some or all of the following changes may be recognised:

(i) *Increase in size*—comparatively rapid enlargement is always suspicious, e.g. a neurofibroma which is becoming sarcomatous.

(ii) *Increased vascularity*—dilated cutaneous veins, expansile pulsation of the tumour, or ulceration and bleeding in the case of a superficial growth.

(iii) *Fixity*—due to invasion of surrounding structures, e.g. carcinomatous changes in a prostatic adenoma may cause 'tethering' of the rectal mucosa.

(iv) *Involvement of adjacent structures*—carcinomatous changes in an adenoma of the thyroid should be suspected if the recurrent laryngeal nerve is implicated. Facial palsy suggests a malignant parotid tumour.

(v) *Dissemination*—discovery of secondary deposits is occasionally the clue to malignancy.

Examples.—The true nature of a doubtful lump in the breast is rendered evident if involved lymph nodes or osseous metastases are detected. The discovery of a secondary deposit in a bone may lead to detection of, say, a carcinoma of the kidney.

CYSTS

The word 'cyst' is derived from the Greek word meaning 'bladder'. The pathological term 'cyst' means a swelling consisting of a collection of fluid in a sac which is lined by epithelium or endothelium.

True cysts are usually lined by epithelium or endothelium. If infection

Johann Conrad Peyer, 1653–1712 (see p. 32).

supervenes, the lining may be composed of granulation tissue. The fluid is usually serous or mucoid and varies from brown-staining by altered blood to almost colourless. In epidermoid, dermoid, and branchial cysts the contents are like porridge or toothpaste, as a result of the accretion of desquamated cells. Cholesterol crystals are often found in the fluid.

False Cysts.—Certain collections of fluid are not regarded as true cysts. They are usually exudation and degeneration cysts. A pseudo-cyst of the pancreas is an encysted collection of fluid in the lesser sac. In tuberculous peritonitis fluid may be walled off in cystic form by adherent coils of intestine. Fluid may collect in the centre of a tumour (cystic degeneration), due to hæmorrhage or colliquative necrosis. This can also happen in the brain as a result of ischæmia, and an ' apoplectic cyst ' is formed.

A Classification of Cysts:-

1. CONGENITAL
   - Sequestration dermoids.
   - Tubulo-embryonic (tubulo-dermoid).
   - Cysts of embryonic remnants.

2. ACQUIRED
   - Retention.
   - Distension.
   - Exudation.
   - Cystic swellings.
   - Implantation.
   - Trauma.
   - Degeneration.

3. PARASITIC — Hydatid. Trichiniasis. Cysticercosis.

Congenital Cysts.—*The sequestration dermoid* is due to dermal cells being buried along the lines of closure of embryonic clefts and sinuses by skin fusion (fig. 61). The cyst is therefore lined by epidermis and contains paste-like desquamated material. The usual sites are (*a*) the midline of the body—especially in the neck, (*b*) above the outer canthus (external angular dermoid) (Chap. 29), (*c*) in the anterior triangle of the neck (branchial cyst, Chap. 32).

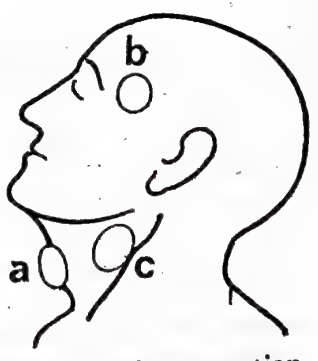

FIG. 61.—Sequestration dermoids—see text.

Tubulo-embryonic (tubulo-dermoid) cysts occur in the track of an ectodermal tube used in development, e.g. a thyroglossal cyst from the thyroglossal duct; a post-anal dermoid from the post-anal gut. In the brain, ependymal cysts arise from the sequestration of cells of the infolding neurectoderm.

Cysts of Embryonic Remnants.[1]—These arise from embryonic tubules and ducts which normally disappear or are only present as remnants. There are many examples

[1] These cysts are not to be confused with teratomatous cysts (e.g. Dermoid, p. 46).

in the urogenital system, e.g. in the male from remnants of the paramesonephric duct (Müllerian)—the hydatid of Morgagni, or from the mesonephric body and duct (Wolffian) (Chapter 54). Cysts of the urachus, and the vitello-intestinal duct are other examples of cysts of embryonic remnants.

Acquired Cysts.—*Retention cysts* are due to the accumulated secretion of a gland following obstruction of a duct. Examples are seen in the pancreas, the parotid, the breast, the epididymis, and Bartholin's gland. A sebaceous cyst starts with the obstruction of a sebaceous gland, but this is followed by the downgrowth and the accumulation of desquamated epidermal cells, thus making it an epidermoid cyst.

Distension cysts occur in the thyroid from dilatation of the acini, or in the ovary from a follicle. Lymphatic cysts and cystic hygromas are distension cysts. *Exudation cysts* occur when fluid exudes into an anatomical space already lined by endothelium, e.g. hydrocele, a bursa, or when a collection of exudate becomes encysted. These are false cysts (p. 57).

Cystic Tumours.—Examples are cystic teratomas (dermoid cyst of the ovary (p. 46)) and cystadenomas (pseudomucinous, and serous cystadenoma of the ovary).

Implantation dermoids arise from squamous epithelium which has been driven beneath the skin by a penetrating wound. They are classically found in the fingers of women who sew assiduously (fig. 62). The contents are therefore desquamated cell-debris which may undergo mucoid degeneration.

FIG. 62.—Implantation dermoid.

Trauma.—A hæmatoma may resolve into a cyst. This sometimes happens to hæmatomas of muscle masses in the loin and antero-lateral aspects of the thigh or the shin. They are located between muscle, fascial, or subcutaneous planes and contain straw- or brown-coloured fluid containing cholesterol crystals. They become lined by endothelium and calcium salts may be laid down. Aspiration is only of temporary value, and a cure depends upon complete excision of the lining.

Degeneration Cysts.—These have already been discussed under false cysts.

Parasitic Cysts.—These are encysted forms in the life-cycle of various worms.

Hydatid Cyst of the *Tænia Echinococcus.*—This is described later according to the organ involved, e.g. liver, Chapter 43; lung Chapter 38.

Trichiniasis.—Cysts of the *Trichina spiralis*, affecting muscle.

Cysticercosis.—Cysts of *Tænia solium*. A disease of the pig, man being rarely affected. Eosinophilia is present. The cysts occur in any organ. They calcify and may cause clinical effects according to their situation, especially in the brain. Only those cysts which are actually causing symptoms should be excised.

Clinical Features of a Cyst.—The swelling usually has a smooth spherical appearance. Fluctuation depends upon the pressure of fluid within; a tense cyst feels like a solid tumour, though careful palpation between two fingers may elicit a characteristic elasticity. In addition, a solid tumour is most hard at the

ULCERS

An ulcer is a discontinuity of an epithelial surface. There is usually progressive destruction of surface tissue, cell by cell, as distinct from death of macroscopic portions (e.g. gangrene or necrosis). Ulcers are classified as *non-specific*, *specific* (e.g. tuberculous or syphilitic), or *malignant*.

Non-specific ulcers are due to infection of wounds, or physical or chemical agents. Local irritation, as in the case of a dental ulcer, or interference with the circulation, e.g. varicose veins (p. 166), are predisposing causes.

Trophic Ulcers[1] are due to an impairment of nutrition, which normally depends upon an adequate blood supply and a properly functioning nerve supply. Ischæmia and anæsthesia will therefore cause these ulcers. Ulcers of the tips of the fingers occur in chronic vasospasm (Raynaud's disease, p. 151) and in syringomyelia. In the leg, ischæmic ulcers occur around the ankle or on the dorsum of the foot (p. 124). They are very painful and resistant to local treatment. Ulcers due to anæsthesia (diabetic neuritis, spina bifida, tabes dorsalis, leprosy, or a peripheral nerve injury) are often called *perforating ulcers* (fig. 64). Starting in a corn or bunion, they penetrate the foot, and the suppuration may involve the bones and joints and spread along fascial planes upwards, even involving the calf.

FIG. 64.—Perforating ulcer in a diabetic.

The life-history of an ulcer consists of three phases; these are extension, transition, and repair. During the *stage of extension* the floor is covered with exudate and sloughs, while the base is indurated. The edge is sharply defined, and discharge is purulent and even blood-stained. The *transition stage* is occupied in preparation for healing. The floor becomes cleaner, the sloughs separate, induration of the base diminishes, and the discharge becomes more serous. Small reddish areas of granulation tissue appear on the floor, and these link up until the whole surface is covered (fig. 6). The *stage of repair* consists of the transformation of granulation to fibrous tissue, which gradually contracts to form a scar. The edge of the ulcer becomes more shelving, and epithelium gradually extends from it to cover the floor (at a rate of 1 mm. per day). This healing edge consists of three zones—the outer of epithelium, which appears white, the middle one bluish in colour (where granulation tissue is covered by a few layers of epithelium), and the inner reddish zone of granulation tissue covered by a single layer of epithelial cells.

Local (Topical) Treatment of Non-specific Ulcers.—In addition to the general treatment (where applicable) of an underlying cause (e.g. diabetes, arterial disease), many lotions and non-adhesive applications are used to aid the separation of sloughs, hasten granulation, and stimulate epithelialisation of non-specific ulcers of the skin. Hypochlorite solution (e.g. Eusol[2]) and 0·5% silver nitrate are popular in the early

[1] Trophē (Greek) = Nutrition.
[2] Eusol = *E*dinburgh *U*niversity *SOL*ution.

stages, and 1% zinc sulphate solution (e.g. Lotio rubra) later[1]; ointments incorporating zinc oxide, 1% hydrocortisone cream; silver foil; household vinegar (1:6) (efficacious against pyocyaneus). Excessive granulations, commonly known as 'proud flesh', need to be discouraged by excision, curettage, or by the application of a caustic, such as silver nitrate. Tetracycline (10%) in propylene glycol solution helps to clean an ulcer prior to skin grafting. Chronic or indolent ulcers often respond to infra-red radiation, short-wave therapy, or ultra-violet light.

Large ulcers in the healing phase should be covered by a free split skin graft as soon as the granulations are healthy (p. 119). Healthy granulations are flat, are below the level of the surrounding skin, are pink in colour, and do not discharge pus.

CLINICAL EXAMINATION OF AN ULCER

This should be conducted in a systematic manner. The following are, with brief examples, the points which should be noted:

Site, e.g. 95 per cent. of rodent ulcers (p. 109) occur on the upper part of the face. Carcinoma typically affects the lower lip, while a primary chancre of syphilis is usually on the upper.

Size, particularly in relation to the length of history, e.g. a carcinoma extends more rapidly than a rodent ulcer, but more slowly than an inflammatory ulcer.

Shape, e.g. a rodent ulcer is usually circular. A gummatous ulcer is typically circular (fig. 65), or serpiginous, due to the fusion of multiple circles.

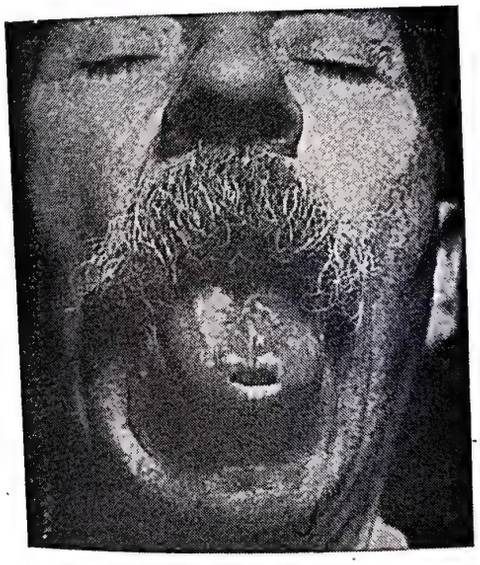

FIG. 65.—Syphilitic gumma of the tongue. Note the punched-out appearance of the ulcer.

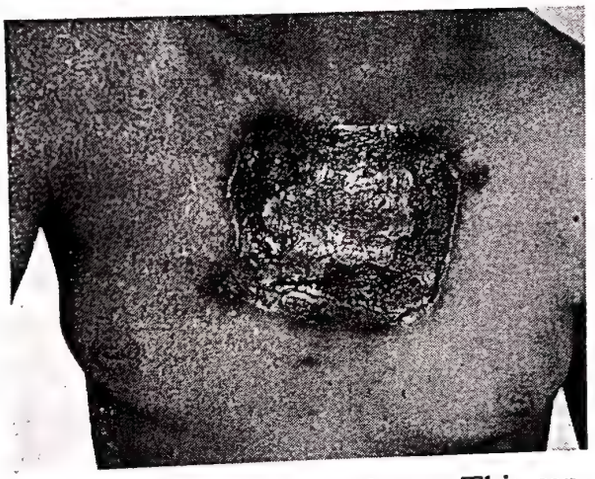

FIG. 66.—Dermatitis artefacta. This condition is due to self-mutilation, e.g. by the application of irritants, such as corrosives. The patient usually has a hysterical temperament, or litigation may be involved. The ulcer will begin to heal if protected by a dressing which cannot be disturbed by the patient.

An ulcer with a square area or straight edge is suggestive of 'dermatitis artefacta' (fig. 66).

Edge (fig. 67).—A healing non-specific ulcer has a shelving edge. It is undermined and often bluish if tuberculous, vertically punched-out if syphil-

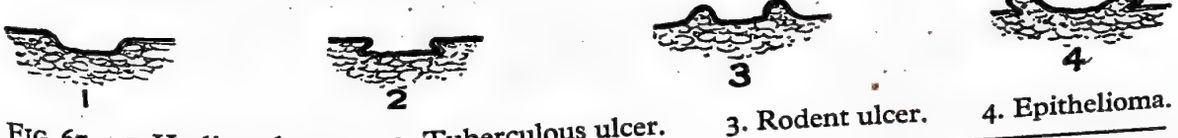

FIG. 67.—1. Healing ulcer. 2. Tuberculous ulcer. 3. Rodent ulcer. 4. Epithelioma.

[1] Zinc sulphate capsules (200 mg.) thrice daily by mouth have been recommended.

itic (fig. 65), rolled or rampart if a rodent ulcer, and raised and everted if malignant (e.g. epithelioma).

Floor.—The floor is that which is seen by an observer, e.g. watery or apple-jelly granulations in a tuberculous ulcer, a wash-leather slough in a gummatous ulcer.

Base.—The base is what can be palpated. It may be indurated as in a carcinoma, or a syphilitic chancre, or attached to deep structures, e.g. a varicose ulcer to the tibia.

Discharge.—A purulent discharge indicates active infection. A blue-green coloration suggests infection with *Pseudomonas pyocyaneus*. A watery discharge is typical of tuberculosis. It is blood-stained in the extension phase of a non-specific ulcer. *Bacteriological examination* may reveal colonisation by coagulase positive staphylococci. Spirochætes are found in a primary chancre (p. 40).

Lymph nodes are not enlarged in the case of a rodent ulcer, unless due to secondary infection. In the case of carcinoma, they may be enlarged, hard, and even fixed. The inguinal nodes draining a syphilitic chancre of the penis are firm and ' shotty ', but the submandibular nodes draining a chancre of the lip are greatly enlarged.

Pain.—Non-specific ulcers in the extension and transition stages are painful (except the anæsthetic trophic type). Tuberculous ulcers vary, that of the tongue being very painful. Syphilitic ulcers are usually painless, but the anal chancre of the homosexual may be painful (cf. anal fissure, Chap. 50).

General Examination.—Evidence of debility, cardiac failure, anæmia, or diabetes must be sought. A gummatous ulcer may be associated with other stigmata, e.g. chronic superficial glossitis.

Pathological examinations, e.g. biopsy, may confirm carcinoma. The W.R. or Mantoux test may be of value.

Marjolin's Ulcer. See p. 109.

FIG. 68.—Oriental sore, boy aged eight years. (*Professor Riyaz-i-Qadeer, F.R.C.S., Lahore.*)

ORIENTAL SORE (*syn.* DELHI BOIL, BAGHDAD SORE, ETC.)

This disease is due to infection by a protozoal parasite, *Leishmania tropica*, and is a common condition in Eastern countries which is occasionally imported to Western zones. An indurated papule appears on an exposed surface, usually the face. If untreated this breaks down to form an indolent ulcer (fig. 68), which eventually leaves an ugly, pigmented scar. The condition readily responds to intravenous injections of antimony tartrate, but very small lesions can be treated by carbon dioxide snow.

Bazin's disease (*syn.* erythema induratum) is due to localised areas of fat necrosis and particularly affects adolescent girls. Symmetrical purplish nodules appear, especially on the calves, and gradually break down to form indolent ulcers, which

Charles Mantoux, 1877–1947. Physician, Le Cannet, France.
Sir William Leishman, 1865–1926. Professor of Pathology, Royal Army Medical College.
Pierre Antoine Ernest Bazin, 1807–1878. Dermatologist, Hôpital St. Louis, Paris.

leave in their wake pigmented scars (fig. 69). Tuberculosis may be a cause in many instances, the ulcers responding to antituberculous drugs (p. 32). Sympathectomy also may be curative.

FIG. 69.—Bazin's disease.

SINUSES AND FISTULÆ

A sinus[1] is a blind track lined with granulations leading from an epithelial surface into the surrounding tissues. *A fistula*[2] is an abnormal communication between the lumen of one viscus and the lumen of another, or the body surface. Sinuses and fistulæ may be congenital or acquired. Forms which have a congenital origin include pre-auricular sinuses (p. 508), branchial fistulæ (Chap. 32), and tracheo-œsophageal fistulæ (Chap. 40). The acquired forms often follow inadequate drainage of an abscess. Thus a perianal abscess may burst on the surface and lead to a sinus (erroneously termed a blind external 'fistula'). In other cases the abscess opens both into the anal canal and on to the surface, resulting in a true fistula-in-ano (Chap. 50).

Persistence of a Sinus or Fistula.—The reason for this will be found amongst the following:

(1) A foreign body or necrotic tissue is present (e.g. a suture, sequestrum, a fæcolith or even a worm (see below)).

(2) Inefficient or non-dependent drainage.

(3) Unrelieved obstruction of the lumen of a viscus or tube distal to the fistula. Irritating discharges, such as urine or fæces, maintain continuous inflammation.

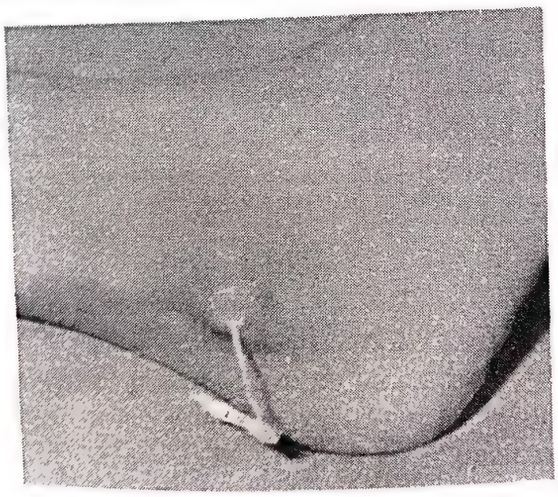

FIG. 70.—?Ulcer ?Sinus—presenting in a U.K. outpatient department! The 30-cm female Guinea worm is carefully extricated by being wound on a matchstick, a few turns a day to prevent breakage and retraction.

(4) Absence of rest, such as occurs in fistula-in-ano due to the normal contractions of the sphincter.

(5) The walls have become lined with epithelium.

(6) Dense fibrosis prevents contraction and healing.

(7) Type of infection, e.g. tuberculosis or actinomycosis.

(8) The presence of malignant disease.

Treatment.—The remedy depends upon the removal or specific treatment of the cause.

[1] Sinus (Latin) = A hollow; a bay or gulf. [2] Fistula (Latin) = A pipe or tube.

The treatment of sinuses and fistulæ affecting different sites and organs will be found on the appropriate pages.

Guinea Worm (Syn. Dragon worm, *Dracunculus mediensis*) (fig. 70). The larval form enters through the skin of the foot, and gains the blood-stream after the journey *via* the lymphatics. The adult worms appear in the subcutaneous tissues and cause cellulitis, abscesses, ulcers and sinuses through which the ova are shed to the ground. Baid travelled the interior of India and in 500 cases discerned a syndrome of the infestation, presenting with conjunctivitis (allergic) in 11%, fibrous contracture of joints in 19%, periostitis with osteomyelitis in 21% and acute arthritis in 65%.

J. C. Baid, Contemporary. Surgeon, Jodhpur, India.

CHAPTER 5

HÆMORRHAGE. BLOOD TRANSFUSION. SHOCK

HÆMORRHAGE

TYPES OF HÆMORRHAGE

1. Arterial. Venous. Capillary.

Arterial hæmorrhage is bright red. The blood spurts as a jet which rises and falls in time with the pulse. In protracted bleeding, particularly when quantities of intravenous fluids other than blood are given, it can become watery in appearance.

Venous hæmorrhage is a darker red and escapes as a steady flow. The colour darkens still further from excessive oxygen desaturation when blood loss is severe, or in respiratory depression or obstruction.[1]

Venous bleeding can be under increased pressure as in asphyxia, or from ruptured varicose veins (Chap. 9). Also portal vein pressures (Chap. 39) are high enough to cause rapid blood loss, especially in portal hypertension with œsophageal varices. Pulmonary artery hæmorrhage is dark red (venous blood) at around 30 mmHg* (≈4kPa), and bleeding from the pulmonary veins is bright red.

Capillary hæmorrhage is a bright red, often rapid ooze. If continuing for many hours blood loss can become serious (as in hæmophilia, p. 76).

2. Primary. Reactionary. Secondary.

Primary hæmorrhage is that which occurs at the time of injury or operation.

Reactionary hæmorrhage may follow primary hæmorrhage within 24 hours (usually 4–6 hours) and is mainly due to rolling (' slipping ') of a ligature or dislodgement of a clot. The precipitating circumstances are (a) the rise of blood pressure and the refilling of the venous system on recovery from shock, (b) restlessness, coughing and vomiting which raise the venous pressure (e.g. reactionary venous hæmorrhage within a few hours of thyroidectomy).

Penetrating wounds involving main veins in the thigh or groin are potentially fatal, as exsanguination may follow the removal of a first-aid dressing which has apparently controlled the bleeding (Butcher's thigh, p. 134). Such a wound should never be treated in a perfunctory manner; it requires careful examination and closure in an operating theatre. Venous hæmorrhage, whether primary or reactionary, can tax the skill of even an experienced surgeon.

Secondary hæmorrhage occurs after 7–14 days, and is due to infection and sloughing of part of the wall of an artery. Predisposing factors are pressure

[1] Occasionally dark blood is due to the presence of sulph- or met-hæmoglobin.

* 1 mmHg ≈ 133 Pascals in the S.I. system. Since blood pressure is commonly measured by a column of mercury, the Editors find themselves in sympathy with the Society for the Preservation of the mmHg.

of a drainage tube, a fragment of bone, a ligature in an infected area, or cancer. It is also a complication of arterial surgery and amputations. It is heralded by 'warning' hæmorrhages, which are bright red stains on the dressing, followed by a sudden severe hæmorrhage which may be fatal. A warning hæmatemesis may occur in the case of a peptic ulcer and is a danger signal which it is imprudent to ignore. In advanced cancer the erosion of a main vessel (e.g. carotid, uterine) by a locally ulcerating growth is a swift and merciful termination to the patient's suffering.

3. Internal (concealed) and External (revealed) Hæmorrhage.

Internal bleeding may be *concealed* as in ruptured spleen or liver, fractured femur, ruptured ectopic gestation, or in cerebral hæmorrhage. Concealed hæmorrhage may become *revealed* as in hæmatemesis or melæna from a bleeding peptic ulcer, as in hæmaturia from a ruptured kidney, or via the vagina in accidental uterine hæmorrhage of pregnancy.

SIGNS OF HÆMORRHAGE. PHYSIOLOGICAL AND PATHOLOGICAL EFFECTS (OLIGÆMIC SHOCK)

Acute Blood Loss.—*Signs.*—External bleeding is obvious, but a serious internal hæmorrhage must be recognised without delay by the general signs of blood loss:— *increasing pallor and pulse rate, restlessness* and, in protracted bleeding, deep sighing respirations (*air hunger*). These signs are accompanied by a cold and clammy skin, empty veins, and later, by thirst, tinnitus and blindness (see also fig. 75).

The pulse volume will be low (thready pulse) as the blood-pressure falls, though it is important to remember that this is *not* a sign to be relied upon. A normal or raised blood-pressure can occur in the face of other signs of hæmorrhage in an apparently healthy person, and collapse and death can occur suddenly. This phenomenon was noticed in the first world war (1914–18) by front-line research.

Effects.—In short, blood loss threatens the oxygen supply to, and therefore the life of, tissue cells. Pending the arrest of hæmorrhage and the replacement of blood, the function of vital structures such as the heart and brain stem is largely preserved by the increasing pulse rate and peripheral vasoconstriction (even though vasoconstriction may have deleterious effects on the liver, kidneys and also the adrenals (Egdahl)). Unchecked or untreated blood loss results in failure of the heart and vasomotor centre to maintain a sufficient perfusion of oxygen for their own purposes and death follows (the death cycle —see below).

Hæmorrhage results in loss of circulating blood volume from the whole of the vascular system. . 60–70 per cent. of the blood volume is accommodated in the low pressure venules and veins and in the splanchnic vessels, and a loss of up to 10 per cent. (500–600 ml.) is adequately compensated for by venoconstriction and therefore the contraction of this large venous reservoir. (The spleen contributes only about 50 ml.) Further blood loss results in a diminished venous return and therefore a fall in cardiac output. The blood pressure, and therefore the perfusion of oxygen, is threatened, so a fall is prevented by increased heart rate and vasoconstriction. This is effected via sympathetic nervous activity, adrenaline, noradrenalin and the adrenal corticoids—which probably sensitise the vasoconstrictor nerve endings to noradrenalin.

Richard H. Egdahl, Contemporary. Surgeon, University Hospital, Boston, Massachusetts, U.S.A.

Clinically this compensation is shown as pallor, cold clammy skin, empty veins and increased pulse rate. Restlessness comes with the effects of hypoxia on the midbrain (mesencephalic reticulum) while changes in the rate and depth of respiration are due partly to effects on the brain stem (chemoreflex), and partly in response to an increase in the airway dead space and metabolic acidosis.

The brain and the myocardium, which are the structures vital to the preservation of life in this emergency, are spared from vasoconstriction. The liver and kidneys, however, may suffer irreparable damage from the tissue anoxia caused by the intense and prolonged vasoconstriction in severe blood loss, with liver failure or acute renal failure claiming victims, even though the hæmorrhage is successfully treated (e.g. in ruptured abdominal aneurysm).

Vasoconstriction fails to maintain the blood pressure when blood loss increases beyond 20–30 per cent. Hypotension becomes severe with a 50 per cent. loss, and the perfusion of myocardium and the brain stem is affected. Thus the heart fails and vasoconstriction of the venous reservoir fails—each affecting the other in a vicious circle which ends in the death cycle.

Failure of vasoconstriction will occur sooner if any conditions causing vasodilation are present (alcohol, anæsthesia, infection, heating the patient by too many blankets or a heat cradle).

Infants are intolerant of blood loss because a small amount may represent a considerable percentage of the total blood volume, and also because the peripheral circulatory resistance is normally high and so cannot be so effectively increased. In the elderly, arteriosclerosis affecting brain, heart and the peripheral circulation will hinder an adequate response.

Natural Blood Volume and Red Cell Recovery.—The recovery of blood volume begins immediately by the withdrawal of fluid from the tissues into the circulation. There is hæmodilution. Plasma proteins are replaced by the liver. Red cell recovery takes some five to six weeks. The iron content will be less than normal if stores are depleted or absorption is impaired (e.g. after gastrectomy, Chap. 41).

Chronic Hæmorrhage.—Examples of causes in surgical practice are bleeding hæmorrhoids, fibroids, carcinoma of the caecum, peptic ulcer. There is no diminution of the blood volume as there is time for plasma replacement, but red cell replacement lags behind (microcytic hypochromic anæmia) resulting in a state of anæmic hypoxia, requiring an increased cardiac output. These patients develop high-output cardiac failure; they must not be transfused with normal blood, but require packed cells instead. Acute hæmorrhage in such cases is poorly compensated, as oxygen carriage is already depleted.

CLINICAL AND LABORATORY MEASUREMENT OF HÆMORRHAGE

1. **Bedside observation** of the appearance of the patient is essential (see signs of hæmorrhage, p. 66). The severity of blood loss and shock can be gauged by feeling the temperature of the nose. A cold nose usually means that shock is severe and peripheral failure is imminent.

2. **Record keeping** of the pulse rate and the blood pressure are also essential (in spite of the fact that the blood pressure can be misleading). Readings are taken at ¼ or ½ hourly intervals during an emergency and thereafter 4-hourly. The patient is not roused from sleep for a blood pressure reading if the pulse is not raised.

3. **Hæmoglobin level.**—This is estimated in g/100 ml. (g/dl), normal values being 12–16 g/100 ml. (12–16 g/dl). There is no immediate change in

Haemodilution ↓ P.C.V ↑ haemo concentration

hæmorrhage, but within the space of a few hours the level is lowered by the hæmodilution caused by the movement of tissue fluid into the vascular compartment in order to restore the blood volume. The degree of dilution can be gauged by the hæmatocrit reading (P.C.V.).

4. The hæmatocrit (fig. 71) is a stout glass tube 110 mm. long with a 2·5–3·00 mm. bore and it is graduated 0–100. It is filled up to the 100 mark with a small quantity (about 0·8 ml.) of oxalated or heparinised freshly drawn blood, and centrifuged at 3000 rev/min. for 30 minutes. The packed cell volume (P.C.V.) is then read from the millimetre reading gradations. The normal range for venous blood is: men, 40–56 per cent.; women, 35–48 per cent.; children, 32–44 per cent. The P.C.V. can also be measured on capillary blood, using very small amounts, in the microhæmatocrit centrifuge. This is particularly useful in shocked patients where it is often difficult to obtain a sample from a vein.

FIG. 71. — A hæmatocrit.

As explained above, some hours after the start of hæmorrhage, the P.C.V. will be lowered by a hæmodilution. In dehydration states and the plasma loss in burns, the P.C.V. will be increased (hæmoconcentration), because the plasma volume is diminished without a concomitant loss of red cells and hæmoglobin.

5. Measuring Blood Loss

(*a*) *Blood Clot.*—Blood clot the size of a clenched fist is roughly equal to 500 ml.

(*b*) *Swelling in Closed Fractures.*—Moderate swelling in closed fracture of the tibia equals 500–1500 ml. blood loss. Moderate swelling in a fractured shaft of femur equals 500–2000 ml. blood loss (Ruscoe Clarke).

(*c*) *Swab Weighing.*—In the operating theatre, blood loss can be measured by weighing the swabs before and after use and adding the total so obtained (1 g = 1 ml.) to the volume of blood collected in the suction or drainage bottles. In extensive wounds and operations, the blood loss estimated in this way is much less than the total amount of blood, plasma and water actually lost from the body. For operations such as radical mastectomy or partial gastrectomy it is necessary to multiply the swab weighing total by $1\frac{1}{2}$. For larger wounds, as in abdomino-thoracic or abdomino-perineal operations, multiply by 2 (fig. 72). *Washing swabs* and estimating the Hb content of the washings is another method.

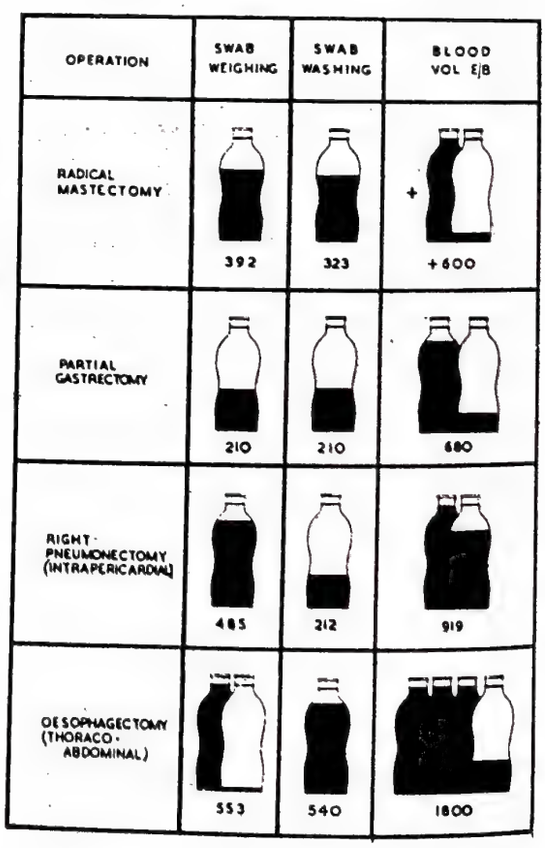

FIG. 72.—Measuring blood loss. Comparison of results obtained in a series which yielded the Rains factor (see swab weighing).

(*d*) *Blood Volume Determinations.*—Either the volume of circulating plasma, or the volume occupied by the red cells, must be measured first. The hæmatocrit reading will give the ratio of plasma to red cells, and thus the total blood volume can be arrived

Alan Ruscoe Clarke, 1908–1959. Surgeon, Birmingham Accident Hospital, Birmingham, England.

at. *Methods.*—The measurement of the circulating plasma or red cell volume involves the injection of a known quantity of a substance which will be evenly diluted as it mixes with, and circulates in, the blood. Radioactive iodinated serum albumin (RISA) is used to give plasma volume, and red cells 'tagged' with radiochromium or radioiron are used for red cell volume measurement. After allowing time for the substance to mix, a sample of blood is withdrawn. A measured volume of this sample is examined in the scintillation counter to give the dilution of the amount originally injected, and from this the whole of the diluting volume (plasma or red cells) can be arrived at. The normal blood volume is 70–85 ml. of whole blood per kilogram body weight, or 35–50 ml. plasma/kg. Thus it varies between a few hundred ml. in a neonate, up to 5–6 litres in an adult (more in certain pathological conditions, e.g. high output cardiac failure from chronic anæmia or arteriovenous fistula).

(*e*) *Measurement of Central Venous Pressure* (*C.V.P.*) (figs. 73 and 76)

An immediate definitive diagnosis of a collapsed patient is often difficult. Hæmorrhage, pulmonary embolism, cardiac infarction, mesenteric thrombosis, acute pancreatitis, also pleural, peritoneal, intestinal and bacteriæmic shock may present similarly. Delay in giving blood or other intravenous fluids (too little as well as too late) to those in need of it, denies them the chance of survival, while on the other hand, a patient's condition may be worsened by infusion if the cardiac function is impaired. Measurement of the C.V.P. is of practical value because it indicates the state of the venous reservoir, the venous return, and cardiac efficiency, and therefore whether a transfusion should be given, or should be continued.

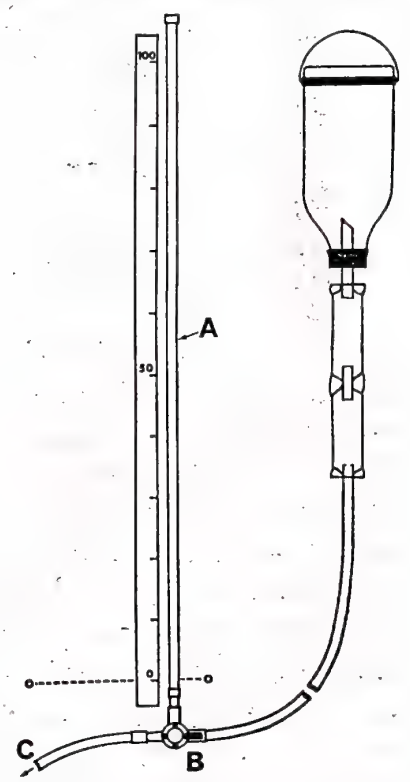

FIG. 73.—Saline manometer for measuring central venous pressure. A = The sterile glass or plastic tube manometer against a centimetre scale; a spirit level is used to set zero (o) to the mid-axillary point or to the manubrium sterni. B = The three-way stop-cock allows (i) saline to run via C into the vein from the reservoir, (ii) to fill the manometer, and (iii) to exclude the reservoir and to allow the fluid in A to fall to the level of the C.V.P.

Method.—It can be measured by an intravenous catheter connected to a simple saline manometer, the range being 15 cmH_2O* (high) to 5 cmH_2O (low) if zero is the mid-axillary point. Therefore, if the C.V.P. is low the venous return should be supplemented by intravenous infusion, but not if the pressure is high. By careful monitoring, keeping the pressure between 5–15 cm. saline, a rapid transfusion can be given in a low pressure state. Any sustained rise of pressure to the maxima demands immediate cessation of the infusion.

THE TREATMENT OF HÆMORRHAGE

This can be summarised :—

1. Stop the blood loss by—Pressure and Packing. Position and Rest. Operation. Ligation, Repair, Excision.
2. Restore blood volume by—Blood Transfusion (p. 71): Saline; Dextran (p. 76); Plasma (p. 76).

* Since C.V.P. is measured using a column of water, no alterations to S.I. units will be used.

Methods of Stopping Hæmorrhage

Pressure and Packing.—*The first-aid* treatment of hæmorrhage from a wound is a pressure dressing, this being made from anything handy which is soft and clean (linen), but even a rolled up forage cap stuffed into a wound has been effective in battle (Drummond). The dressing or pack should be bound on tightly.

Other examples of pressure being used to control hæmorrhage include: the use of forefinger and thumb or a clothes-peg for epistaxis (Chap. 29); the use of a double balloon in the œsophagus and the stomach to control the bleeding from œsophageal varices (Chap. 43).

Packing by means of rolls of wide gauze is an important standby in operative surgery. If several rolls are used the ends must be tied together to ensure complete removal later.

N.B.—If on removal of pressure or packing, bleeding appears to have ceased completely, do not assume that all is well, especially when dealing with deep wounds involving large veins. Continued close observation is required.

Tourniquets are to be avoided in *first aid*. They can only be used around the thigh or upper arm; they are difficult to apply tightly enough to interrupt arterial blood flow, and only cause venous congestion and increased blood loss. There have been many examples of tourniquets of some kind being used for ruptured varicose veins causing exsanguination by only occluding venous return. (For example, a policeman was brought into a casualty department with seven tourniquets in place. The venous bleeding ceased as soon as they were removed!) Tourniquets tight enough to obstruct arterial flow may cause contusion of the artery wall and thrombosis, especially if atheroma is present. Nerve conduction can also be seriously impaired, while to leave a tourniquet on for over an hour is to invite muscle death and the risk of renal failure (crush syndrome, p. 81). To sum up, it can be said that tourniquets are dangerous because they may be applied too loosely, too tightly, or for too long.

In the operating theatre tourniquets are used (a) to control hæmorrhage temporarily while exploration and repair are being carried out: (b) for some amputations (not for atherosclerotic gangrene); (c) in order to obtain a bloodless field for orthopædic and soft tissue operations (cartilage, tendon, nerves, ganglia of tendon sheaths). The sphygmomanometer cuff is very satisfactory as a pneumatic tourniquet; the cuff is inflated after elevation of the limb for five minutes has materially reduced the vascularity. Alternatively, a bloodless operation field can be obtained by an Esmarch bandage applied spirally to the elevated limb commencing distally, and then bound on tightly. The distal spirals are unwound to expose the limb for operation.

Removal of a Tourniquet.—The fact that a tourniquet is in place and the time of application must be written large on the theatre blackboard and deleted only when it is removed. It is a wise precaution to attach the tourniquet to the operating table, so that it cannot be overlooked when the patient is lifted on to the trolley.

Venous Tourniquet.—A light rubber or a pneumatic tourniquet is applied to the upper arm prior to intravenous injections and sampling. It is also used in the diagnosis of varicose veins (p. 168).

Position and Rest.—*Elevation of limbs* (in ruptured varicose veins) employs gravity to reduce bleeding. Elevation also causes vasoconstriction (Lister). *A bed elevator* is often used to raise the foot of the bed as an aid to vasoconstriction in reducing the size of the vascular compartment, so facilitating blood flow to the brain and the restoration of a satisfactory blood pressure. Gravity is also used in certain operations, as in thyroidectomy when the

Sir William Alexander Duncan Drummond, Contemporary. Deputy Director-General, St. John Ambulance Association and Brigade. Formerly Director-General, Army Medical Service (1956–1961).
Johann Friedrich August von Esmarch, 1823–1908. Professor of Surgery, Kiel, Germany (1857–1899). Developed the 'Esmarch Bandage' whilst working as a Military Surgeon during the Franco-Prussian War (1870–1871), and reported on its use in 1873.
Joseph Lister (Lord Lister), 1827–1912 (see footnote, p. 1).

patient is tilted feet downwards (anti-Trendelenburg position) or as in stripping of varicose veins when a head-down tilt is used (Trendelenburg).

In the ward as well as the theatre, Esmarch bandages may be applied temporarily to the limbs in order to reduce the vascular compartment in shock, so aiding the heart to maintain blood flow to vital structures.

Absolute rest is vital. This means nursing the patient in a comfortable recumbent position, and he should be relieved of unnecessary exertion. He does not wash or feed himself, and assistance is given for turning in bed, which must be at least two-hourly to prevent pressure sores.

Sedation also brings rest. Morphine (10–20 mg.) relieves pain, calms restlessness, and aids coronary and cerebral blood flow. Though it is contraindicated where there is respiratory depression (as in head injuries), its use is invaluable where respiratory movements and coughing are inhibited because of chest pain. Morphine is best given intramuscularly, or intravenously in hæmorrhage and shock. A subcutaneous dose is not easily absorbed because of vasoconstriction, and if repeated doses are given in this way an excessive amount is liable to be absorbed when the circulation improves. Morphine does not in itself produce sleep, and the patient, though relieved of pain, may remain wakeful and anxious. Amylobarbitone (120 mg.) should be used if there is no respiratory depression, otherwise chloral hydrate (1–2 g) is useful.

Examples of Operative Techniques in Hæmorrhage.—Artery forceps (e.g. Spencer Wells) or 'hæmostats' are mechanical means of controlling bleeding by pressure. The clamped vessel can be ligated with catgut, cotton, thread or silk, or coagulated with diathermy. When an incision is made through the scalp for craniotomy, the profuse bleeding is not easily arrested by direct forcipressure, so the cranial aponeurosis is picked up by a series of forceps which are everted together, thus exerting pressure. Silver clips (Cushing) may be applied to cerebral vessels.

Suturing may be employed. The vessel can be underrun or transfixed by needle and suture and then ligated, while if the continuity of a main vessel is to be restored, 4/0 silk or polypropylene is used (p. 133) on a 20-mm. atraumatic needle.

Pressure by packing, using rolls of wide gauze has been previously mentioned, but light pressure with a 'peanut' of gauze held by forceps aids the sealing of an arterial suture line after reconstruction following trauma, embolectomy, or in artery grafting. About five minutes is required for the platelets to seal the join.

Patches of vein or Dacron mesh may be used to repair a vascular defect. A patch of muscle, lightly hammered, provides thrombokinase to stop a troublesome ooze.

Other topical applications for oozing include gauze or sponge which is absorbed by the body. 'Oxycel' or gelatin sponge provides a network upon which fibrin and platelets can be deposited. This is the modern counterpart of the use of cobwebs by our forefathers, or sphagnum moss by our neolithic ancestors.

Gauze soaked in adrenalin soln. (1:1,000) or 'Stypven' (Russell viper venom) are other topical applications. Bone wax (Horsley) is used for oozing bone.

Excision of a bleeding viscus may be necessary, e.g. a ruptured spleen must be excised. However, a ruptured kidney is treated conservatively if possible (Chap. 54).

BLOOD TRANSFUSION

The indications for transfusion in surgical practice are as follows:—

1. Following traumatic incidents where there has been severe blood loss, or hæmorrhage from pathological lesions, *e.g.* from gastrointestinal tract.

Friedrich Trendelenburg, 1844–1924. Professor of Surgery, Rostock (1875–1882), Bonn (1882–1895), and Leipzig (1895–1911). The Trendelenburg Position was first described in 1885.

Sir Thomas Spencer Wells, 1818–1897. Surgeon, Samaritan Free Hospital for Women and Children, London. Introduced the improved version of his Pressure Forceps, used today, in 1879.

Harvey Williams Cushing, 1869–1939. Professor of Surgery, Johns Hopkins University, Baltimore, Maryland, U.S.A. (1903–1912), and Harvard Medical School, Boston, Massachusetts, U.S.A. (1912–1932).

Patrick Russell, 1727–1805. Physician who practised for a time at Aleppo, Syria, and later became naturalist to the East India Company. He produced a memoir on Poisonous Snakes in 1787.

Sir Victor Alexander Haden Horsley, 1857–1916. Surgeon, University College Hospital, London. Horsley's Wax consists of seven parts of Beeswax to one part of Almond Oil. (Died of heatstroke or paratyphoid fever in Mesopotamia. One of the original Authors (McN. L.) attended his funeral.)

2. During major operative procedures where a certain amount of blood loss is inevitable, *e.g.* abdomino-perineal or cardiovascular surgery.

3. Following severe burns where, despite initial fluid and protein replacement there may be associated hæmolysis.

4. Post-operatively in a patient who has become severely debilitated and anæmic as the result of infection, septicæmia, *etc.*

5. Pre-operatively in cases of chronic anæmia where surgery is indicated urgently, i.e. where there is inadequate time for iron or other replacement therapy (see Blood Fractions below and Complications p. 75), or where the anæmia is unresponsive to therapy, e.g. aplastic anæmia.

6. To arrest hæmorrhage or as a prophylactic measure prior to surgery, in a patient with a hæmorrhagic state such as thrombocytopenia, hæmophilia or liver disease. (See Blood Fractions below.)

Preparation of Blood Products for Transfusion.—It is important that blood donors should be fit and with no history of serious disease, in particular hepatitis which is transmitted in donor blood.

Blood is collected into a sterile commercially prepared plastic bag with needle and plastic tube attached in a complete, closed sterile unit.

With the donor lying on a couch, a sphygmomanometer cuff is applied to the upper arm and inflated to a pressure of 70 mmHg (9·3 kPa) or 80 mmHg (10·6 kPa). After introducing 0·5 ml. of local anaesthetic, the 15 gauge needle is introduced into the median cubital vein and 450 ml of blood allowed to run into the bag or bottle containing 120 ml. of anticoagulant solution (ACD).[1]

During collection the blood is constantly mixed with the anticoagulant to prevent clotting and at the end of the procedure the tube is clamped and the needle removed. Specimens for use in blood grouping and cross-matching procedures may be obtained by clamping off small sections of the plastic tubing containing the donor blood.

Blood Storage.—It is essential that all blood for transfusion be stored in special blood bank refrigerators controlled between temperatures of 2°C and 7°C. Blood allowed to stand at higher temperatures for more than 2 hours is in danger of transmitting infection, whereas at temperatures below 2°C there is liable to be hæmolysis of the red cells resulting in a severe pyrexial reaction and possibly renal damage in the recipient.

Red blood cells remain suitable for transfusion for at least 3 weeks. The cells from blood stored for this length of time, however, show some changes in metabolism resulting in a temporary reduction in their ability to release oxygen to the tissues of the recipient. This defect is restored in the body in about 72 hours and is therefore probably not clinically significant except in a patient requiring massive transfusion. In this case it is wise to give at least one or two units of blood which are less than 7 days old.

White blood cells are rapidly destroyed in blood stored by these procedures. Blood platelets similarly do not remain functional for more than 72 hours.

Blood Fractions.—Whole blood may be divided into various fractions. This is not only more economical of blood donors but certain fractions are more appropriate than whole blood transfusion for certain clinical conditions. Fractionation procedures are relatively safe and simple, using sealed sterile plastic bag units.

1. *Packed red cells.*—These are prepared by centrifugation of whole blood at 3,000 rev/min and removal of the supernatant plasma. Packed red cell transfusion is the most suitable form of therapy in patients with chronic anæmia, and particularly elderly patients or small children in whom introduction of large volumes of fluid may cause cardiac failure.

2. *Platelet rich plasma.*—This is prepared by centrifugation of freshly donated

[1] (ACD. Acid citrate dextrose solution containing 3 g anhydrous dextrose, 2 g disodium citrate monohydrate and water to 120 ml. The solution is placed in the bottle or bag and sterilised.)

blood at 1000 rev/min for 20 minutes. The supernatant plasma containing the majority of the platelets is separated and is suitable for transfusion to patients with thrombocytopenia who are either bleeding or require surgery.

3. *Platelet concentrate.*—This is prepared by centrifugation of platelet-rich plasma at 3000 rev/min, the supernatant plasma is removed, and the precipitate forms a very rich source of platelets for transfusion to patients with thrombocytopenia.

4. *Plasma.*—This is removed after centrifugation of whole blood at 3000 rev/min and it may be further processed or fractionated in various ways.

(a) *Freeze-dried plasma.*—Plasma from 8–10 units of blood may be pooled and lyophilised. The resulting product may be stored for many years in the dried form and reconstituted by dissolving in sterile distilled water. Owing to its potential danger of transmitting serum hepatitis its use has been largely superseded by purified protein fraction (see below).

(b) *Fresh frozen plasma.*—Plasma removed from fresh blood obtained within 4 hours is rapidly frozen by immersing in solid carbon dioxide and ethyl alcohol mixture. This is stored at −20°C and is a good source of all the coagulation factors. It is the treatment of choice when considering surgery in patients with abnormal coagulation due to severe liver failure. It may also be given in any of the congenital clotting factor deficiency diseases especially *Christmas disease* (Factor IX deficiency) or hæmophilia (Factor VIII deficiency).

(c) *Cryoprecipitate.*—When fresh frozen plasma is allowed to thaw at 4°C a white glutinous precipitate remains and if the supernatant plasma is removed, this cryoprecipitate is a very rich source of Factor VIII. It is stored at −20°C and immediately available for treatment of patients with hæmophilia (Factor VIII deficiency). The advantage of cryoprecipitate treatment in hæmophilia is the simplicity of administering large quantities of Factor VIII in relatively small volumes by intravenous injection.

(d) *Purified protein fraction.*—Repeated fractionation of plasma by organic liquids followed by heat treatment results in a plasma fraction rich in protein but free from the danger of transmission of serum hepatitis. This may be stored for several months in liquid form at 4°C and is suitable for replacement of protein, e.g. following severe burns.

(e) *Fibrinogen.*—This is prepared by organic liquid fractionation of plasma and is stored in the dried form. When reconstituted with distilled water it is suitable for transfusion in patients with severe depletion of fibrinogen, e.g. disseminated intravascular coagulation or congenital afibrinogenæmia.

Blood Grouping and Cross-Matching

Human red cells have on the cell surface many different antigens. For practical purposes, there are two groups of antigens which are of major importance in surgical practice:

(1) **Antigens of the ABO Blood Groups.**—These are strongly antigenic and are associated with naturally occurring antibodies in the serum. Individuals show four different ABO cell groups viz:

Red cell group	*Serum contains*
A	Anti B antibody
B	Anti A antibody
AB	No ABO antibody
O	Anti A and Anti B antibody

(2) **Antigens of the Rhesus Blood Groups.**—The antigen of major importance in this group is Rh(D) which is strongly antigenic and is present in approximately 85% of the population in the United Kingdom. Antibodies to the D antigen are not naturally present in the serum of the remaining 15% of individuals but their formation may be stimulated by the transfusion of RhD positive blood. Such acquired antibodies are capable, during preg-

nancy, of crossing the placenta and if present in a RhD negative mother may cause severe hæmolytic anæmia and even death (hydrops fœtalis) in a Rhesus D-positive fœtus *in utero*. The other minor blood group antigens may be associated with naturally occurring antibodies or may stimulate the formation of antibodies on relatively rare occasions.

Incompatibility.—If antibodies present in the recipient's serum are incompatible with the donors cells a transfusion reaction will result. This is the result of agglutination and hæmolysis of the donated cells leading in severe cases to acute renal tubular necrosis and renal failure. For this reason therefore, it is essential that all transfusions should be preceded by:—

(1) *ABO and Rhesus grouping* of the recipient's and donor's cells so that only ABO and RhD compatible blood is given.

(2) Direct matching of the recipient's serum with the donor's cells to confirm ABO compatibility and to test for any minor blood group antibody in the serum of the recipient.

Blood grouping and cross-matching require full laboratory procedures, each technique requiring 2 hours. In emergencies it may be necessary to reduce this time but the risk of undertaking urgent techniques must be weighed against the danger to the patient by the delay in transfusion entailed by the full laboratory procedures. In such emergencies it may be advisable to restore the patient's blood volume by dextran, plasma or saline, until blood has been made available. Alternatively donor blood, group O Rhesus D-negative, which is compatible with the majority of individuals should be given and this should always be available in acute emergency situations.

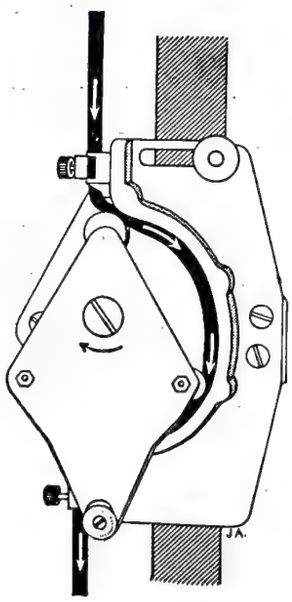

FIG. 74.—Martin's pump.

Giving Blood.—Blood transfusion is commenced by:—

(a) selection and preparation of the site (p. 91).

(b) careful checking of the donor blood:—this should bear a compatibility label stating the patient's name, hospital reference number, ward and blood group.

(c) Insertion of the needle or cannula:—the latter may be valuable if intravenous therapy is required for any length of time.

(d) Giving detailed written instructions as to the rate of flow (e.g. 40 drops per minute allows one 540 ml unit of blood to be transfused in 4 hours).

In acute emergencies it may be necessary to increase the rate of flow and it is possible to give 1–2 units in 30 minutes by using a positive pressure Martin pump (fig. 74) or a simple pressure cuff around the plastic bag of blood.

Warming Blood.—During cardiopulmonary operations the blood may be warmed before reaching the patient by passing it through a blood warming unit thus reducing the risk of cardiac arrest from large volumes of cold blood direct from the refrigerator.

Autotransfusion.—This is an old, well-tried and satisfactory method of restoring a patient's blood volume; transfusion with his or her own blood. For example, in a case of ruptured ectopic gestation, the blood is collected from the peritoneal cavity and put into a sterile container suitable for connecting to transfusion tubing. The classical method of filtration of this blood to prevent the transfusion of any small clots is to place a piece of sterile gauze within the container. Nowadays special apparatus is being marketed.

Peter Guy Cutlack Martin, Contemporary. Surgeon, Hammersmith Hospital, London.

Buffy coats

Complications of Blood Transfusion

(1) **Congestive Cardiac Failure.**—This is especially liable to occur in the elderly or where there is cardiovascular insufficiency and may result from too rapid infusion of large volumes of blood. It is advisable in the individual with chronic anæmia to give packed red cells and at the same time give diuretic drugs. The transfusion should be given slowly, *i.e.* 1 unit over 4–6 hours and if necessary on 2 separate occasions.

(2) **'Transfusion Reactions'.**—These may be the result of:—

(i) *Incompatibility.*—This should be avoided if the correct procedures of grouping and cross-matching have been adopted but in fact it is nearly always due to human error in the collection, labelling or checking of the specimens and donor bottles. The patient develops a rigor, temperature, pain in the loins and may become extremely alarmed. The transfusion should be immediately stopped and a fresh specimen of venous blood and urine from the patient be sent together with the unwashed donor bottle to the laboratory for checking.

A close watch should be kept on the patient's pulse, blood pressure and urinary output and if renal failure develops it may be necessary to institute hæmodialysis.

(ii) *Simple pyrexial reactions* in which the patient develops pyrexia, rigor and some increase in pulse rate. These are the result of 'pyrogens' in the donor apparatus and are largely avoided by the use of plastic disposable giving sets.

(iii) *Allergic reactions* in which the patient develops mild tachycardia and an urticarial rash. This is the result of allergic reaction to plasma products in the donor blood and is most common in those individuals receiving repeated transfusions. The reaction is treated by slowing the transfusion and giving the patient an appropriate antihistamine drug.

(iv) *Antibody production.*—This is not uncommon in those patients who have received many transfusions in the past, *e.g.* for hæmophilia or thalassæmia. The individual develops antibodies to donated white cells, platelets or to plasma proteins which cause reactions with each transfusion. They may be minimised by giving packed red cells from which plasma and 'buffy coat layers' have been removed or by 'washing' of donor cells. Antihistamines or steroids may also be given to the recipient if necessary.

(3) **Infections.**—There are two main reasons for blood transfusion causing infection in the recipient.

(i) *Serum hepatitis virus* may be transmitted from the donor and is usually a severe hepatitis arising approximately 3 months after the transfusion. It should be avoided by adequate verbal screening of the blood donor and by testing for the presence of the hepatitis associated antigen in his blood prior to transfusion.

(ii) *Bacterial infection* as the result of faulty storage of blood. This arises most commonly from the donor blood being left in a warm room for some hours before the transfusion is commenced. This allows proliferation of any

bacteria and transfusion of such an infected blood bottle may result in severe septicæmia in the recipient and rapid death.

(4) **Thrombophlebitis** (p. 162).

(5) **Air Embolism** (p. 144).

(6) **Disseminated Intravascular Coagulation.**—This may occur in patients receiving massive transfusions and may be contributed to by the underlying pathology. There is an acute fall in the level of fibrinogen, platelets and some other clotting factors resulting in further hæmorrhage. It may be treated by replacement of the deficient factors such as fibrinogen and platelets, and heparin may indeed be advisable if the coagulation process is continuing.

Hæmophilia and the Congenital Hæmorrhagic Diseases

Hæmophilia (hæmophilia A) is a hæmorrhagic diathesis caused by the congenital deficiency in the blood of Factor VIII (antihæmophilic globulin AHG). It is a sex-linked characteristic, transmitted by the asymptomatic female carriers, and manifest only in males.

The levels of Factor VIII in the blood of severe hæmophiliacs may be as low as 0–3% of the average normal level. In the case of spontaneous hæmorrhage, e.g. into joints, treatment should aim at raising the level to at least 20%. Should surgery be anticipated in the hæmophiliac, the level should be raised to 50–100%.

Factor VIII therapy is best done by intravenous administration of cryoprecipitate, 5–10 units being given by simple injection. This should be done *immediately* prior to surgery since the half-life of Factor VIII is only 18 hours and the levels should be maintained daily after operation depending on the extent of the surgery.

Alternative forms of therapy include fresh blood if necessary, fresh-frozen plasma, or dried concentrates of human or animal A.H.G.

Christmas Disease[1] (hæmophilia B) is a congenital disease resulting from the deficiency of Factor IX (Christmas factor). Clinically the manifestations of the disease are similar to hæmophilia, but treatment is less predictable. Factor IX is replaced by the transfusion of fresh-frozen plasma, or by reconstituted dried concentrates of human Factor IX.

Hæmophilic Joints.—In both hæmophilia and Christmas disease hæmorrhage into joints is very common, and persistent and recurrent hæmarthrosis may result in permanent damage to the articular surfaces and disorganisation of the joint. The most important feature of treatment is that it should be prompt and efficient. Replacement of the clotting factor should be instituted immediately and before severe tension is allowed to build up in the joint. Should this occur, however, aspiration may be advisable under cover of clotting factor replacement therapy.

BLOOD SUBSTITUTES—PLASMA, DEXTRAN

One of the most urgent requirements in a patient suffering from acute blood loss is the re-establishment of a normal blood volume. This may be achieved satisfactorily with a number of plasma substitutes.

Plasma can be used without delay and cross-matching is unnecessary, but dried plasma carries with it a 1·3% risk of transmitting hepatitis and has been largely superseded by the use of plasma protein fraction. Excellent results may be obtained in severely shocked patients by giving as much as 2 or 3 bottles (1·7 l.) of plasma intravenously in half an hour. It is particularly valuable in patients with burns where there has been severe loss of protein.

Dextrans are polysaccharide polymers of varying molecular weight producing an osmotic pressure similar to that of plasma.

[1] So-called after the name of the first patient in whom the disease was discovered.

The high molecular weight dextrans (110,000 and 70,000) (Dextran 110 and Dextran 70) are less effective in the early phase of hypovolæmia but are longer-acting since they are retained for some time within the circulation. Dextrans have the disadvantage of inducing rouleaux of the red cells which may lead to problems in blood grouping and cross-matching procedures.

Low molecular weight dextran (40,000) (Dextran 40, Rheomacrodex) has a more immediate effect in restoring plasma volume but the smaller molecules are more readily excreted by the kidney and the effect is thus less prolonged. It may be of advantage in preventing sludging or stasis of red cells in the smaller blood vessels, *e.g.* of the kidney, and thus preventing the 'renal shut-down' sometimes associated with severe hypotension. It is less likely to induce rouleaux formation than the high molecular weight compounds.

All the dextrans may be associated with abnormal bleeding and this appears to be more marked the higher the molecular weight, presumably because of the longer period of retention in the circulation. The cause for this increase in hæmorrhagic tendency is not known, but is not uncommonly seen when the blood volume has been inadvertently overexpanded. For this reason it is recommended that the total volume of Dextran given should not exceed 1,000–1,500 ml.

Mannitol, a sugar of low molecular weight, while not a substitute for blood, is of value in preventing the acute renal failure which follows renal arteriolar constriction in all types of shock, and in the crush syndrome (p. 81). It reduces the mortality from renal failure after operations for obstructive jaundice (Dawson). It promotes an osmotic diuresis and may have a specific renal vasodilator action. Dose.—Up to 1 g/kg body weight i.v. in 12 hr as a 20% solution, e.g. three infusions of 100 ml during and after operation. Test doses of mannitol may be used in cases of diminished urine output to determine whether hydration therapy or the strictly-limited-fluid regimen (Chap. 53) is to be adopted. Catheterisation (indwelling) is helpful to prevent retention due to rapid overfilling of the bladder and to provide means of accurate recording of the response to therapy.

SHOCK

Shock is a combination of 1. a threat to existence and 2. the response of the body to this threat. The common factors are:—

1. *A loss or withdrawal of blood volume* from the main vascular channels of the body, affecting cardiac output, central blood pressure and the perfusion pressure of oxygen into the tissues, particularly the heart and brain.

2. *Vasoconstriction* (Nature's first aid for 1.), which serves to maintain the peripheral vascular resistance, the arterial pressure, and therefore the oxygen perfusion of the vital structures. This is a protective mechanism which plays for time—time for the threat to cease (e.g. arrest of hæmorrhage and blood transfusion), so that full recovery is possible (reversible shock). If the threat persists, is repeated, or replacement of blood volume is not carried out, the anoxia to heart muscle and brain stem causes failure of these organs, thus impairing oxygen perfusion of tissues still further and causing a vicious circle (irreversible shock) ending in death (p. 66). Contributory causes are exposure, fatigue and starvation, and the extremes of life.

Clinically the condition of (1) loss of blood volume and (2) vasoconstriction is manifest as pallor, empty veins, cold skin, sweating and increased pulse.

John Leonard Dawson, Contemporary. Surgeon, King's College Hospital, London.

The Types of Shock

Vasovagal Shock. Neurogenic Shock. Psychogenic Shock.—Occurs immediately as a result of a sudden fright (e.g. bad news) or severe pain (e.g. a blow on the testes). The effect varies in intensity from a slight faint to sudden death. The expression ' I nearly died of fright ' is not necessarily hyperbolical. The hypoxia of the vital centres is brought about by pooling of blood in the large vascular reservoirs (limb muscles), and by dilatation of the splanchnic arteriolar bed, with consequential low cardiac output and fall of arterial pressure until restored by peripheral vasoconstriction. A similar phenomenon of pooling and fainting occurs in guardsmen or other service personnel standing to attention for long periods.

Hæmorrhagic Shock.—See hæmorrhage, p. 66.

Burns Shock (p. 115).—The loss of blood volume is due to rapid plasma loss from the damaged tissues and whole blood destruction. A delayed form of burns shock may be caused by a breakdown product of cell membranes as well as from infection.

Dehydration, Diarrhœa, and Vomiting.—Severe extravascular fluid loss is usually associated with infection (exotoxins and endotoxins) and loss of protein as a result of inflammation of the intestinal mucous membrane (e.g. staphylococcal enterocolitis (p. 19), cholera, etc.).

Pleural, Peritoneal, Mediastinal, Retroperitoneal Shock.—Sudden leakage of blood, or alimentary secretions into these compartments will cause sudden collapse. Examples are penetrating chest wounds and hæmothorax, a leaking œsophageal or intestinal anastomosis, acute pancreatitis, biliary peritonitis.

Endotoxin Shock (*syn. Gram Negative Shock, E. Coli Shock*).—Multiplication of bacillus coli occurs in segments of strangulated intestine (strangulated hernia, mesenteric thrombosis), and in peritonitis. The endotoxin from the bacilli causes splanchnic arteriolar dilatation (splanchnic pooling) and blood volume discrepancy. Release or removal of the strangulated segment, or the drainage of pus is the important practical factor in recovery of the patient.

Bacteræmic Shock from other Infections.—Gas gangrene is a typical example, causing decreased blood volume and also anæmia from hæmolysis.

Anaphylactic shock, histamine shock, may follow injection of serum (e.g. A.T.S.), in spite of precautions; into patients who have had serum before, or who have a history of allergy. There is wide dilatation of the splanchnic vessels (splanchnic pooling) with consequential fall of venous return and cardiac output (Chap. 39).

Diagnostic Difficulties in Shock.—Because of a thready and irregular pulse, cardiac infarction and even pulmonary embolism are notoriously confusing to the clinician. In both cases there is a shock-like state from a degree of failure of cardiac output and compensatory vaso-constriction. An E.C.G. and an X-ray of the chest do not always determine the diagnosis. The measurement of the central venous pressure (C.V.P.) (p. 69) and its response to a small rapid transfusion may be of assistance. With intra-abdominal catastrophes the surgeon cannot escape the responsibility of performing an exploratory operation for suspected peritonitis, for after

Hans Christian Joachim Gram, 1853–1938 (*see p. 15*).

adequate operative treatment intravenous fluids, hitherto ineffective, have their desired effect and the patient begins to recover.

Treatment of Shock

Treatment, in principle, is the removal of the cause and the replacement of lost blood-volume. In hæmorrhage this implies the arrest of hæmorrhage and blood transfusion. In burns the loss of plasma is replaced by plasma, dextran and blood.

Endotoxin and bacteræmic shock require equally vigorous 'aggressive' treatment. This means immediate and adequate transfusion of blood or

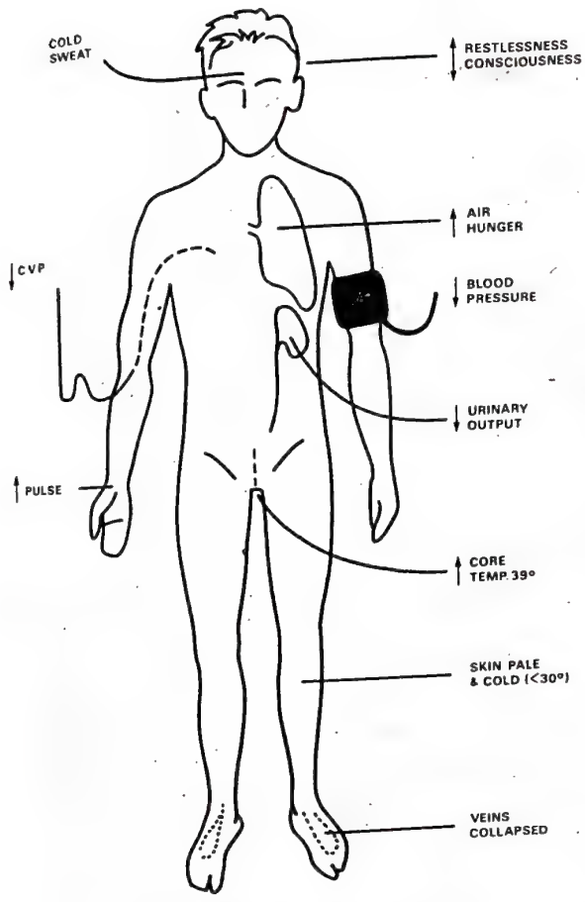

FIG. 75.—Clinical features of shock.

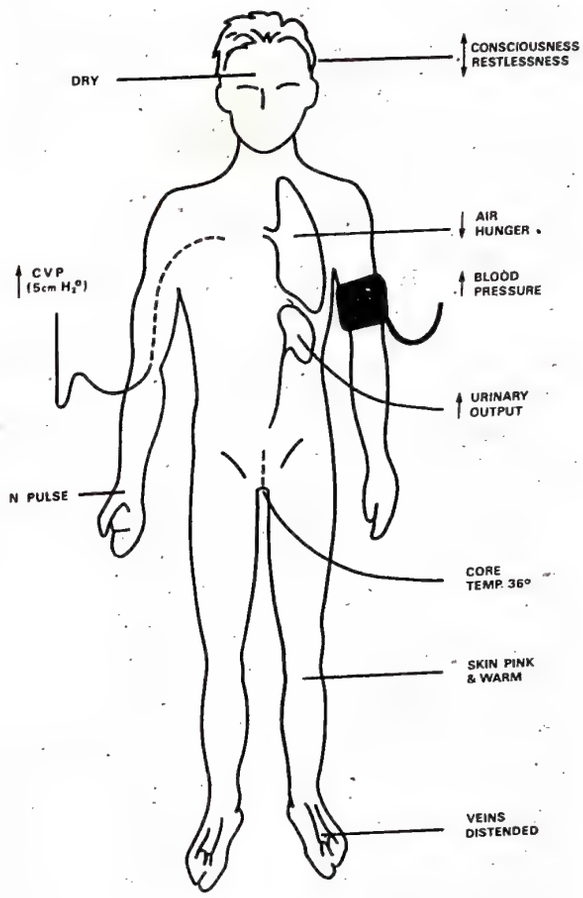

FIG. 76.—Response of patient to adequate volume replacement.
(*W. F. Walker, F.R.C.S., Dundee.*)

substitutes, with central venous pressure control (page 69), full doses of the currently favoured broad spectrum antibiotic (e.g. ampicillin and gentamycin) and the appropriate treatment of the causal lesion.

Hydrocortisone 200 mg i.v. is usually given immediately and the dose, or 100 mg, repeated. A good example of this clinical situation is gas gangrene (page 28).

Position and Limb Compression.—Venous return is improved, and pooling of blood in the large muscles of the legs is reduced by raising the foot of the bed and bandaging the limb so as to compress the peripheral blood-vessels.

Relief of pain is achieved by giving morphine 10–15 mg i.m. or i.v. It is not given subcutaneously as it is not easily absorbed, and if repeated doses

are administered, an excessive amount is liable to be absorbed when the circulation improves. It is not to be given in head injuries.

Sedation for a frightened patient may be by phenobarbitone, 60–100 mg. i.m.

Vasoconstrictor Drugs.—These should be given early. Given late, their action, if any, will only serve to accelerate the damage caused to kidneys and liver by intense vasoconstriction. The substances used include intravenous hydrocortisone 100 mg., and methylamphetamine (Methedrine) 15 mg. Hydrocortisone raises the blood pressure possibly by sensitising the peripheral vascular nerve endings to naturally circulating noradrenaline.

Vasodilator Drugs.—Research (Lillehei) confirms that excessive adrenergic activity with high levels of circulating catecholamines—adrenaline and noradrenaline—is a causal factor in production of manifestations of clinical shock. α-blocking agents and chlorpromazine have been used with encouraging results but they are not without their own disadvantages and *should be used with caution.* The sudden production of vasodilation in a vasoconstricted and dehydrated patient can be followed by a catastrophic fall in arterial blood pressure, unless *vigorous intravenous infusion*, with C.V.P. monitoring (p. 69), accompanies the use of these agents, which should be given in small repeated doses only until extremities become warm and pink and the veins dilated and well filled.

It must be emphasised that the best chance of success in *clinical situations* would therefore appear to be to use drugs *early* rather than late, i.e. as soon as it becomes evident that conventional treatment is not resulting in any clinical improvement.

OXYGEN THERAPY

Indications in Surgery.—In shock its value has been disputed, but it is of special value in chest injuries, in severe hæmorrhage, in toxic hæmolysis, e.g. gas gangrene, in coal gas poisoning and in over-morphinisation. It may also be used in pulmonary embolism, fat embolism, spontaneous pneumothorax, acute pulmonary œdema, and cardiac infarction, and in cases of acute bronchitis, pneumonia, and anoxic cor pulmonale. The usual method employs a disposable polythene mask, delivering 4–6 litres per minute. For patients with chronic bronchitis and emphysema there is a risk of a high concentration of oxygen reducing the carbon dioxide drive for respiration, so causing carbon dioxide narcosis. The safe concentration (Campbell) is about 27 per cent. oxygen delivered by a Venturi or disposable Ventimask in which a jet of oxygen at 4 litres per minute strikes the side walls of the air intake aperture and sucks in about 50 litres of air per minute thus giving the necessary mixture.

Oxygen tents may also be used if a high concentration of oxygen is required. Children should be reassured, as they are likely to be frightened by confinement in an enclosed space, and, if possible, nervous patients should be accustomed to a tent before the necessity arises. Nurses are warned against the risk of explosion, and naked lights and smoking are forbidden in the proximity of the tent.

Hyperbaric Oxygen. Oxygen Drenching.—Oxygen, when it is administered at 1 or 2 atmospheres above atmospheric pressure in a compression chamber (fig. 77) will at least double the arterial plasma oxygen saturation and so the oxygen perfusion of tissues can be increased. When such a chamber is available it can supplant the use of carbogen (oxygen with 5 or 7 per cent. carbon dioxide) in the treatment of carbon monoxide poisoning, and may be used for the treatment of anaerobic infections, e.g. tetanus and gas gangrene, bedsores and frostbite. Oxygen is also a radio-sensitiser in the treatment of cancer. Drenching has been used to treat paralytic ileus and meteorism, for since the gas in the distended bowel is nitrogen, breathing pure oxygen so reduces the partial pressure of nitrogen in the lungs and plasma that reabsorption from the bowel takes place.

Edward James Moran Campbell, Contemporary. Professor of Medicine, McMaster University, Hamilton, Ontario, Canada.

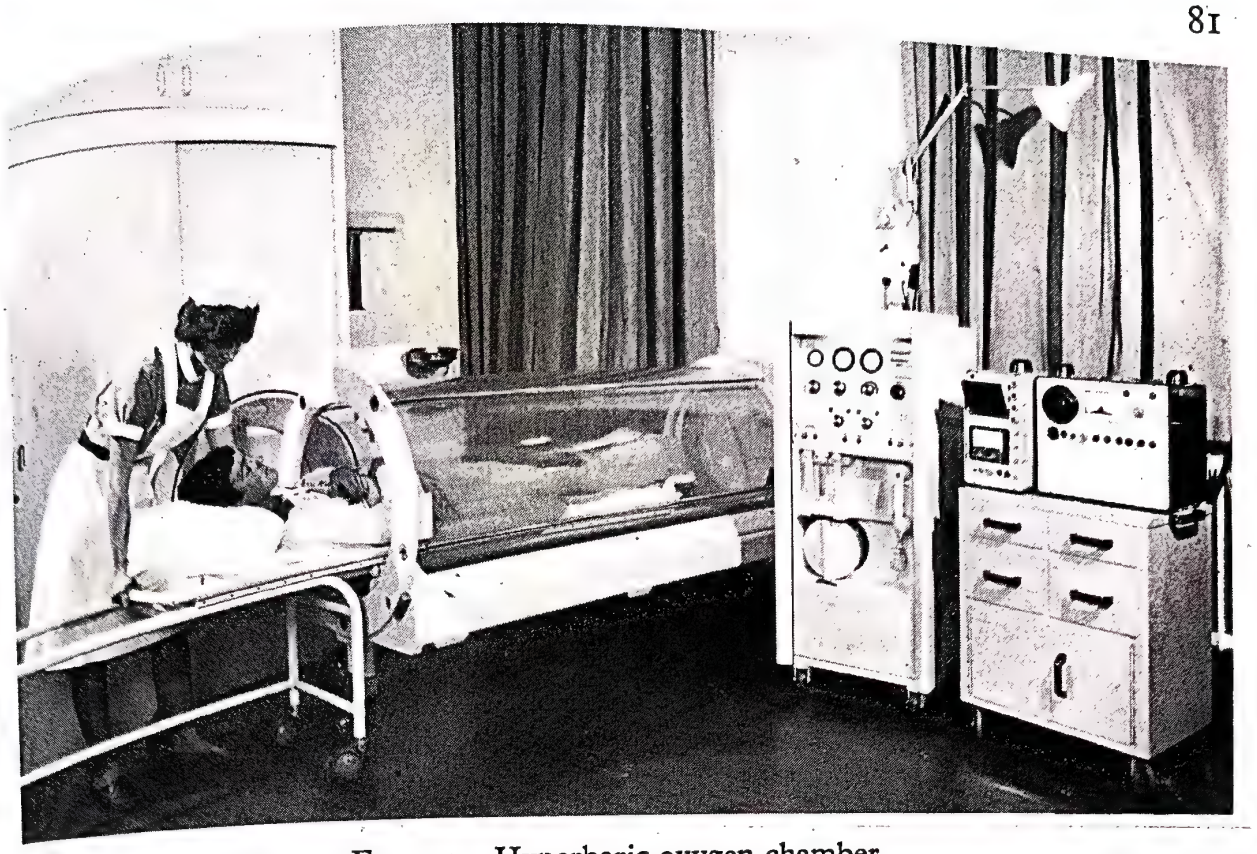

FIG. 77.—Hyperbaric oxygen chamber.
(*Vickers Ltd.*)

Topical Oxygen Therapy.—Hydrogen peroxide 5 or 10 volumes, and 2 per cent. zinc peroxide, giving off nascent oxygen are used locally on wounds infected with anaerobic or microaerophilic organisms, e.g. spreading symbiotic gangrene of the abdominal wall (Chap. 51). It is also used to free the sloughs of ulcers.

CRUSH SYNDROME

This syndrome is commonly associated with earthquakes, air-raids and with mining and other accidents. As a result of massive crushing of muscles, oligæmic shock occurs, due mainly to extravasation of blood into adjacent muscles. Myohæmoglobin enters the circulation and acute renal tubular necrosis is likely to result. The degree of shock has no relation to the development of the syndrome. A similar effect may follow the application of a tourniquet for too long a period (p. 70)!

First-aid treatment may necessitate the application of a tourniquet to the affected limb, which is gradually released so that deleterious substances are admitted to the circulation in small quantities. The crushed muscle often swells considerably, and being confined within unyielding deep fascia, tension develops, impeding the circulation and increasing the extent of ischæmic damage. The limb feels tense and pain is severe. Tension should be relieved by parallel incisions, through which the swollen muscle protrudes. The patient may appear to be comparatively well for two or three days following the accident, but excretion of urine is scanty. Apathy, restlessness, and possibly mild delirium indicate deficient renal function, and uræmia supervenes. If oliguria develops, the fluid intake must be restricted to 'x' plus 400 ml., 'x' being the urinary output for the previous twenty-four hours. The urine should be rendered alkaline by the administration of sodium citrate and sodium bicarbonate. *Rheomacrodex* (p. 77), by clearing blood sludging and myohæmoglobin, or *mannitol* (p. 77), help to re-establish renal cortical blood flow. If there is no response to these measures, dialysis may be life-saving.

CHAPTER 6

FLUID, ELECTROLYTE AND ACID-BASE BALANCE[1] SURGICAL NUTRITION

DAILY WATER BALANCE OF A HEALTHY ADULT (70 kg.)

Intake		*Output*	
Water from beverage	1,200 ml.	1,500 ml.	Urine
Water from 'solid food'	1,000 ml.	900 ml.	Insensible loss from skin and lungs
Water from oxidation	300 ml.	100 ml.	Fæces

It will be noted that:

The Intake is derived from two sources (*a*) exogenous, and (*b*) endogenous.

Exogenous water is either drunk or ingested in solid food. The quantities vary within wide limits,[2] but average 2 to 3 litres per twenty-four hours, of which nearly half is contained in solid food.

Taking into consideration their body-weight, the water requirements of infants and children are relatively greater than those of adults because of (*a*) the larger surface area per unit of body-weight; (*b*) the greater metabolic activity due to growth; (*c*) the comparatively poor concentrating ability of the immature kidneys of the neonate.

Endogenous water is released during the oxidation of ingested food and the amount is less than 500 ml. per twenty-four hours. During starvation this amount is supplemented by water released from the breakdown of body tissues.

The Output.—Water is lost from the body by four routes:

1. *By the Lungs.*—About 400 ml. of water is lost in expired air each twenty-four hours. In a dry atmosphere, and when the respiratory rate is increased, the loss is correspondingly greater.

2. *By the Skin.*—When the body becomes overheated there is visible perspiration, but throughout life invisible perspiration is always proceeding. The cutaneous fluid loss varies within wide limits in accordance with the atmospheric temperature and humidity, muscular activity, and body temperature. In a temperate climate the average loss is between 600 and 1,000 ml. per twenty-four hours.

3. *Fæces.*—Between 60 and 150 ml. of water are lost by this route daily.

---

[1] Francis Moore, Contemporary, and Professor of Surgery, Peter Bent Brigham Hospital, Boston, Mass., has pioneered this important aspect of surgical practice for over 30 years.

[2] The wide individual variation of patients' habitual water intake deserves greater consideration than it receives at present. It may be as great a hardship, and actually harmful, for an elderly patient to drink 3–4 litres as for others to do without water entirely (Wilkinson).

Andrew Wood Wilkinson, Contemporary. Nuffield Professor of Pædiatric Surgery, Hospital for Sick Children, Great Ormond Street, London. President, Royal College of Surgeons of Edinburgh.

In diarrhœa this amount is multiplied not only by the number of stools, but according to their fluidity and size.

4. *Urine.*—The output of urine is under the control of a secretion of the posterior lobe of the pituitary gland (the anti-diuretic hormone) which controls the tonicity of the body fluids, a function that it performs by stimulating the reabsorption of water from the renal tubules, thus varying the amount excreted after the requirements of the first three routes have been met. The normal urinary output is 1,500 ml. per twenty-four hours, and provided the kidneys are healthy, the specific gravity of the urine bears a direct relationship to the volume. A minimum urinary output of 400 ml. per 24 hours is required to excrete the end products of protein metabolism.

Water Depletion.—*Pure water depletion*, apart from the concomitant electrolyte depletion which follows diarrhœa or vomiting, is usually due to a diminished intake. The causes include: (*a*) weakness, exhaustion, mental changes, and cerebrovascular states, (*b*) restricted intake after gastro-intestinal operations, or (*c*) inability to swallow as in painful conditions of the mouth or throat or in œsophageal obstruction. The main symptom is intense thirst and the leading sign is oliguria. As the dehydration progresses, these features (and weakness) increase, but the patient still remains capable of physical and mental exertion. Pure water depletion causes intracellular dehydration and is not accompanied by peripheral circulatory failure. Pure water depletion may also follow the increased loss from the lungs after tracheostomy and may amount to as much as 500 ml. in twenty-four hours in excess of the normal insensible loss. After tracheostomy humidification of the inspired air is an important preventive measure.

Treatment.—The intake of water must be increased. If swallowing is possible, much depends upon the nursing staff ensuring a regular half hourly or hourly intake. Intravenous 5 per cent. dextrose or dextrose saline (p. 89) is given if swallowing is impossible (water is not isotonic and would hæmolyse blood). Careful charting of intake and output is essential. A diuresis signals that enough has been given, and thereafter care must be taken not to overload and cause water intoxication.

Thirst.—The seat of the osmoreceptors (drinking centre) is in the supra-optic nucleus of the anterior hypothalamus (E. B. Verney). Thirst is experienced in acute hypovolæmic shock and after major surgical operations. This is due to intracellular dehydration and corresponds to the period of rapid loss of potassium from the cells of the body. If necessary, the urge to satisfy thirst can be temporarily assuaged by sham drinking—contact of water with the pharynx—by washing out the mouth with ice-cold water.

Water Intoxication, which can occur without sodium loss, especially if the excessive intake of water is rapid, is more likely to supervene when impaired renal function leads to slowing of diuresis. There is always a danger of this happening when there is (1) failure to keep accurate intake and output fluid-balance charts, (2) failure to add up the twelve- or twenty-four-hourly totals on the charts (fig. 84), as well as (3) failure to be aware that water intoxication can actually occur. It is particularly likely (*a*) when isotonic (5 per cent.) dextrose solution is being administered intravenously,

Ernest Basil Verney, 1894–1967. Shield Professor of Pharmacology, Cambridge, England.

ADS- Secreting tumour.

(*b*) when fluid therapy is being undertaken by the administration of tap water per rectum and (*c*) following recto-colonic washouts of plain water or sodium-free solutions, particularly in children with Hirschsprung's disease (Chap. 47).

Other causes of water intoxication may need to be considered. These include lung conditions such as lobar pneumonia and empyema, ADH-secreting tumours such as oat-cell carcinoma of the bronchus, and hypo-pituitary states.

Clinical Features.—These include drowsiness, apathy, weakness, sometimes periods of excitement and delirium, and later convulsions and coma. The patient is pale and cold and bathed in sweat and the patient appears to be in shock—which is incorrect, because the blood-pressure is not low and the pulse is not unduly rapid until the patient is moribund. Nausea and vomiting of clear fluid are common, and usually the patient passes a considerable amount of dilute urine. The diagnosis can be confirmed biochemically by finding a reduced plasma-sodium value.

Treatment.—The intake of water having been stopped, the best course is masterly inactivity. If after several days the water-logged patient is still stuporous (due, no doubt, to renal inactivity), it is permissible to infuse *very slowly* not more than 200 ml. of hypertonic (5·85 per cent.) saline solution intravenously. If this brings about improvement and a diuresis begins the infusion should be stopped forthwith, otherwise circulatory failure from overloading (due to the sudden shift of fluid from cells and tissue spaces) or cardiac arrest is liable to ensue.

ELECTROLYTE BALANCE

When inorganic salts are in solution, as in the extracellular or intracellular fluids of the body, they dissociate into ions. Ions are of two kinds (*a*) *Cations*, which are electropositive and (*b*) *Anions*, which are electronegative: collectively these are the electrolytes. The most accurate way of describing the chemical concentration, reactivity, and osmotic power of these ions is in terms of their milli-equivalents per litre (mEq/l) or in S.I. units as milli-moles per litre (mmol/l), see page 88. The cations include sodium, potassium, calcium, and magnesium ; the anions chloride, phosphate, bicarbonate, and sulphate. The distribution of the salts within the fluid compartments of the body controls the passage of water through the cell walls and maintains acid-base equilibrium.

In S.I. units, mEq/l is replaced by mmol/l. Thus comparing the total of anions with the total of cations is no longer possible. However for monovalent ions (sodium, potassium, chloride and bicarbonate) 1 mEq. = 1 mmol, so numerically at least the additions are possible.

Sodium Balance

Sodium is the principal cation content of the extracellular fluid. The total body sodium amounts to approximately 5,000 mEq (5 000 mmol), of which 44 per cent. is in the extracellular fluid, 9 per cent. in the intracellular fluid, the remaining 47 per cent. being in bone. The sodium housed in bone merits special notice: a little more than half of it is osmotically inactive, and requires acid for its solution; the remainder is water-soluble and exchangeable. Thus there is a large storehouse of sodium ready to compensate abnormal loss from the body. The daily intake of sodium is inconstant. On an average it is 80 to 100 mEq (80–100 mmol) (5 to 6 g) sodium chloride or 570 ml. of isotonic 0·9 per cent. saline solution. An equivalent amount is excreted daily, mainly in the urine, also a little in the fæces. The loss in perspiration normally is negligible; however, in persons not acclimatised to tropical heat prolonged profuse sweating results in a considerable loss of sodium—as much as 85 mEq (85 mmol) per hour (J. Nash). If water alone is given to

Michael Faraday, 1791–1867. Pioneer of electro-magnetism, introduced the words 'electrolyte', 'cation', 'anion'.
Joseph Nash, 1902–1945. Assistant Professor of Surgery, New York College of Medicine, New York, U.S.A., Died in Germany on active service while Surgical Chief of the Ninetieth General Hospital, U.S. Army.

5–6 gm NaCl excreted in urine daily

counterbalance the fluid loss, serious sodium depletion can occur from excessive sweating. (See also mucoviscidosis, Chap. 45.)

Control by Adrenal Corticoids.—The output of sodium, governed by the variation in the avidity with which the renal tubules reabsorb sodium from the glomerular filtrate and the amount of sodium excreted by the sweat glands, is under the control of the adrenal corticoids, the most powerful conservator of sodium being *aldosterone*. When the adrenal glands have been destroyed by disease or extirpated, there is an unbridled loss of sodium in the urine.

The Sodium Excretion Shut-down of Trauma.—Following trauma of any kind (including operation trauma) there is a spell, the length of which varies directly with the degree of tissue damage, of almost non-excretion of sodium. During this period the output of sodium, reduced to not more than 10 mEq (10 mmol) *per diem*, cannot be increased by a supplemented intake of sodium. For this reason it is most inadvisable to administer large quantities of isotonic (0·9 per cent.) saline solution soon after an operation. The period of sodium shut-down lasts for at least forty-eight hours and is due to increased adrenocortical activity.

Sodium Depletion (*syn.* **Hyponatræmia**).—The most frequent cause of sodium depletion seen in surgical practice is obstruction of the small intestine, with its rapid loss of gastric, biliary, pancreatic, and intestinal secretions by antiperistalsis and ejection, whether by vomiting or aspiration. Duodenal, total biliary, pancreatic, and high intestinal external fistulæ also are all notorious for bringing about early and profound hyponatræmia.

There is one other less obvious, nay surreptitious, means whereby the patient is robbed of sodium, and that is by gastric aspiration combined with allowing the patient to drink as he pleases and promptly aspirating the fluid swallowed. The act of drinking excites the flow of gastric juice, and this is also aspirated. During this form of therapy, should the patient be receiving intravenous dextrose solution, as opposed to dextrose-saline solution, to maintain fluid balance, he will soon become a victim of hyponatræmia.

Clinical features of hyponatræmia with salt and water depletion are due to extracellular dehydration. In established cases the eyes are sunken and the face is drawn. In infants the anterior fontanelle is depressed. The tongue is coated and dry; in advanced cases it is brown in colour. Unlike the dehydration produced by loss of water only, in water + salt depletion thirst is not particularly in evidence. The skin is dry and often wrinkled, making the patient look older than his years. The subcutaneous tissue feels lax. Peripheral veins are contracted and contain dark blood. The arterial blood-pressure is likely to be below normal. The urine is scanty, dark in colour, of a high specific gravity, and except in cases of salt-losing nephritis contains little or no chloride.

Presuming that the hæmoglobin level before the dehydration commenced was normal, the hæmatocrit reading (P.C.V.) provides an index of the degree of hæmoconcentration. On the other hand, hæmoconcentration can be masked by pre-existing anæmia (p. 68).

Treatment.—The sodium deficit is replaced by an intravenous infusion of 0·5 to 2 litres of isotonic saline or Ringer's solution (p. 90), depending on the severity of the hyponatræmia. It is important to watch the plasma protein levels in order to avoid overdosage, thus causing hypoproteinæmia and œdema. In severe cases the first step is to restore the circulating blood volume by a rapid infusion of plasma or plasma substitute.

Post-operative Hyponatræmia.—Hyponatræmia with a normal or increased extracellular fluid volume arises as a result of too prolonged administration of a sodium-free solution (5 per cent. dextrose) intravenously. Symptoms seldom present until such treatment has been in progress for more than forty-eight hours (cf. Water Intoxication, p. 83). Early symptoms are headache and giddiness. Hyponatræmia causes pylorospasm and the resulting vomiting adds to the sodium deficit. Should renal function be impaired there will be an associated low level of urinary chlorides.

Treatment.—See water intoxication, p. 83.

Sodium excess (**syn. Hypernatræmia**) is likely to arise if a patient is given an excessive amount of 0·9 per cent. saline solution intravenously during the early post-operative period when, as has been described, some degree of sodium retention is to be expected. The result is an overloading of the circulation with salt and its accompanying water. Even a sub-clinical degree of sodium excess is harmful, for it results in œdema of intestinal and other suture lines. In addition there is danger of pulmonary œdema.

Clinical Features.—Slight puffiness of the face is the only early sign. The patient himself makes no complaint. Pitting œdema should be sought, especially in the sacral region, but for pitting œdema to be present at least 4·5 litres excess fluid must have accumulated in the tissue spaces (Marriott). The patient's weight increases *pari passu* with the water-logging, and the aid of bed-scales should be sought. Signs of overhydration in infancy (infants are very susceptible) are increased tension in the anterior fontanelle, increased weight, increase in the number of urinations, and œdema.

Treatment.—The infusion must be stopped. In established cases with distended jugular veins and pulmonary œdema, treatment should follow the lines suggested in Chap. 38.

Potassium Balance

Potassium is almost entirely intracellular. No less than 98 per cent. is intracellular, and only 2 per cent. is present in the extracellular fluid. Three-quarters of the total body potassium (approximately 3,500 mEq (3 500 mmol)) is found in skeletal muscles. When the body needs endogenous protein as a source of energy, potassium, as well as nitrogen, is mobilised. The mobilised potassium passes to the extracellular fluid, but the surplus over and above the normal content is so rapidly excreted by healthy kidneys that the concentration of potassium in the plasma remains unaltered. Each day a normal adult ingests 2 to 3 g (52 to 78 mEq (52–78 mmol)) of potassium in food; fruit, and milk and honey, are rich in this cation. Except for a very small quantity in formed fæces and a still smaller quantity in sweat, an amount corresponding to the intake is excreted in the urine.

Hugh Leslie Marriott, Contemporary. Emeritus Physician, Middlesex Hospital, London.

Trauma Stress = K↓ Na↑

Potassium Depletion

The Augmented Potassium Excretion of Trauma.—Following trauma, including operation trauma, there is a spell, varying directly with the degree of tissue damage, of increased excretion of potassium by the kidneys. This loss is greatest during the first twenty-four hours and lasts, for example in the case of partial gastrectomy, about three or four days. It will be noticed that the behaviour of the body's potassium in the post-trauma phase is the exact opposite to that of sodium—the potassium flees; the sodium stays. So great are the body's reserves of potassium that, unless the patient was severely depleted at the time of the operation, the therapeutic administration of potassium (always a responsible undertaking) does not arise until the fourth day of intravenous alimentation.

Hypokalæmia can occur suddenly or gradually.

Sudden hypokalæmia is unlikely to be encountered in surgical practice. It occurs most frequently in diabetic coma treated by insulin and prolonged infusion of saline solution.

Gradual hypokalæmia is the type met with in surgical practice. The diarrhœa from ulcerative colitis, villous tumours of the rectum (Chap. 50) and the loss from external fistulæ of the alimentary tract are common causes (e.g. duodenal fistula, ileostomy); the potassium content of the discharge from some of these fistulæ is twice that of the plasma potassium concentration. Another frequent cause of hypokalæmia is prolonged gastroduodenal aspiration with fluid replacement by intravenous isotonic saline solution. It is also prone to occur in the post-operative period following extensive resections for carcinoma of the alimentary tract, because often the operation has to be undertaken after months of weight-loss and potassium depletion.

Clinical Features.—The patient lies listlessly in bed. Speech is slurred and slow; often the patient fails to complete a sentence. Intense drowsiness soon follows and all the patient desires is to be left in tranquillity to sleep. Muscular hypotonia is the outstanding physical sign. Reflexes are lost and incontinence of urine is common. Abdominal distension amounting to paralytic ileus is a constant accompaniment, and in all cases of paralytic ileus the plasma-potassium value should be investigated.

Weakness of the respiratory muscles frequently occurs and results in rapid, shallow, gasping respirations; these are conducive to post-operative pulmonary complications. The diastolic blood-pressure is low, but there is usually a bounding pulse and a presystolic murmur. The diagnosis should be confirmed by electrocardiography, which may show a prolonged QT interval, depression of the ST segment, and a lowering or inversion of the T wave (fig. 78).

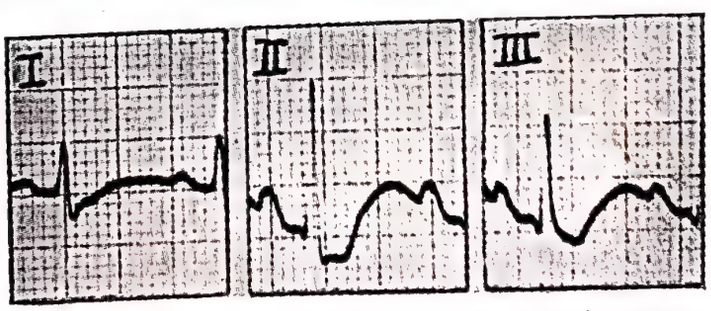

FIG. 78.—Electrocardiographic changes in severe hypokalæmia. The plasma potassium estimation was 1·6 mEq/l (1·6 mmol/l). (*W. F. Walker, F.R.C.S., Dundee.*)

Treatment

Oral Potassium.—Potassium is usually given in the form of milk, meat

Urine output = 20 ml/hour.

extracts, fruit juices and honey. Potassium chloride, 2g effervescent tablets, is given by mouth six-hourly.

Intravenous Potassium.—Should ingestion be inadequate or contraindicated, this route must be used. It is not without the danger of giving too much too quickly (especially when renal function is impaired), thus raising the plasma concentration to a dangerous level and causing cardiac arrest. Administration should be properly controlled; the plasma level of potassium should be checked daily; the urine output must be adequate (500 ml. per twenty-four hours—20 ml. per hour). *When there is no associated alkalosis*, the potassium deficit can be restored by adding 20 mEq or mmol potassium chloride to a litre of 5 per cent. dextrose or 0·9 per cent. normal saline solution, which is given over eight hours.

Hypokalæmic alkalosis, see p. 96.

Estimation of Electrolyte Balance.—For full electrolyte determinations it is best to take sufficient blood from a vein to fill to the brim a small tube (6–7 ml.) into which a small quantity of standard lithium heparin solution has been introduced and dried. Replace the stopper, mix by repeated inversion and dispatch to the laboratory immediately. Every effort must be made to avoid hæmolysis. The plasma separated from hæmolysed blood is useless for potassium estimations.

The Plasma-Sodium Level.—Sodium, with its equivalent anions, accounts for about 90 per cent. of the osmotic pressure of the plasma. Changes in the sodium content coincide with changes in the osmolality of the plasma, and so of all the body fluids. The best index of the total electrolyte concentration of the plasma is the sodium value, which normally is between 137 and 147 mEq. (137 and 147 mmol) per litre. Whenever possible the *plasma chloride* and *bicarbonate* should be estimated simultaneously, since variations in the one may be accompanied by opposite changes in the other. The normal level of chloride is 95 to 105 mEq/l (mmol/l), and of bicarbonate 25 to 30 mEq/l (mmol/l); the sum of the two remains roughly constant at 120 to 135 mEq. per litre.

Potassium deficiency is present if the plasma-potassium value is less than 3·5 mEq/l (mmol/l). The normal range is 3·5 to 5·0 mEq/l (mmol/l). It must be remembered that intracellular potassium deficiency may be present although the plasma concentration is normal, and that deficiency is to be expected if oral feeding has been withheld for more than four days. Estimation of potassium in the urine or aspirated gastro-intestinal contents serve as a guide to the rate of depletion and the replacement necessary (W. J. Griffiths). Electrocardiography may also be used (fig. 78).

Calcium

Calcium is an extracellular cation with a plasma concentration of 4·5–5·5 mEq/l (2·2–2·5 mmol/l). It exists in three forms: bound to protein, free non-ionised and free ionised, the last form being the component necessary for blood coagulation and affecting neuromuscular excitability. The ionised proportion falls with increasing pH; thus in respiratory alkalosis due to hyperventilation there may be tetany—with an apparently normal total plasma calcium level. In the urine the ionisation and the solubility of calcium is similarly depressed if the pH is elevated, thus promoting stone formation. The plasma level of calcium is likely to be modified by any factor promoting or inhibiting its absorption from the bowel, its storage in bone or its elimination by the kidneys: such factors include vitamin D and phytic acid, parathormone and calcitonin (Chap. 34), and the state of renal and small bowel function.

The management of abnormal calcium blood levels depends, where possible, on removal of the cause, e.g. removal of a parathyroid tumour (Chap. 34). In hypocalcæmia with tetany (Chap. 34) or in the coagulation disorder due to massive transfusion of blood containing acid citrate dextrose (ACD, p. 72), 10 ml. of 10% calcium gluconate may be injected slowly intravenously. If oral administration is possible, calcium aspirin is useful (Chap. 34). On a long term basis the diet should be adjusted to provide a high calcium and a low phosphate intake.

William James Griffiths, Contemporary. Formerly Chemical Pathologist, St. Thomas's Hospital, London.

Magnesium

Magnesium is an intracellular cation which shares some of the properties of potassium and some of calcium. The normal magnesium concentration is 1·8 mEq. to 2·2 mEq. (0·7–0·9 mmol) per litre. The average daily intake is approximately 20 mEq. (10 mmol). Magnesium deficiency may occur when there is prolonged loss of gastrointestinal secretions due to fistulæ or ulcerative colitis, very prolonged administration of intravenous fluids without magnesium supplements, following massive small bowel resections, and in some cases of cirrhosis of the liver or disease of the parathyroids. The clinical picture of magnesium deficiency is marked by central nervous system irritability, E.C.G. changes, lowered blood pressure and lowered protein synthesis. The best method of diagnosing magnesium deficiency is the measurement of urinary magnesium after an intravenous loading dose. Normally 90% of the loading dose is promptly excreted in the urine.

Treatment.—In severe depletion 80 mEq (40 mmol) as magnesium sulphate can be given in 5% dextrose or normal saline over a 24-hour period. Magnesium supplements are essential in hyperalimentation.

PARENTERAL FLUID THERAPY

To overload the circulation is a grievous fault, and grievously does the patient pay for it

The administration of fluid by any route other than the alimentary canal, i.e. intravenous, intramuscular, subcutaneous, or into the bone marrow, is known as parenteral administration (fig. 79).

The sterility of a solution for parenteral use must be assured. Furthermore, the solution must be free from dead bacteria and other particulate matter, as also must the delivery tube.

Solutions mainly in use:—1. **Plasma** (p. 76).

2. **Dextrose 5 per cent.** is an isotonic solution that supplies calories without electrolytes. It is useful mainly in the very early post-operative period when sodium excretion is reduced (p. 85). It is also valuable when the salt requirements of a patient needing much fluid have been satisfied on a particular day. Prolonged administration of 5 per cent. dextrose solution is liable to result in hyponatræmia, and may cause thrombosis of the vein used.

3. **Isotonic (0·9 per cent.) saline solution** is needed in the following conditions: when a large amount of sodium has been lost by vomiting, or by gastric, duodenal, or intestinal aspiration or through an alimentary fistula. Possibly, on occasions, excessive sweating may justify its use.

These two solutions meet all the requirements in 95 per cent. of cases.

4. **Dextrose 4·3 per cent. with Saline 0·18 per cent.** (one fifth normal saline).—This solution is isotonic. Usually it is referred to as dextrose-saline.

It must not be confused with 5 per cent. Dextrose in normal saline which is hypertonic.

FIG. 79.—Various types of containers for intravenous fluids are now in use. Here a spring balance registers the quantity given.

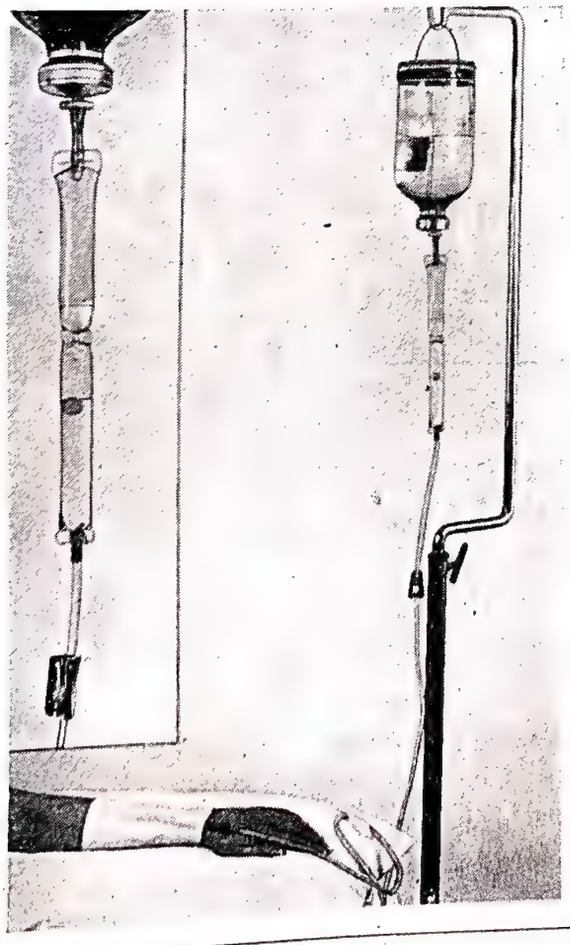
5. **Ringer's Lactate solution** contains sodium, potassium and chloride in almost the same concentrations as they are in the plasma. It also contains some calcium and some lactate. This solution can be used in hypovolæmic shock while awaiting blood. It is also suitable for replacing lost intestinal secretions.

6. **Darrow's solution** contains sufficient potassium to combat hypokalæmia and in surgical practice it is a safe and convenient method of supplying this cation provided alkalosis is not present (p. 95). The rate of infusion should not exceed 60 drops a minute.

COMPOSITION OF PLASMA AND INTRAVENOUS FLUIDS (mEq/l = mmol/l)

	Na	K.	Cl.	HCO_3	Lactate
Plasma	137–147	4–5·5	95–105	22–25	—
Isotonic[1] Saline	153	—	153	—	—
1/5 Isotonic Saline 4·3% Dextrose	30·6	—	30·6	—	—
Ringer Lactate	130	4	110	—	28
Darrow's	124	36	104	—	56

A Suggested Routine Post-operative Fluid Regime.—From the above information we know the average patient requires (1) 2,000/3,000 ml of water daily; (2) At least 100 mEq. (mmol) of Na daily; (3) about 60 mEq. (mmol) of K. daily. These requirements are altered by the metabolic response to trauma. In the first 24 hours after surgery there is an increased secretion of anti-diuretic hormone and aldosterone. The patient will require no salt and less water than normal in this 24-



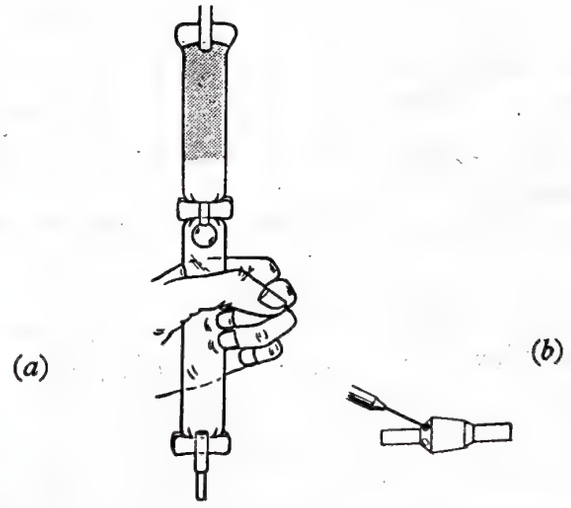


FIG. 80.—(*a*) An intravenous infusion using a plastic giving-set. Inset — Double drip chamber with plastic ball which prevents air embolus by dropping down and occluding the tubing should the bottle empty unnoticed. The infusion can be pressurised. (*b*) Supplementary injections may be given via the diaphragm of the connector close to the cannula.

[1] It is inadvisable to use the term 'normal' saline because chemically normal saline contains 5·85 g/100 ml.

Sydney Ringer, 1835–1910. Physician, University College Hospital, London.
Daniel Cady Darrow, 1895–1965. Professor of Pediatrics, Duke University School of Medicine, Durham, North Carolina, U.S.A.

hour period. Two litres of 5% dextrose is sufficient intravenous fluid when all abnormal operative loss has been replaced. During the second and subsequent 24-hour periods the metabolic response to trauma diminishes and the patient needs 2 litres of 5% dextrose and 1 litre of isotonic saline per 24 hours. On the 4th post-operative day and thereafter 20 mEq (mmol) of potassium is added to each litre to give a total of 60 mEq (mmol) per 24 hours.

An alternative regime is to give 3 litres of solution 4·3% dextrose 0·18% isotonic saline daily and add 20 mEq (mmol) of potassium chloride to each litre on the 4th post-operative day.

Continuous Intravenous Infusion (Venoclysis) (fig. 80).—Because of the certainty with which the fluid enters the circulation without the necessity of being absorbed, this is by far the most usual method of parenteral administration. If a suitable vein can be rendered prominent by the application of a light tourniquet, it can be entered by a hollow needle (venepuncture) (fig. 81). The limb is then immobilised by placing it on a light splint or, if a vein of the forearm is used, with a few strips of adhesive plaster. Frequently a length of silicone-treated P.V.C. catheter[1] is threaded through a wide-bore needle into a large vein.

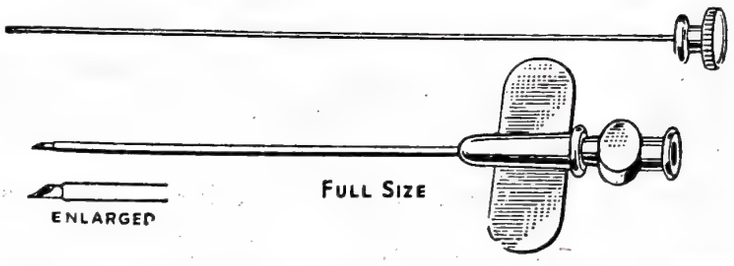

FIG. 81.—Intravenous Guest cannula. The modern tendency is to replace the metal cannula by a plastic one or a length of P.V.C. silicone-treated tube (e.g. ' Intracath ').

Site.—As a routine measure, a vein on the forearm, or on the back of the hand is chosen (fig. 82). In women, young children, and even some men, especially when the venous pressure is low, a visible or palpable vein may not be found in the arm; consequently another site must be used. The external jugular vein, or the cephalic vein in the deltopectoral groove, can be selected (Antia). Because of the risk of thrombo-phlebitis and pulmonary embolism, a vein of the leg (e.g. the long saphenous vein in front of the medial malleolus) should not be selected if it can reasonably be avoided. This injunction does not hold good for infants and small children, who are singularly immune to thrombo-phlebitis.

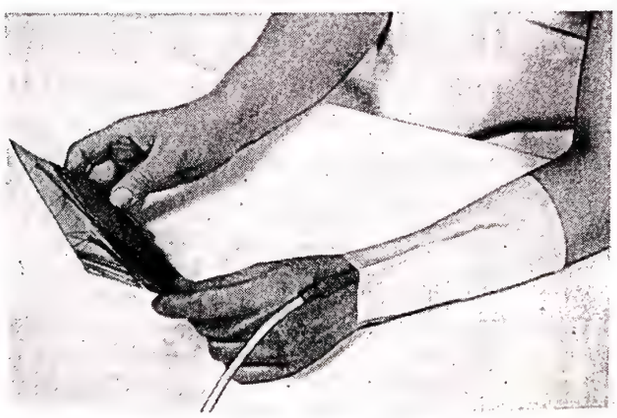

FIG. 82.— Hand or forearm veins are used to give the patient maximum mobility.

[1] The manufacturer's instructions concerning the insertion and fixation of a plastic catheter must be followed carefully, as fracture of the tube and disappearance of part of it up a vein has occurred. The catheter must never be withdrawn through the needle as it is likely to be stripped or cut by the sharp edge of the bevel. If difficulty is encountered, both needle and catheter should be withdrawn at the same time.

Noshir Hormasji Antia, Contemporary. Lecturer in Plastic Surgery, Grant Medical College, Bombay, India.

Contraindications to Intravenous Therapy.

1. *The Failing Heart.*—A history of dyspnœa on exertion, uncompensated valvular disease, or any possibility of myocardial insufficiency should call for hesitation in increasing the bulk of circulating fluid.

2. *Pulmonary Congestion.*—Where there are signs of œdema of the bases of the lungs the method should be absolutely forbidden.

Clinical Guide to Fluid Requirements.—When a patient is admitted in a dehydrated condition it is of course impossible to measure the loss of fluid and electrolytes he has sustained, but a detailed history of the nature and quantity of the fluid lost (usually, in surgical practice, by vomiting), and particularly the appearance of the patient (p. 93), are the means by which the amount of electrolytic solution he should receive is estimated. The hæmatocrit reading (p. 68) may be a help in this direction. In most instances the replacement is commenced by giving isotonic (0·9%) saline solution intravenously. When the bulk of the loss has been made up in this way, the *maintenance* of fluid balance is effected with dextrose-saline solution. In cases of extreme dehydration, where peripheral circulatory impairment (shock) is in evidence, it is necessary to commence by supplementing the volume of circulating fluid by dextran or plasma infusion (p. 76), and to follow this by substituting isotonic saline solution. When the fluid loss is considered to be rectified and fluid by mouth is contraindicated, it is again advisable to supply the maintenance fluid requirements in the form of dextrose-saline solution.

In infants with dehydration, the amount of fluid required will be approximately the same as the weight loss, i.e. the difference between the estimated and the actual weight. (1 g equals 1 ml.)

Rate of Flow.—Using a plastic transfusion set, 15 drops of fluid are approximately equal to 1 ml. At a rate of 30 drops per minute 1 litre will be given in eight hours, at 45 drops per minute it will take six hours, and at 60 drops some four hours. In severely dehydrated patients the rate of the first hour can be accelerated to well over 100 drops per minute, after which it should be cut to 50 or 60 drops. The maintenance dose rate is about 30 drops (3 litres in twenty-four hours).

The programme of rates to be used should be written down on the treatment card or fluid balance chart, and without further instructions the nursing staff should not exceed this rate.

Continuous rectal infusion (proctoclysis) was introduced by the celebrated J. B. Murphy, of Chicago, yet to-day it is seldom employed. The administration of fluid via the rectum has the advantage of simplicity. It requires but little apparatus, and neither asepsis nor isotonicity.

Avery Jones advises *dilute* saline solution for proctoclysis, *viz.* to 1 pint (568 ml.) of isotonic saline solution is added 4 pints (2·3 litres) of *tap water*. Dilute saline given per rectum avoids the absorption of an excessive quantity of water that may well result in hydræmia. Via a catheter in the rectum, the fluid is given by the drip method according to the needs of the patient. The rate of administration should not be greater than 50 drops a minute. It

John Benjamin Murphy, 1857–1916. Professor of Surgery, Northwestern University, Chicago, Illinois, U.S.A. Introduced Continuous Rectal Infusion in 1908.
Sir Francis Avery Jones, Contemporary. Physician, Central Middlesex Hospital, London.

Maintenance fluids — DNS

should be noted that there is no point in administering dextrose per rectum for its calorie value, because too little of it is absorbed.

Charting Fluid Intake and Output (figs. 83 and 84).—When fluid is administered intravenously, or by any alternative route, it is absolutely essential that the amount of fluid the patient receives should be recorded. It is equally

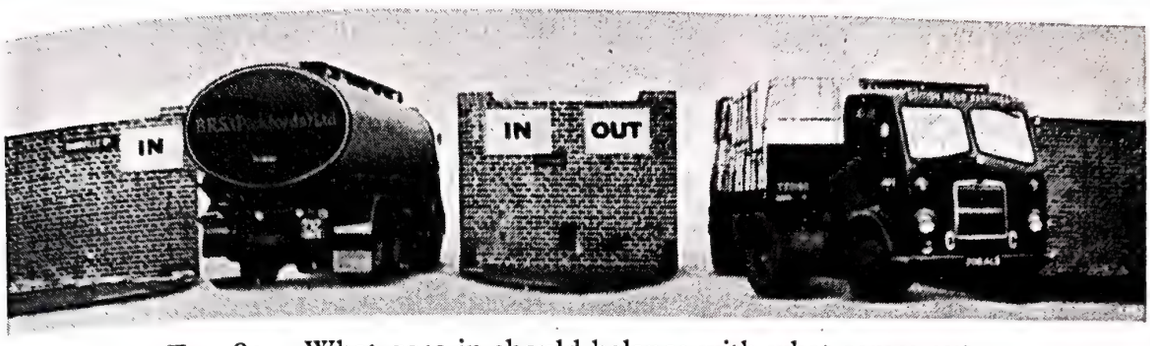

FIG. 83.—What goes in should balance with what comes out.

important that all urine passed during each twenty-four hours should be measured and recorded. To this figure is added fluid recovered by gastro-intestinal aspiration, and that lost from an intestinal, urinary, biliary, or pancreatic fistula plus 1,000 ml. for insensible loss from the lungs and skin. If the patient has been sweating, the last figure is increased.

FLUID BALANCE CHART

HOUR ENDING	ORAL		INTRAVENOUS		URINE	ASPIRATION OR VOMIT	OTHER
	AMOUNT	TYPE	PUT UP	GIVEN			
24 hour TOTALS							

FIG. 84.—Fluid balance chart. There is no column for insensible loss because the nurse is unable to measure this. Insensible loss is taken into consideration by the Medical Officer when he writes up orders for the ensuing twenty-four hours.

Other Aids to Maintaining Correct Fluid Balance.—In addition to the fluid balance chart, the following also are important:

1. **Clinical.**—Much information can be gleaned at the bedside.

If the fluid balance is correct, a warm, dry, pink, elastic skin denotes a good circulation and a satisfactory blood volume.

Circulatory overloading requires constant watchfulness, for the initial symptoms are nil and the signs non-proclamatory. A raised jugular venous pressure (fig. 85) indicates that the patient has received too much fluid, or too much salt.

2. **Blood Indices.**—Plasma electrolyte estimations, as well as those of the hæmoglobin, hæmatocrit and the plasma-proteins, are all helpful in ascertaining that the amount of fluid the patient is receiving is adequate, yet not excessive.

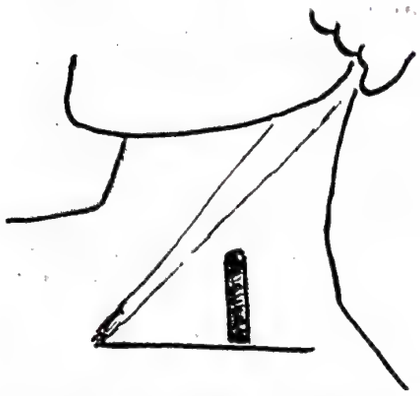

FIG. 85.—Fullness of the external jugular vein in a patient undergoing fluid therapy indicates that too much fluid has been given (see Central Venous Pressure, p. 69).

3. **Weight.**—Daily weighing is extremely useful in assessing that the amount of fluid given is correct. In patients subsisting entirely on parenteral fluid there should be a daily *loss* of weight of 150 g.

4. **Blood Volume Estimations** (p. 68).—These are valuable especially if a preoperative base line reading has been obtained in patients undergoing operations that are likely to lead to circulatory disturbances.

Vitamin Requirements.—Unless total intravenous therapy continues for more than a week, there is no need to supply fat-soluble vitamins, of which there is an adequate store in the body. The requirements of the vitamin B complex vary considerably, but more is required if there is any disturbance of dextrose metabolism. Antibiotics produce vitamin deficiency, notably of complex B. Therefore it is best to err on the side of safety and assume that a liberal amount of vitamins B will be required. Vitamin C should be given in large doses, to ensure saturation.

Twin ampoules of Parenterovite[1] are recommended daily. They should be mixed before being injected intramuscularly or via the intravenous drip.

Hypoproteinæmia.—Except in the presence of a profuse discharge from a duodenal or jejunal fistula, or extensive burns, hypoproteinæmia is most unlikely to develop within five days of total parenteral sustenance with crystalloid solutions. As a rule the patient has a lean and hungry look. Œdema is likely to develop, especially in the area of the wound, leading to delayed healing. Œdema of the pyloric mucous membrane, causing delay in gastric emptying, is frequently present in this condition. Œdema does not develop until the plasma albumin[2] is grossly depleted and the body reserves of mobile proteins are exhausted. Once present, hypoproteinæmia takes a long time to remedy, even when the patient can take nourishment by mouth. Milk fortified with powdered skimmed milk is an excellent source of protein, see Surgical nutrition (p. 98).

ACID-BASE BALANCE

In health the reaction of the blood lies within the range pH 7·36 to 7·44. The terms acidosis and alkalosis in clinical practice indicate a change or a tendency to a change in the pH of the blood in a particular direction. In acidosis there is an accumulation of acid or a loss of base causing a fall or a tendency to a fall in the pH. The converse occurs in alkalosis. The pH of the blood is regulated and controlled by various buffering systems essentially consisting of weak acids and bases, of which the most important is the

[1] Contains large doses of vitamin B complex and ascorbic acid (Vitamins Ltd.).
[2] Normal value 3·6 to 4·5 g per 100 ml.

bicarbonate-carbonic acid ratio $\left[\frac{HCO_3}{H_2CO_3}\right]$. It is also regulated by the removal of CO_2 by the lungs and by the excretion of both acids and bases by the kidneys.

The ratio of bicarbonate to carbonic acid is normally 20:1. Alteration in this ratio alters the pH regardless of the absolute values of the bicarbonate and carbonic acid. A decrease in the ratio leads to increased acidity, and vice versa.

The bicarbonate level can be altered by metabolic factors, while the carbonic acid level is subject to alteration by respiratory factors. Alteration of one is followed automatically by a compensatory alteration in the other so that the ratio (HCO_3:H_2CO_3) and therefore the pH of the blood remains constant.

Measurement of Acid-base Disturbances.—The Astrup apparatus (fig. 86), and similar equipment has facilitated the measurement of acid-base disturbances in routine clinical practice. This equipment with the aid of nomograms allows rapid calculations of the blood pH, PCO_2, PO_2, standard bicarbonate and base excess or deficit. These measurements are 'normally made on arterial or arterialised capillary' blood. PCO_2 is a measurement of the tension or partial pressure of carbon dioxide in the blood. The normal arterial PCO_2 is 31–42 mmHg (4·1–5·6 kPa). PO_2 is a measurement of the tension or partial pressure of oxygen in the blood. The normal arterial PO_2 is 80–110 mmHg (10·5–14·5 kPa).

Standard bicarbonate is the concentration of the plasma bicarbonate after *fully oxygenated* blood has been equilibrated with CO_2 at 40 mmHg. (5·3 kPa) at 38°C. This eliminates respiratory causes and respiratory compensation for altered bicarbonate levels. Normal 22–25 mEq/l (mmol/l).

Base excess or deficit expresses in mEq. (mmol) the total of buffer anions present in the blood in excess or deficit of normal. (Normal base excess or deficit + 2·5). Base excess or deficit multiplied by 0·3 times the body weight in kg. gives the total extracellular excess or deficit of base in mEq. (mmol) (Mellemgaard and Astrup). Metabolic causes of acid base disturbances are indicated by changes in the standard bicarbonate level and base excess or deficit. Respiratory causes of acid base disturbances are indicated by changes in the PCO_2 and PO_2.

ALKALOSIS

Metabolic alkalosis (a condition of base excess or a deficit of any acid other than H_2CO_3) can be caused by:

(*a*) Excessive ingestion of absorbable alkali. Such is not uncommon in patients who take proprietary indigestion remedies without medical supervision.

(*b*) Loss of acid from the stomach by repeated vomiting or aspiration.

(*c*) Cortisone excess, usually the result of over-administration of adrenal corticoids, but occasionally due to Cushing's syndrome (Chap. 34).

Compensation is effected by (i) retention of carbon dioxide by the lungs and (ii) excretion of bicarbonate base by the kidneys (alkaline urine).

Alkalosis due to loss of acid from the stomach is by far the most common and most important. In its most typical form it is seen in patients with pyloric stenosis in whom the loss of acid by repeated vomiting is often accentuated by the taking of medicines containing sodium bicarbonate. The most striking feature of severe alkalosis is Cheyne-Stokes' respiration with periods of apnœa lasting from five to thirty seconds. Tetany sometimes occurs. Latent tetany (in which the serum calcium remains just above the low value necessary for tetanic muscular contractions) is more common, and

K. Mellemgaard, Contemporary. Physician, Rigshospitalet, Copenhagen.

John Cheyne, 1777–1836. Physician, Meath Hospital, Dublin (1811–1831). First Professor of Medicine, Royal College of Surgeons in Ireland (1813–1828), and Physician General to the Forces in Ireland (1820–1831). Described this type of Periodic Respiration in 1818.
William Stokes, 1804–1878. Physician, Meath Hospital, Dublin (1826–1875), and Regius Professor of Medicine, Dublin (1845–1878). In an account of Periodic Breathing in 1846, he acknowledged Cheyne's observation.

can be unveiled by Trousseau's sign (Chap. 34). Regarding other signs, the dual phenomenon of severe alkalosis and hypokalæmia (p. 87) are so interwoven that their clinical separation is well-nigh impossible. Subclinical degrees of alkalosis are recognisable only by a raised standard bicarbonate concentration and a positive base excess. Severe alkalosis may result in renal epithelial damage, and consequent renal insufficiency.

Treatment.—Metabolic alkalosis without hypokalæmia seldom requires direct treatment. The cause of the alkalosis should be removed where possible and a high urinary output encouraged.

Hypokalæmic Alkalosis is seen in patients who have lost potassium and acid due to repeated vomiting from pyloric stenosis. The low serum potassium causes potassium to leave the cell and be replaced by Na^+ and H^+ ion. The shift of H^+ ion into the cell causes intracellular acidosis and increases the extracellular alkalosis. The kidneys continue to excrete K^+ and an acid urine due to intracellular acidosis of the kidney cells themselves.

Treatment.—An ampoule of 20 mEq. (mmol) of potassium chloride is added to 500 ml. 5% dextrose solution and given intravenously.

Respiratory alkalosis a condition where the CO_2 tension in the arterial blood (PCO_2) is below the normal range of 31–42 mmHg (4·1–5·6 kPa), is caused most commonly in surgical practice by excessive pulmonary ventilation carried out upon an anæsthetised patient who has been given a muscle relaxant. Other causes are hyperventilation occasioned by high altitudes hyperpyrexia, a lesion of the hypothalamus, and hysteria. Compensation, which depends on increased renal excretion of bicarbonate, usually is inadequate. During anæsthesia alkalosis is accompanied by pallor and a fall of blood-pressure. In severe cases respiratory arrest follows.

Treatment.—Respiratory arrest due to alkalosis is rectified by insufflation of carbon dioxide.

ACIDOSIS

Metabolic acidosis (a condition where there is a deficit of base or an excess of any acid other than H_2CO_3) occurs as a result of:

(*a*) *Loss of bases* such as occurs in sustained diarrhœa, ulcerative colitis, gastrocolic fistula, a high intestinal fistula, or prolonged *intestinal* aspiration.

(*b*) *Increase in fixed acids* due to the formation of ketone bodies as in diabetes or starvation, the retention of metabolites in renal insufficiency, and the rapid increase of lactic and pyruvic acids due to anaerobic tissue metabolism which follows cardiac arrest (Chap. 39), or the release of the clamped aorta in the surgery of abdominal aneurysm (p. 138). Acute acidosis with pH levels of 7·1 are frequently encountered in such cases.

Clinical Features.—In severe acidosis the leading sign is rapid, deep, noisy respirations which are unremittent save, perhaps, momentarily while the patient endeavours unsuccessfully to moisten his dry lips with his parched tongue. The hyperpnœa is due to over-stimulation of the respiratory centre by the reduction of pH of the blood, and the physiological purpose of overbreathing is to eliminate as much as possible of the acid substance H_2CO_3. Except in renal acidosis, the pulse-rate and the blood-pressure are raised. The urine is strongly acid. The standard bicarbonate level is lowered and there is a base deficit (p. 95 acid-base measurements).

Treatment.—Cases belonging to class (*a*) are readily rectified by the administration of Ringer's lactate solution or slow infusion of dilute sodium bicarbonate solution. When dehydration is in evidence the prelude to treatment with sodium bicarbonate solution should be rapid infusion of sufficient isotonic saline solution to restore the extracellular fluid volume. The treatment of acidosis due to renal failure is discussed in Chap. 53.

The acute acidosis after releasing a cross-clamped aorta or in cardiac arrest requires the infusion of 50–150 mEq (mmol) of 8·4 per cent. sodium bicarbonate solution (see base excess, p. 95).

Acidosis due to transplantation of the ureters into the colon is discussed in Chap. 54.

Respiratory Acidosis (a condition where the PCO_2 is above the normal range) is caused by impaired alveolar ventilation.

In practice this problem most commonly occurs when there is inadequate ventilation of the anæsthetised patient, or when the effects of muscle relaxants have not worn off or been fully reversed at the end of the anæsthetic. There is also a risk of respiratory acidosis when the patient undergoing surgery already has pre-existing pulmonary disease, (e.g. chronic bronchitis or emphysema), and this is accentuated by thoracic and upper abdominal incisions.

MEASUREMENT OF ACID-BASE DISTURBANCES (BEDSIDE BIOCHEMISTRY)

In addition to the older and better known methods of assessing the metabolic balance of the patient (such as the standard bicarbonate), it is important to know the respiratory balance of a patient. This increasing need for complex 'bedside biochemistry' (C. F. W. Illingworth) is met with to some extent by direct estimations of the pH, PCO_2 and PO_2 of arterial blood, though in most situations the pH and POC_2 can be measured using capillary blood. The Astrup apparatus (Radiometer) (fig. 86), is commonly used for such estimations in the surgical laboratory.

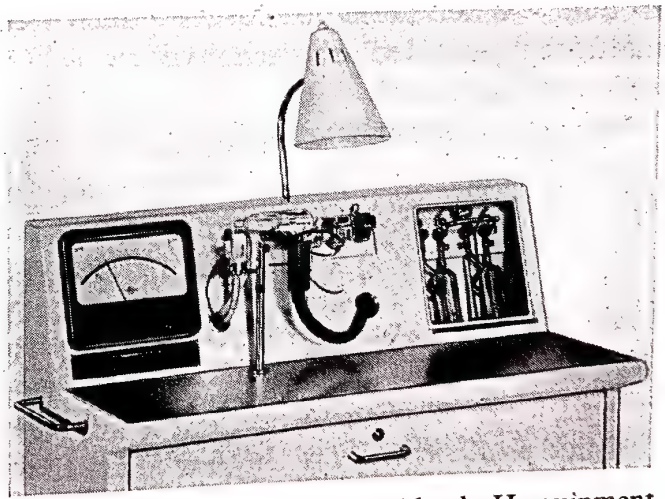

FIG. 86.—The micro-Astrup blood pH equipment consists of a pH meter calibrated from pH 6·8 to 8·2 In the centre is the micro-electrode unit which includes glass and calomel electrodes and the microtonometer which equilibrates heparinised blood samples with two CO_2 and O_2 mixtures of known carbon dioxide tensions. Both the electrode unit and tonometer are enclosed in a water jacket thermostatically controlled at 38°C. To the right of the instrument is found the humidifier assembly where the two gas mixtures are bubbled through water at 38°C. The cabinet underneath contains the cylinders of CO_2–O_2 mixtures.

Examples of acid-base disturbances

1. pH 7·30, P_{CO_2} 60 mmHg (8kPa), Base excess + 1. This is uncompensated respiratory acidosis.

2. pH 7·21, P_{CO_2} 40 mmHg (5·3 kPa), Base excess — 10.

Sir Charles Frederic William Illingworth, Contemporary. Emeritus Regius Professor of Surgery, Glasgow, Scotland.

This is a severe metabolic acidosis. A 70 kg. man with this acid-base picture would require 70 × 0·3 × 10 mEq. (mmol) of bicarbonate (see base excess, p. 87).

3. pH 7·29, Pco_2 60 mmHg (8 kPa), Base excess + 5. This is a respiratory acidosis with a compensatory metabolic alkalosis.

4. pH 7·20, Pco_2 64 mmHg (8·5kPa), Base excess − 8. This is a mixed respiratory and metabolic acidosis.

SURGICAL NUTRITION

Nutritional requirements vary with the size and muscular activity of an individual. A healthy adult at rest requires nitrogen in the form of protein or amino acid and about 2,000 Calories per day. Calories can be provided by carbohydrate, protein or fat but protein is essential for normal tissue turnover.

Nitrogen requirements.—The minimum protein intake necessary to keep a healthy adult in positive nitrogen balance is about 35–40 g of protein or 5·5–6·5 g of nitrogen per day. The hypercatabolic patient requiring hyperalimentation may need three or four times this amount of protein. A daily negative nitrogen balance of 10 g N is not unusual and is equivalent to a loss of 62·5 g of protein or 300 g of muscle tissue. Urinary nitrogen is easily measured and can be used as a guide to the patient's nitrogen requirements, provided he does not have a fistula.

Calories are best provided by carbohydrate, fat and a limited amount of alcohol. The number of Calories given should bear a definite relationship to the nitrogen intake. A Calorie nitrogen ratio of 200:1 is usually adequate but a higher ratio is sometimes necessary. A Calorie nitrogen ratio of 200:1 is another way of saying 12·5% of the total Calories should be derived from protein. When fat is used as a source of Calories, 30% of the total Calories should be provided by carbohydrate. 'Carbohydrate provides the fire in which fat is burnt.'

Nutritional Effects of Trauma.—Trauma, including surgical trauma is accompanied by a period of increased protein catabolism of varying duration and severity. The catabolic phase in cases of mild trauma is mainly due to starvation, but in major trauma and trauma complicated by fistulæ and severe sepsis the stimulus to protein breakdown is greatly increased. Loss of fat also occurs.

Artificial methods of feeding are unnecessary in the immediate postoperative period and when the patient is able to take food by mouth, but they are justified and necessary in those who are likely to experience prolonged periods of negative nitrogen balance.

Intravenous alimentation like all other methods of feeding, must provide protein and Calories in correct proportions. Protein is provided as amino acids. This is best given as casein hydrolysate (Aminosol) or as a mixture of synthetic lævorotatory amino acids (Vamin or Aminoplex). Intravenous fat has a high Calorie content and is given as a 10–20% emulsion. Intralipid is an emulsion prepared from soya bean oil; it is relatively inactive osmotically and has a low degree of acute and chronic toxicity when not more than 3 g of fat per kg body weight is given in 24 hours (Clark). Fat

Charles Grant Clark, Contemporary. Professor of Surgery, University College Hospital, London.

emulsions are contraindicated in pregnancy and liver disease. Carbohydrates such as dextrose and fructose which provide 4 kCal/g (16·8 MJ/g) are also used for intravenous feeding.

High concentrations cause thrombosis in the veins used for infusion. Ethyl alcohol (Ethanol), yielding 7 kCal/g (29·4 MJ/g) is a valuable source of Calories and the total dosage depends on the central effects of alcohol and on the state of the liver.

SOLUTIONS FOR I.V. FEEDING

	Calories per litre	N.g.	Na. (mEq or mmol/litre)	K. (mEq or mmol/litre)
10% Dextrose	400	—	—	—
Aminosol Ethanol fructose	880	4·25	54	0·15
Aminosol 10%	330	12·5	160	0·15
Vamin 7%	650	9·4	50	20·00
Aminoplex 14	340	13·0	35	30·00
Intralipid 20%	2,000	—	—	—

By selecting a combination of the above preparations 2,000–4,000 Calories (8·4–16·8 MJ) in 2,000–4,000 ml of fluid can be given daily. The amino acid content should be based on the nitrogen output and should account for about 12·5% of the total Calories. For maximum utilisation of amino acids it is best to give the amino acids and Calories (fats) simultaneously using two drips with a Y connection (Lawson). It may be necessary to add sodium, potassium, magnesium and vitamin supplements to the above solutions to meet the normal daily electrolyte requirements. For prolonged i.v. feeding, trace elements can be provided by giving an occasional unit of plasma or blood.

Elemental or 'space' diets[1] are a mixture of essential elemental nutrients containing amino acids, simple sugars and fat in the triglyceride form. Other essential electrolytes, vitamins, and trace elements are also included. The elemental diet arrives as a powder and is made into a solution by adding water. The liquid diet is absorbed from the upper gastrointestinal tract without stimulating biliary, pancreatic or intestinal secretions. This diet leaves little or no residue. Elemental diets are suitable for patients with intestinal fistula, inflammatory bowel disease, maldigestion or malabsorption states such as chronic pancreatitis or short bowel syndrome. Elemental diets have been used in pre-operative bowel preparation. Nausea, vomiting and diarrhœa may occur due to hyperosmolarity.

Tube feeding can be used as a means of providing a maintenance diet for an unconscious patient, or a paralysed patient on a ventilator, or as a means of providing extra Calories in a patient with severe infection or burns. Tube feeding is established by passing a nasogastric tube into the stomach. Water, electrolytes, Calories and vitamins are given through the tube and there is no need to continue with intravenous fluids. When the diet requirements of the

[1] As designed for use on flights into outer space.

Lincoln James Lawson, Contemporary. Surgeon, North Staffordshire Royal Infirmary, Stoke-on-Trent, England.

patient have been calculated with regard to volume, Calories and protein content, it is given in divided doses at two-hourly intervals over the 24 hours.

It may also be given by a constant infusion pump. The stomach should be aspirated intermittently to check for gastric stasis. Diarrhœa is a complication of tube feeding which can be eliminated by maintaining the osmolarity of the feed at approximately 300 mmol/l (Masterton). Electrolytes and carbohydrates have the greatest influence on osmolarity. Elemental diets may be used for tube feeding if the hospital cannot prepare its own tube-feeding diet.

John Potter Masterton, Contemporary. Associate Professor of Surgery, Monash University, Melbourne, Australia.

CHAPTER 7

SKIN. BURNS. SKIN GRAFTING

CALLOSITIES, CORNS, AND WARTS

A **callosity**[1] (*French : callosité*) is a localised thickened or hardened part of skin caused by friction. It is commonly occupational, e.g. on a gardener's hand or the finger of a violinist.

A **corn** (*Old French : corn = grain*) is a horny induration of the cuticle with a hard centre, caused by undue pressure, chiefly affecting toes and feet. Most corns yield to the chiropodist, provided that footwear is suitable. Skilled treatment is important in patients with diabetes or a poor peripheral circulation, as secondary infection may precipitate gangrene Salicylic acid in collodion (20 per cent) applied for a few nights, followed by soaking in hot water, is often effective in removing a corn.

A **wart** (*Old English : wearte*) is a dry rough excrescence on the skin. *The common wart* usually occurs on the hands, particularly in children. It is due to a virus and is infectious. As warts often disappear spontaneously, any treatment which is in use at the time will gain an undeserved reputation as a wart 'cure'. Curetting and cauterisation of the centre is the radical treatment, but further crops may appear.

Plantar warts occur in the sole, and are usually multiple. They may be so tender as to render standing or walking exceedingly uncomfortable. *Treatment.*—The nightly application of formaldehyde lotion for six to eight weeks is effective in 60 per cent. of cases. Curettage is more certain. Under a local or general anæsthetic, a scalpel, held vertically to the skin, incises the hard skin at the boundary of the lesion. A sharp curette can be inserted beneath the wart to remove it.

The footwear must be treated if re-infection by the virus is to be avoided. Cotton socks should be worn, as these can be boiled. Shoes can be disinfected by formalin vapour.

Seborrhœic (*syn.* '*Senile*') warts, see p. 105.

Venereal warts and moist warts (papillomata acuminata), see Chapter 57.

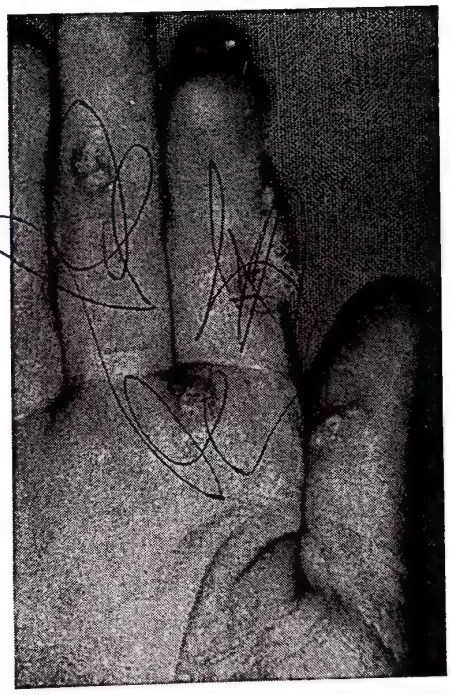

FIG. 87.—Warts on the hand.

INFECTIONS

Impetigo is an intradermal infection. When caused by the streptococcus the primary lesion is bullous, which soon ruptures to form an erosion and then a crust. In the staphylococcal type, the primary lesion is also bullous, but the bullæ are more durable (e.g. in neonatal pemphigus). The infection is contagious, and in rugby football one player so infected can spread the disease amongst his team mates and the opposing side (the condition being known as 'scrum-pox'). *Treatment* includes the careful washing of the face to remove crusts, using hexachlorophene soap and lotion (1 per cent.). Systemic antibiotics, according to the sensitivity tests, are only used in those cases which are resistant to local treatment.

---

[1] Other definitions of names of skin lesions in common usage include:
Nævus (*Latin : Nævus*) = A birth mark, but often used to mean simply a mark or blemish on the skin (see Hæmangioma and Melanoma).
Mole (*Anglo-Saxon : Mâl = a lump*) = A spot or blemish on the skin, sometimes hairy.
Mollusc (*Latin : Molluscus = soft*) = A soft protuberance on the skin.

Boil (*syn.* Furuncle).—A boil is an acute staphylococcal infection of a hair follicle, with perifolliculitis, which usually proceeds to suppuration and central necrosis. A painful and indurated swelling appears which gradually extends. After two or three days, the centre softens and a small slough is discharged with a bead of pus, and in the large majority of cases the condition then subsides. A 'blind boil' is one which subsides without suppuration. Boils are common on the back of the neck.

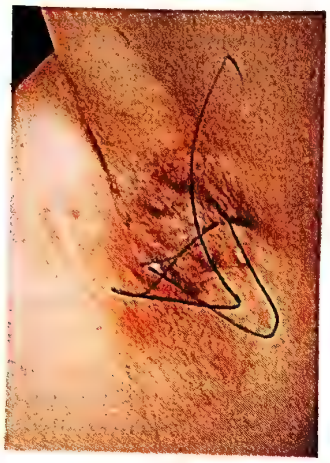

FIG. 88.—Hydradenitis-infection of axillary sweat glands and hair follicles (see also hyperhidrosis (Chap. 26).

Infection of the perianal hair follicle (perianal abscess), with suppuration, is likely to result in a sinus. Furunculosis of the external auditory meatus is extremely painful, as the skin is attached to the underlying cartilage, and swelling is accompanied by considerable tension.

Complications of Boils.—(i) Cellulitis, especially in debilitated subjects. (ii) Infection of the lymph nodes draining the affected part. (iii) Secondary boils due to infection of neighbouring hair follicles (e.g. in hydradenitis fig. 88).

Stye (*syn.* hordeolum).—A *stye* is due to infection of an eyelash follicle.

Treatment consists of improving the general health of the patient, since boils are frequently associated with overwork, worry, debility, examinations, or other undermining influences. Incision is unnecessary, as a touch of iodine or liquid phenol on a skin pustule will hasten necrosis of the overlying skin so that pus can then escape. Should softening occur around a hair follicle, particularly an eyelash (stye), removal of the appropriate hair allows the ready escape of pus. The sensitivity of the organisms is determined and the appropriate antibiotic may be given. Washing the surrounding skin twice a day with suitable disinfectant, e.g. hexachlorophene, discourages the development of secondary boils. A paste, composed of anhydrous magnesium sulphate (24 parts) and glycerin (11 parts) exercises a valuable osmotic effect.

FIG. 89.—Carbuncle of the neck. (*Herbert Bourns, F.R.C.S., Bristol.*)

Carbuncle.—This is an infective gangrene of the subcutaneous tissues, due to staphylococcal infection. It is uncommon before the age of forty, and males are the usual sufferers. *Diabetes* may be present.

A carbuncle often occurs in the nape of the neck, where the skin is coarse and ill-nourished. The patient complains of tenderness and stiffness at the site of origin of the carbuncle. The subcutaneous tissues become painful and

Carbunculus in Latin, Anthrax in Greek, is the word for charcoal. The ancients saw in these conditions burning sores upon the skin—hence they likened them to glowing coal.

indurated, and the overlying skin is red (fig. 89). Unless the condition is aborted by prompt treatment, extension will occur, and after a few days areas of softening appear. The skin then gives way and thick pus and sloughs discharge. Usually there is one central large slough, surrounded by a 'rosette' of smaller areas of necrosis. Infection sometimes extends widely, and fresh openings appear on the surface and coalesce with those previously formed.

A carbuncle on the cheek or upper lip is particularly dangerous, owing to the risk of cavernous sinus thrombosis (Chap. 28).

Treatment.—The general treatment and organism identification is similar to that described for boils. However, many carbuncles are aborted if penicillin is used adequately in the early stages. Local treatment by osmotic pastes is often supplemented by infra-red or short-wave diathermy.

Cellulitis and **Erysipelas** (pp. 22 and 29).

Lupus vulgaris (tuberculosis of the skin) usually occurs between the ages of ten and twenty-five, the face being the site of election. One or more cutaneous nodules appear, with congestion of the surrounding skin. On applying pressure with a glass slide the nodules are seen to be the colour of apple jelly. Extension occurs very slowly, but ulceration is likely to follow sooner or later. The resulting ulcer tends to heal in one situation as it extends to another. The mucous membranes of the mouth and nose are sometimes attacked, either primarily or by extension from the face. Œdema occurs if the fibrosis caused by the lupus obstructs the normal lymphatic drainage. Infection in the nasal cavity may be followed by necrosis of underlying cartilage. Epithelioma is prone to occur in a lupus scar (fig. 90).

Treatment is by chemotherapy (p. 15). If healing is slow, the lesion should be excised.

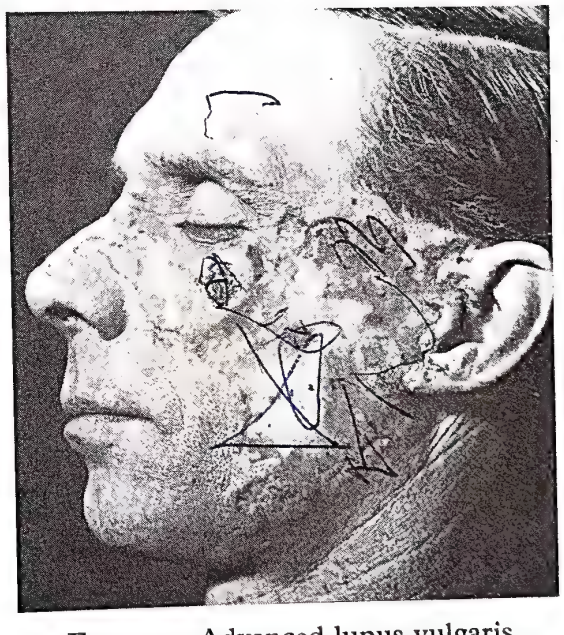

FIG. 90.—Advanced lupus vulgaris. Carcinoma has developed on the cheek.

CYSTS

A sebaceous cyst (*syn.* a wen) follows obstruction to the mouth of a sebaceous duct, and is therefore a retention cyst. Pathologically, it is classed as an epidermoid cyst (p. 46). It commonly occurs on the face or scalp (Chap. 24), but can occur anywhere except on the palms and soles, which are devoid of sebaceous glands.

A typical cyst appears as a hemispherical swelling, firm or elastic in consistency, and with no definite edge. It is more or less adherent to the skin, especially if it has been previously inflamed or is subjected to pressure. The punctum of the obstructed duct can sometimes be seen on the summit of the cyst, and sebaceous material may be expressed from the duct. An uncomplicated cyst contains yellowish-white material composed of fat and epithelial

Sir Astley Paston Cooper, 1768–1841. Surgeon, Guy's Hospital, London (1800–1825). In 1821 he received a Baronetcy and one thousand guineas for successfully removing an infected sebaceous cyst from the head of King George IV.

cells, of a putty-like consistency, so it can often be indented by a finger-tip. Rarely, a minute worm, *Demodex folliculorum*, which is harboured in sebaceous glands, may be seen on microscopy of the cyst wall.

Complications.—(i) *Infection.*—The cyst becomes enlarged and painful, and the overlying skin is red. Recurrent attacks cause the cyst wall to become adherent to surrounding subcutaneous tissue, and consequently more difficult to remove. The contents of an infected cyst become semi-liquid and usually very fœtid.

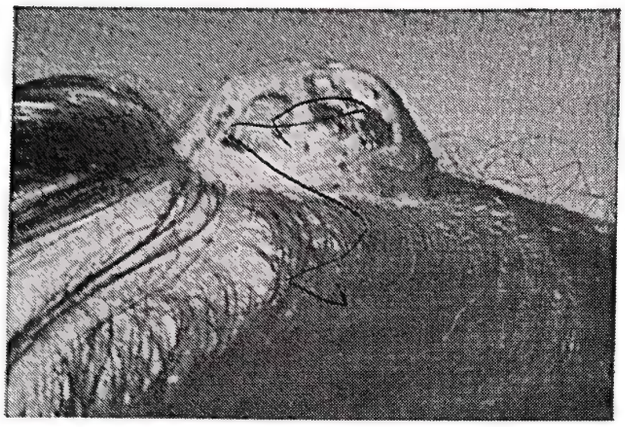

FIG. 91.—Cock's 'peculiar tumour' of the scalp.

(ii) *Ulceration.*—An infected cyst may discharge its contents. An ulcerated surface remains, which resembles an epithelioma, and to which the term Cock's 'peculiar tumour' is applied (fig. 91).

(iii) *Sebaceous Horn.*—The contents of a cyst sometimes escape slowly from the duct orifice and dry in successive layers on the skin, forming a sebaceous horn (see frontispiece).

Treatment.—(*a*) Incision–Avulsion.—Under local anæsthesia an incision is made through the skin, into the cyst. The contents are squeezed out and the cyst wall is seized with artery forceps and carefully avulsed.

(*b*) Dissection is necessary for cysts which have been previously inflamed. An incision is made over the cyst, the wall is defined, and the cyst is dissected from adjacent tissue and removed intact. Unless the wall is completely removed recurrence is probable.

Sequestration and **Implantation Dermoid Cysts** are described on p. 46.

PAPILLOMAS AND MISCELLANEOUS SKIN LESIONS

Papilloma

A papilloma of the skin may be derived from either the squamous or the basal cell layers. The *squamous cell papillomas* include the following types:

(1) *Congenital* (*syn. Nævus Verrucosus*), which may be single or multiple, and it appears either at birth or in early life. It is a warty growth of brownish colour, but large horny excrescences may be present. (2) *Infective Wart* (*verruca vulgaris*)—the common wart—described on p. 101. (3) *Soft Papilloma*, which often occurs on the eyelids of elderly people (fig. 92). (4) *Keratin Horn* (fig. 93).—This is also seen in old people and is a papilloma with excess keratin formation.

FIG. 92.—Soft papilloma.

Edward Cock, 1805–1892. Surgeon, Guy's Hospital, London.

Basal Cell (Seborrhœic, or Senile, Wart).—Often develops in large numbers on the trunk, face, and arms of persons in or past middle life. Circular, slightly raised, warty, often brownish, they look as if they are stuck on the skin (fig. 94).

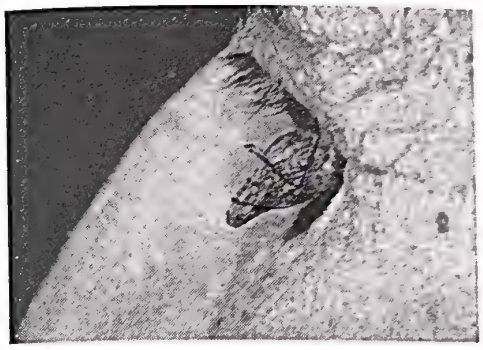

FIG. 93.—Keratin horn beside the eye.

FIG. 94.—Basal cell seborrhœic wart.

Molluscum Fibrosum.—Soft fleshy skin tags which may be polypoid or filiform and which may occur in large numbers on the neck, trunk, and face in persons past middle age.

Molluscum Sebaceum (*syn.* Keratoacanthoma).—Commonly occurs on the face or hand during the fifth and sixth decades. It presents as a firm hemispherical nodule, which may reach a size of up to 2 cm. in diameter in six weeks (fig. 95). The summit of the tumour ulcerates and forms a crust beneath which is a crater. After a time, the crust is shed and spontaneous healing occurs. This may leave a scar. The tumour may be curetted and a caustic (e.g. carbolic or silver nitrate) applied to the crater. A quicker cure is obtained by excision, which permits adequate microscopy. Undoubtedly in the past many cases were regarded as epitheliomas and helped to swell the number of 'cures' for this condition.

FIG. 95.—Molluscum sebaceum.

Sclerosing Angioma (*syn.* Dermatofibroma; Subepidermal Nodular Fibrosis).—This occurs in skin as firm, indolent, single, or multiple nodules. The nodules, in adults, are situated most commonly on the extremities. As a rule they are only a few millimetres in diameter. Most are reddish, others are yellowish-brown (due to lipid) or blue-black (due to hæmosiderin). The latter may resemble melanoma. *Dermatofibroma protuberans* grows persistently outwards to attain considerable size (fig. 96). It may be a low-grade fibrosarcoma.

Granuloma Pyogenicum (fig. 97).—This is a traditional but misleading name. The lesion looks like a hæmangioma but has a typical natural history. Usually single, it consists of a dull red, soft or moderately firm, more or less pedunculated nodule which grows rapidly to a size varying from 0·5 to 2 cm. in diameter. The surface shows atrophic epidermis, but often has crusts. It may occur anywhere on the skin,

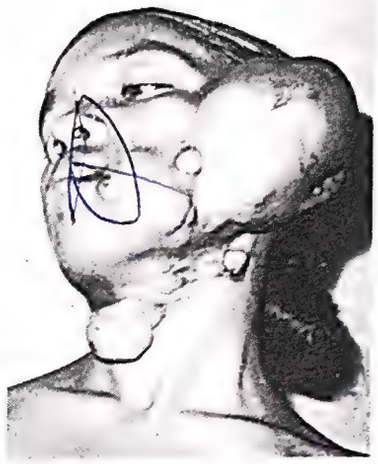

FIG. 96.—Dermatofibroma protuberans.
(R. Naik M.S. Durg. India.)

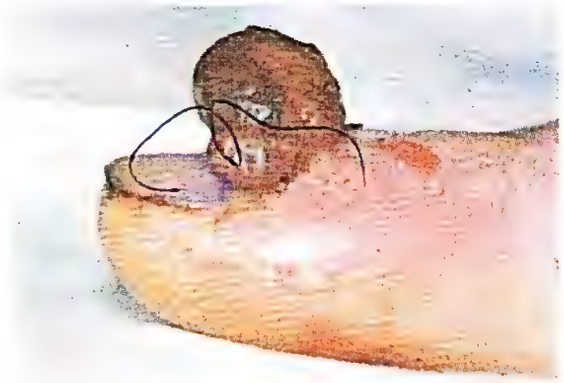

FIG. 97.—Granuloma pyogenicum.

but most commonly it is seen on the face, the fingers and toes. Treatment is excision.

Benign Calcifying Epithelioma.—These are solitary, hard, tumours that appear to be growing from the deep surface of the skin. They occur most frequently on the face and upper extremities. The size usually varies between 0·5 to 3 cm. in diameter. The tumour may arise at any age but is common in childhood. Clinically it resembles a rather hard sebaceous cyst.

Tumours of Accessory Skin Structures.—These are rare. (1) *Sebaceous nævus:* A congenital condition presenting as a pinkish-yellow plaque in the scalp. (2) *Sebaceous adenoma:* Isolated lesions are very rare. Multiple sebaceous adenomata occur in association with epilepsy and mental deterioration. (3) *Tumours of sweat glands:* Are closely related to the basal cell carcinomata but present deep to the skin and are often cystic (Papilliferous cystadenoma).

FIG. 98.—Rhinophyma.

Sarcoid (Boecks) (p. 187).—This is a generalised disease which may affect skin. In the skin it occurs as reddish-brown nodules which are soft, and rarely ulcerate. Giant cells are found, but tubercle bacilli can never be isolated.

Rhinophyma (*syn.* Potato nose) (fig. 98).—This is a glandular form of Acne Rosacea. The skin of the nose, particularly the distal part, becomes immensely thickened and the openings of the sebaceous follicles are easily seen. The capillaries become dilated and the nose assumes a bluish-red colour. Surgical treatment, by paring away the excess tissue, gives a great improvement.

HÆMANGIOMA

A hæmangioma is a developmental malformation of blood-vessels rather than a true tumour, and is therefore an example of a hamartoma (p. 53). It may occur in any tissue of the body, but is most common in the skin and subcutaneous tissues. A hæmangioma is either capillary, venous (cavernous), or arterial in type.

Capillary Hæmangioma

(1) **Salmon Patch.**[1]—This is present at birth over the forehead in the midline, and over the occiput. It disappears by the age of one year.

[1] Also called 'stork bites'! Not to be confused with the patch in syphilis.

(2) **Port Wine Stain** (Nævus flammeus) (fig. 99).—Present at birth, it changes very little throughout life, although the colour may alter a little and it may become nodular in some areas. *Treatment* is for reason of appearance. The texture of the skin is quite normal and in a girl the blemish can be disguised by the skilful use of cosmetics. In a boy, treatment by excision and grafting may be considered. Radiation and other destructive treatment is disappointing.

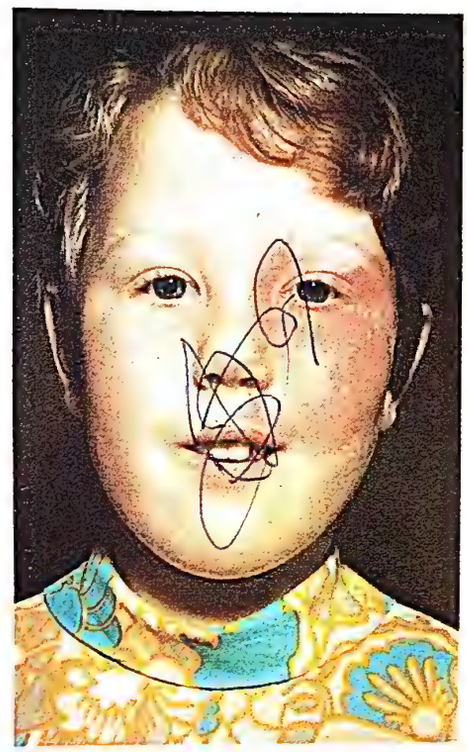

FIG 99.—Port wine stain.

(3) **Strawberry Angioma** (fig. 100).—This common condition has a typical history. The baby is normal at birth and at the age of one to three weeks is noted to have a red mark. This increases rapidly for some weeks or even up to three months, until the typical strawberry or raspberry-like swelling is present. Clinically, the sign of emptying may be demonstrable. The lesion is composed of immature vaso-formative tissue. The subcutaneous tissue as well as the skin is often involved, and in severe cases the muscles may be affected. Sub-mucous nævi are prone to hæmorrhage, which is sometimes alarming.

From the age of three months to one year the nævus grows with the child. Then it ceases to grow. Eventually the colour fades and flattening occurs so that at the age of seven or eight years involution is complete. *Treatment*.—The final result (fig. 101) is better if natural involution is allowed to occur rather than if regression is hastened (as it can be) by any

FIG. 100.—Strawberry angioma.

FIG. 101.—Strawberry angioma. Same case as fig. 100 with conservative treatment, about 7 years.

operative or physical methods (e.g. carbon dioxide snow, injection of hot water or sclerosant fluid or hypertonic saline, etc.). X-ray therapy carries a high risk of disturbance of growth and is dangerous.

Venous Angioma (cavernous) is relatively uncommon. It is present at birth and consists of a multiplicity of venous channels of varying calibre (fig. 102). Usually it shows no tendency to involution and may become larger and more troublesome later. Sometimes the whole of one limb and the adjacent part of the trunk is affected (fig. 173). Occasionally the nævus is associated with a lipoma (nævo-lipoma). In some cases arteriovenous communications are present (p. 140). The skin overlying the nævus may be atrophic, and besides being in danger of severe hæmorrhage from trauma, the patient may suffer from septicæmia if organisms gain entry, in which case the energetic use of antibiotics is an urgent matter. *Treatment.*—In general this is conservative. The repeated injection of hot water and other sclerosing agents may help, but the method is uncertain.

FIG. 102.—Venous angioma.

Arterial (plexiform) Angioma is a type of congenital arteriovenous fistula (p. 140). The pulsating swelling of arteries and arterialised veins is often called a *cirsoid aneurysm* (Chap. 24).

Spider Nævus.—This may be associated with liver disease (Chap. 43) if present in the skin over the manubrium sterni, but it may occur quite innocently. It shows the characteristic sign of emptying.

Nævus tardes are small angiomas occurring *in adults*, often around the mouth. They may be associated with vasospastic conditions and scleroderma (p. 152).

Lymphangiomas are described on p. 177. Sometimes they are associated with a hæmangioma (hæmo-lymphangioma).

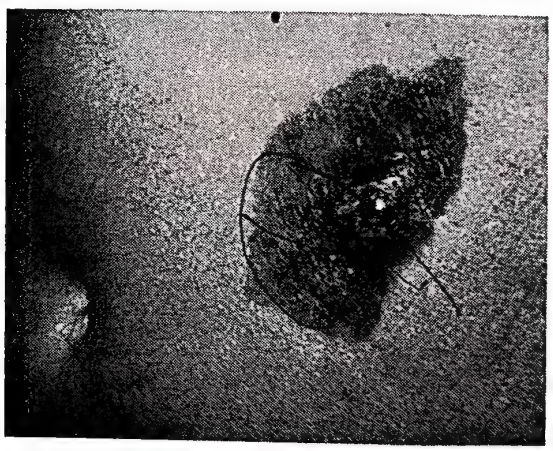

FIG. 103.—Bowen's disease of the abdominal wall, in which epithelioma has developed.

PREMALIGNANT CONDITIONS OF THE SKIN[1]

(1) **Bowen's disease** is an intradermal precancerous condition. A brownish induration with a well-defined edge appears in the skin (fig. 103). Microscopically large clear cells similar to those found in Paget's disease of the nipple (Chap. 35) are in evidence. Sooner or later carcinoma develops, and wide excision is then necessary.

(2) **Paget's Disease of the Nipple** (Chap. 35).

(3) **Leukoplakia** (Chap. 30).

(4) **Senile (or Solar) Keratosis.**—Occurs occasionally as multiple lesions on the face and backs of hands (fig. 104) in persons past middle life. Exposure to sun is the

---

[1] *Acanthosis Nigricans*, a pigmented hypertrophic condition of the skin folds usually in the axillæ *is not* in itself premalignant, but is associated with cancer of the gastro-intestinal tract and the breast.

John Templeton Bowen, 1857–1940. Professor of Dermatology, Harvard Medical School, Boston, Massachusetts, U.S.A. Described Precancerous Dermatosis in 1912.

important predisposing factor. Usually the lesions are less than 1 cm. and have a dry, hard scale with little or no infiltration. Squamous cell carcinoma may develop.

(5) **Radiodermatitis.**—(*a*) *Early:* Erythema occurs which goes on to desquamation and pigmentation. If the dose is very great, ulceration may occur. (*b*) *Late:* Atrophy, irregular hyper-pigmentation and telangiectasis and hair loss occur. Eventually, squamous cell carcinoma may develop.

(6) **Chronic Scars** (Marjolin's Ulcer).—A carcinoma which develops in a scar (fig. 105) presents the following characteristics:

(i) It grows slowly, as the scar is relatively avascular.

(ii) It is painless, as scar tissue contains no nerves.

FIG. 104.—Senile keratosis.

FIG. 105.—X-ray scar of the neck in which carcinoma has developed (Marjolin's ulcer).

(iii) Secondary deposits do not occur in the regional lymph nodes, as lymphatic vessels have been destroyed. If the ulcer invades normal tissue surrounding the scar, it extends at a normal rate, and lymph nodes are then liable to be involved.

MALIGNANT DISEASE OF THE SKIN

Basal Cell Carcinoma (Rodent Ulcer).—A common tumour of low-grade malignancy which occurs in white-skinned people. Exposure to sunlight is a predisposing factor and it is therefore common in Australia. It occurs in middle or late age and ninety per cent. of lesions are found on the face, usually above a line from the lobe of the ear to the corner of the mouth, the commonest site being around the inner canthus of the eye. Although often called a rodent 'ulcer' many of the lesions are non-ulcerated, and have a nodular appearance with a pearly or darkly translucent colour as if containing water, and with a network of fiery red blood-vessels on the surface. Thus the common types are: nodular, cystic, and ulcerated (figs. 106 and 107). An unusual type is the 'field fire' rodent (fig. 108).

FIG. 106.—Rodent ulcer.

Jean Nicolas Marjolin, 1780–1850. Surgeon, Paris. Described the development of Carcinomatous Ulcers in Scars in 1828.

The ulcerated type has a typical appearance—a raised rolled edge, like a motor car tyre, with central ulceration (fig. 106). Temporary healing often takes place, to be followed by further ulceration with serous discharge and

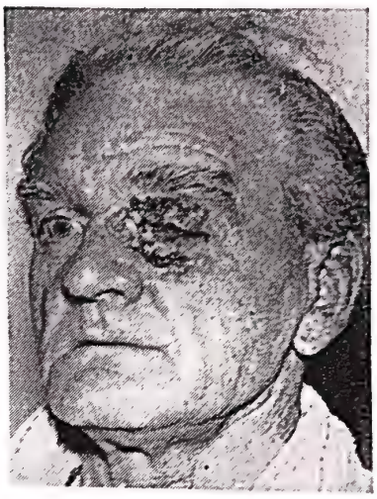

FIG. 107.—Disfigurement caused by rodent ulcer.

FIG. 108.—'Field-fire' type of rodent ulcer.

bleeding. The patient gives a history of a 'spot' which never really heals : 'it keeps scabbing over and breaking down'.

Though the tumours are slow-growing, if ulcerated they will, as the name implies, gradually erode deeper tissues, such as muscles, cartilage, and bone, producing severe disfigurement (fig. 107). Dissemination by lymphatics or the blood-stream does not occur. Rarely the ulcer takes on a squamous-cell carcinomatous change.

FIG. 109.—Squamous-celled carcinoma. The patient was a chemical worker.

Microscopic examination shows masses of darkly staining cells with a characteristic arrangement—an outer palisade layer of columnar cells surrounding a central mass of polyhedral cells. Cystic spaces may be seen.

Treatment. — Surgery or radiotherapy is necessary. Excision allows the whole lesion to be examined. With small lesions the operation can be described as an excision-biopsy. It is essential to excise a margin of healthy tissue around and beneath the tumour. A skin graft (p. 119) may be needed to cover the defect. In large lesions some form of plastic repair by a pedicle-flap graft may be required—cosmetic results should be good (fig. 122).

Cylindroma (*syn.* 'turban' tumour) is so called from the arrangement of the stroma in peculiar transparent cylinders. It is considered by some to be a basal-celled carcinoma, while others classify the tumour as endothelioma (p. 56). The tumour gradually forms an extensive turban-like swelling extending over the scalp. Ulceration is uncommon, and the tumour is relatively benign.

Squamous Cell Carcinoma (Squamous Cell Epithelioma, Epithelioma) (fig. 109).—This is less common, but it is more malignant a[nd] more

rapidly growing than rodent ulcer. A squamous cell epithelioma can occur *de novo* in the skin of the face of elderly people, but more often it occurs in a pre-existing skin lesion, or as a result of past irradiation. The pre-malignant conditions are listed above, and other conditions include long-standing venous ulcers, chronic lupus vulgaris lesions, and the prolonged irritation of the skin by various chemicals, e.g. dyes, tar or soot (p. 45).

A typical carcinomatous ulcer is irregular in outline, and the edges are raised and everted. The base is indurated and sooner or later becomes attached to the deeper structures. A blood-stained discharge occurs, which is increased in amount with the advent of secondary infection. The regional lymph nodes become involved, and the deposits are liable to undergo mucoid degeneration, to which secondary infection is sometimes added.

Treatment.—Treatment must be adequate. Immediately after biopsy confirmation of the diagnosis, the surgical treatment is wide excision, which may require some form of skin graft to the defect. Whether radiotherapy should be employed instead of surgery depends upon the condition of the patient, the size and attachments of the tumour, and the radiotherapy facilities.

The presence, or subsequent appearance, of enlarged mobile lymph nodes is an indication for block-dissection, unless it is considered that secondary infection is responsible, in which case the decision to operate will await the effect of the appropriate antibiotic. Fixed enlarged lymph nodes are not removable; some regression may be obtained by radiotherapy.

MELANOCYTIC TUMOURS AND MALIGNANT MELANOMA

Simple Melanocytic Tumours

The melanocyte is generally believed to be derived from the neural crest. In normal skin, melanocytes appear as clear cells in the basal layer of the epidermis. They may become increased in number in the layers of the skin to form benign pigmented nævi (moles) as follows: 1. within the basal layer of the epidermis (*Lentigo*), 2. as localised aggregations projecting into the dermis (*Junctional nævus*), 3. entirely within the dermis (*Dermal nævus*) and 4. when 2 and 3 are combined (*Compound nævus*). These simple melanocytic tumours may arise anywhere in the skin including the nail bed (fig. 110). They are seen occasionally in the conjunctiva of the eye but are rare in other mucous membranes.

FIG. 110.—Melanoma of the nail bed.

Clinical Features.—Pigmented nævi may occur at any age but commonly appear in childhood and adolescence as small, brown, flat or slightly raised lesions in the skin. These are usually of junctional or compound type but with increasing age they either atrophy or mature into dermal nævi.

Another clinical type is seen in middle-aged patients, particularly in the face. These appear as small, rounded swellings, often non-pigmented and sometimes bear bristly hairs. They are dermal nævi.

Congenital nævi are rare (fig. 111). They are often darkly pigmented and may be hairy and papillary in appearance. Occasionally they cover extensive areas of skin, up to 25% or more of the body surface. They may undergo malignant change even during childhood. With this exception malignant melanoma is very rare before puberty.

FIG. 111.—Congenital melanoma.

Treatment may be indicated (i) for cosmetic reasons, (ii) if by reason of its position the lesion is subject to the nuisance of repeated trauma, e.g. cut when shaving or rubbed by the brassiere strap, though there is no evidence that trauma causes malignant change, (iii) prophylactically in sites where there is a predisposition to malignant change, e.g. the palms, soles or external genitalia, or (iv) if the history suggests that malignant change has occurred (see below).

Surgical excision is the only acceptable treatment, and all lesions should be sent for histological examination.

MALIGNANT MELANOMA

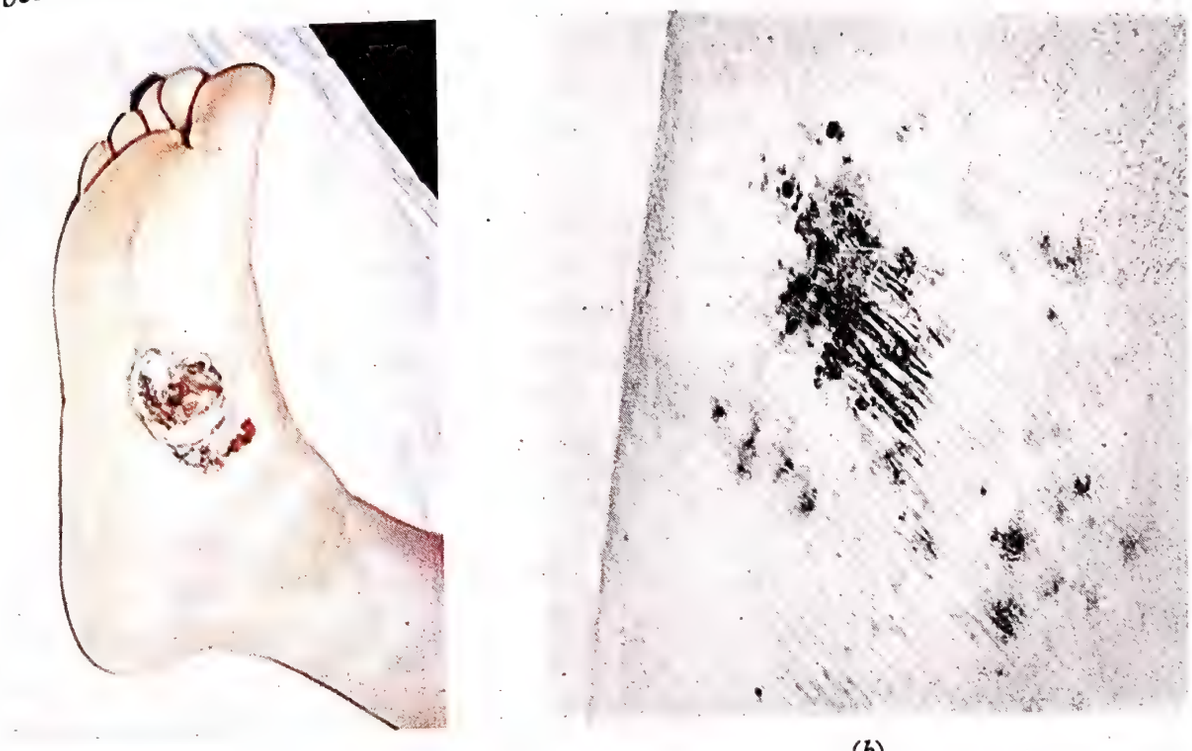
It is now generally agreed that malignant melanoma of the skin should be regarded as a carcinoma—melanocarcinoma. A malignant melanoma may arise (i) in a pre-existing pigmented nævus or (ii) *de novo* in apparently normal skin. Pathological studies suggest that malignant change in a benign nævus occurs only in the junctional or compound varieties; the pure dermal nævus is safe. Little is known of the causation but it is commonest in fair skinned individuals who live in hot climates and prolonged exposure to ultra violet light has been incriminated.

FIG. 112.—Malignant melanoma of the leg, showing pigmented and amelanotic areas.

Clinical Recognition.—Malignant melanoma is almost unknown before puberty. It should be suspected after puberty when 1. a previously existing mole begins to enlarge, itches, weeps, scabs or bleeds, becomes ulcerated or more deeply pigmented, or produces a halo of pigment in the surrounding skin. 2. A pigmented lesion appears in an adult and grows progressively. 3. A rapidly growing, fleshy, ulcerated skin tumour appears which looks as though it may be malignant; some malignant melanomas are amelanotic, so that this may be an amelanotic melanoma. The commonest site in females is the lower leg (fig. 112), and in males the front or back of the trunk. In the African Negro the sole of the foot is the most frequent site; malignant melanoma does not arise from the blacker skin of the remainder of the body for reasons which are not understood.

Differential diagnosis is from (i) histiocytoma (sclerosing angioma), (ii) pigmented seborrhœic wart, (iii) pigmented basal cell carcinoma, (iv) squamous cell papilloma, (v) cavernous hæmangioma.

Spread.—Malignant melanoma may spread by local extension, by the lymphatics or by the blood-stream. Tumour cells may reach the regional lymph nodes by embolism but spread by lymphatic permeation is also seen producing local satellite nodules (fig. 113(*a*)) and/or 'in transit' deposits between the primary growth and the regional nodes (fig. 113(*b*)). Secondary



(*a*) (*b*)

FIG. 113.—(*a*) Melanoma malignum of the foot, with local satellite deposits. (*b*) 'In transit' deposits between the primary growth and the regional nodes.

lymphœdema may occur (fig. 187). Blood borne metastases are seen in the lungs, liver, brain, bones and skin. They may also involve unusual sites, e.g. the breasts, small intestine and heart. Secondary deposits are typically black (fig. 114) but sometimes contain little or no melanin, even when the primary tumour is heavily pigmented. Extensive visceral involvement may cause melanuria.

The Choroid.—Malignant melanoma may arise in the choroid of the eye where it presents with blurring of vision. It spreads by the blood-stream, frequently giving rise to visceral deposits which can be enormous, especially in the liver. These metastases may not appear clinically for many years after the removal of the eye.

Treatment.—Surgical excision is the only certain method of cure. Malignant melanoma of the skin is only rarely radio-sensitive. Excision of skin, subcutaneous fat and sometimes deep fascia must be wide with at least 5 cm clearance all round the tumour where anatomically possible. The large resulting defect almost always requires skin grafting.

Subungual malignant melanoma requires amputation of the affected digit.

When the clinical diagnosis is in doubt local excision biopsy with a narrow margin of clearance is done and either frozen or rapid paraffin sections examined. This is safe provided the wide clearance described is performed within 48 hours of biopsy.

Moles must never be cauterised or curetted because the vital histological evidence is destroyed and if the lesion is malignant the disease may be disseminated.

Malignant melanoma of the choroid is treated by enucleation of the eye.

Malignant melanoma may develop in the conjunctiva but unlike that of skin can be successfully treated by careful radiotherapy.

Malignant melanomas arising in other mucous membranes, e.g. mouth (fig. 598) or anal canal are by contrast highly dangerous and seldom curable.

Management of Lymph Nodes.—If the primary tumour is adjacent to the lymphatic field, i.e. on the face or neck, or near the axilla or groin, it is widely excised in continuity with the regional nodes so as to include all the intervening lymphatic pathways. Excision of lymph nodes must be radical, e.g. the axilla is cleared in the same meticulous manner as for breast carcinoma, and a groin dissection includes not only the inguinal nodes but also those in relation to the three iliac vessels.

FIG. 114.—A malignant melanoma. Block dissection of lymph nodes in the groin.

If the primary tumour is remote from the lymphatic field, e.g. ankle region, it is dealt with as already described. If the regional nodes are not clinically involved, prophylactic block dissection is not carried out but the patient is carefully observed. Only if or when the nodes are enlarged are they dissected as a separate operation (fig. 114).

Other Methods of Treatment.—Cytotoxic agents are only of limited value when the disease is disseminated. They do however help in control of locally advanced disease in the limbs if administered by the specialised technique of isolated perfusion, where high local concentrations of the drug can be produced without generalised side effects. In this way major amputations are often avoided. Immunotherapy has been tried but its value is not yet established.

Prognosis.—The prognosis of cutaneous malignant melanoma depends mainly on the stage at which it is detected and to a lesser degree on the site of the tumour. Small, flat lesions are commonly curable by adequate primary treatment. Larger lesions which are raised and ulcerated, with accompanying tumour penetration into the deeper layers of the skin, carry a much higher mortality. Satellite and ' in transit ' nodules or involvement of the regional lymph nodes are also bad prognostic signs. The importance of early recognition of this disease is therefore crucial. Melanomas of the trunk are less favourable than those arising on the limbs or face. The outlook is better in the female than the male though the disease is not influenced by hormone therapy. Pregnancy makes pigmented moles darker and sometimes larger but does not affect the course of malignant melanoma.

Kaposi's Sarcoma may rarely be confused with malignant melanoma. It occurs mainly in Italians and in Eastern European Jews. It is also prevalent in equatorial Africa. It principally involves males of middle age or above. Multiple bluish nodules occur especially on the limbs. In due course the nodules ulcerate and late on the disease may disseminate widely. These tumours are sensitive to radiotherapy and chemotherapy.

BURNS AND SCALDS

Most burns are due to dry heat and scalds to moist heat. Other causes include actinic (sun) rays, irradiation, chemicals, electricity and friction. The management of a patient with a heat burn depends upon the consideration of:

1. **Shock.**—The area of body surface involved is important in relationship to the development of shock. The surface area is estimated by Wallace's 'Rule of Nine' (fig. 115).

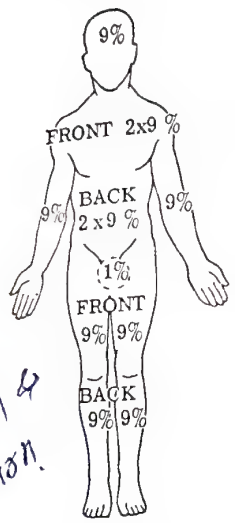


FIG. 115.—'Rule of nine' for estimating the extent of a burn. By adding the affected areas together the percentage of the total body surface burnt can be calculated quickly.

2. **Healing.**—The depth of burns determines the manner of healing. Only two grades need to be considered: (*a*) partial skin thickness burns (fig. 117) and (*b*) a full thickness burn.

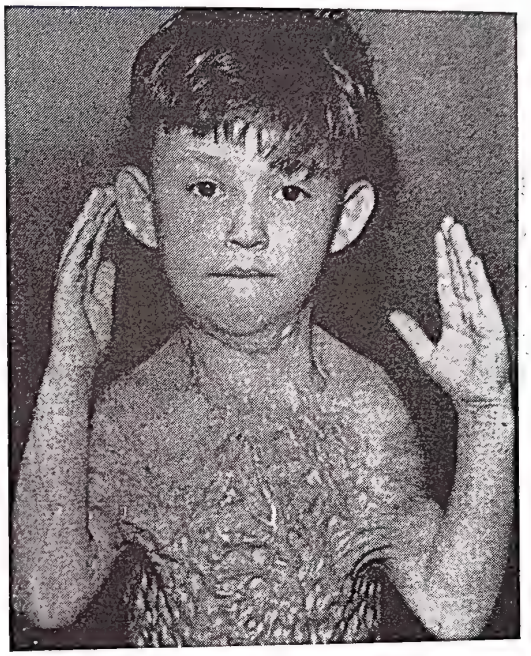

FIG. 116.—Contractures following burns (Children's Burns Unit, Guy's Hospital, London). *(The late Patrick Clarkson, F.R.C.S.)*

(*a*) A partial thickness burn will heal from the epithelial elements in the deeper part of the skin (hair follicles, sebaceous glands, sweat glands).

(*b*) In full thickness burns all the epithelial elements have been destroyed and the dead skin will separate in two to three weeks revealing a red granulating surface. This can only heal from the edge, very slowly, and with the risk of contracture (fig. 116). This type of burn requires treatment by skin grafting (p. 119).

Assessing the depth of burn.—In a partial thickness burn the nerve endings are still viable, so the burn wound is sensitive. A deep burn is insensitive. The simplest method of assessment is the use of a sterile needle with which the clinician can distinguish between the sensitive and the insensitive areas.

3. **Scarring.**—Partial thickness burns usually heal without much scarring. Alteration in pigmentation is quite commonly found. Maltreated and neglected full thickness burns always lead to unsightly, often incapacitating, scars. This may be minimised with properly timed skin grafting. In late

Moritz Kaposi, 1837–1902. Professor of Dermatology, Vienna. Described Pigmented Sarcoma of the skin in 1872.
Alexander Burns Wallace, 1906–1974. Formerly Reader in Plastic Surgery, University of Edinburgh.

contractures it may be necessary to excise the scar completely and replace this with a skin graft.

Treatment of Burns

The sections that follow deal with the treatment programme for burns shock, the local treatment of the wound, and the general treatment. The section on skin grafting follows thereafter.

Treatment of Burns Shock (A treatment programme)

(1) *Estimate percentage of surface burns.*—This is done using the 'Rule of Nine' (fig. 115).

(2) *Estimate weight* (in kg.) from (*a*) known weight or (*b*) measured weight or (*c*) age and height tables.

(3) *Transfusion with Dextran* 110 (*in saline*), *or plasma* (page 76).—(*a*) All adults with burns over 15 per cent. (*b*) All children with burns over 10 per cent. (Some children with 5 to 10 per cent. surface burns need careful watching.)

(4) *Method of intravenous administration.*—In a shocked patient with collapsed veins, do not waste time trying to put up a drip with needles—do a cut-down immediately. Avoid the use of veins in the legs if at all possible (use forearm, arm, or external jugular veins) (p. 91).

(5) *Volume to be transfused.*—The plan is to give six equal 'rations' of Dextran or plasma in six periods. The volume is calculated by the following formula (after Muir and Barclay).

$$\text{One 'ration' (in ml.)} = \frac{\text{Total per cent. of burn} \times \text{weight (kg.)}}{2}$$

Three rations are given in the first twelve hours, two rations are given in the second twelve hours, leaving the last ration for the third twelve hours.

Treatment by electrolyte transfusion only.—Some workers claim that good results can be obtained by transfusion with electrolytes (e.g. Ringer-Locke solution) without any added colloid. The volume required will be 3-4 times greater than the volume indicated by the formula above. Dextrose i.v. solutions (page 89) are used for nutritional requirements.

(6) *Progress and control.*—The need for transfusing and the rate of infusion are adjusted according to clinical and laboratory observations. These are: (i) Blood pressure and pulse rate; (ii) Restlessness; (iii) Hæmatocrit; (iv) Colour; (v) Urine volume; (vi) Nausea, vomiting, or gastric aspirate; (vii) C.V.P. (page 69). If the urine output is poor, insert a C.V.P. catheter and increase the rate of transfusion until the C.V.P. is 10–15 cm. water.[1]

(7) *Blood transfusion.*—In deep burns (as opposed to superficial burns) red cells are destroyed. Blood is given instead of the Dextran or plasma 'ration' in patients with deep burns of over 10 per cent. of the surface of the body. The second ration is replaced by blood in burns of 10 to 25 per cent., and the second and sixth ration in burns of 25 to 50 per cent.

(8) *Morphia.*—10 to 20 mg. is given intravenously or into the drip as indicated.

---

[1] See footnote page 69.

Ian Fraser Kerr Muir, Contemporary. Plastic Surgeon, Royal Aberdeen Children's Hospital, Aberdeen, Scotland.
Thomas Laird Barclay, Contemporary. Plastic Surgeon, Bradford Royal Infirmary, Bradford.

(9) *Urine.*—(*a*) Urine is collected hourly, measured and tested; (*b*) For burns over 35 per cent. all patients are catheterised.

(10) *Oral fluids.*—Water is required for metabolic fluid requirements. Start with 60 ml./hour and proceed to 100 ml./hour if there is no nausea. A nasogastric tube is usually passed in burns of 35 per cent. or over, and the stomach aspirated hourly before giving the oral fluid.

Local Treatment

The aim of local treatment is to achieve skin cover as soon as possible (page 1), and to prevent infection meantime. Quick healing minimises scarring, deformity and loss of function.

In minor burns local treatment can be started immediately. If the patient has to be transfused, local treatment should be delayed until it is certain that the circulation is stable (the burn is covered with a sterile towel).

FIG. 117.—Partial thickness burn. Exposure treatment. (*I. F. K. Muir, F.R.C.S., Aberdeen.*)

(*a*) *Exposure treatment:* The burn is cleaned with cetramide-chlorhexidine solution, loose skin is removed, and blisters are pricked. The area is then exposed to the air (fig. 117) and a crust is allowed to form which protects the burn and permits healing to take place. This method is suitable for burns of the head and neck, and burns of a single surface of trunk or limbs. As the burn heals the crust lifts up at the edge and can then be snipped away.

(*b*) *Dressings:* The burn is cleaned as above and then dressed. The dressings are applied in three layers:

(i) First layer.—The layer next to the skin should be non-adherent and 'antiseptic'. The best available antiseptics now available are silver sulphadiazine, Sulfamylon and framycetin (soframycin).

(ii) The second layer of cotton gauze.

(iii) An outer layer of absorbent wool is applied and held in place with gauze or crepe. This should be sufficiently thick to absorb all exudate without penetration to the surface and yet be porous. Should the wool become saturated, a further layer must then be applied without removing the original dressing. This dressing should be changed on the third and tenth days.

Specific Local Treatment.—(1) *Partial thickness burns:* The treatment should be continued as above until the burn is healed.

(2) *Full thickness burn:* If a full thickness burn is present, the area of dead skin will be obvious as a black slough in two to three weeks. Treatment should therefore be changed to a method which will help separation of the slough. This is achieved by baths and frequent dressings with hypochlorite

solutions, e.g. Eusol.[1] As soon as the slough has separated and clean granulations are present, thin split skin grafts cut from the undamaged areas should be applied to expedite healing.

Amnion dressings.—Amnion, suitably sterilised by boiling or chlorhexidine, is a useful by-product of the labour ward when used as a dressing. Previously used to speed healing of varicose ulcers it promotes granulation tissue and facilitates early and successful skin grafting. Amnion dressings need to be changed every 48 hours.

Lyophilised skin.—Freeze dried skin (human, porcine dermis) is another type of temporary cover which facilitates skin grafting. The dressing may be left *in situ* longer than amnion.

(3) *Special types of burns:* Some well localised deep burns are best treated by early excision and grafting. Electrical burns (fig. 118) are localised and often very deep, and if the patient survives the electric shock, may need a complicated repair.

FIG. 118.—A post-mortem photograph of an electric burn. The deceased touched a live terminal.

Tangential excision of a burn.—Using a skin grafting knife, the burn is shaved layer by layer until it is judged that a viable surface has been reached in order to cover immediately with a split thickness skin graft. The technique requires patience and practice. It is better to slice away more than is at first thought necessary.

General Treatment

The medical and nursing staff should take every precaution to prevent infection of a burn. It is desirable that the patient should be isolated (in a cubicle if possible), and barrier nursing instituted to prevent cross-infection.

(*a*) Respiratory damage may occur due to inhalation of smoke or hot gases and this may require oxygen and/or a tracheostomy.

(*b*) Sedation to reduce pain and restlessness—morphia 10 to 20 mg. may be given intravenously, usually via the drip. In children—Nepenthe (0·06 ml.), or morphia 0·5 mg. for each year of age may be prescribed.

(*c*) Diet: Large amounts of protein are necessary to stimulate healing and to compensate for protein losses due to catabolism.

(*d*) Antibiotics: Systemic antibiotics should be given as the clinical condition demands and in accordance with bacterial cultures.

(*e*) Late blood transfusion: Anæmia commonly develops and blood transfusion must be given if the Hb. falls below 11·7 g/100 ml (g/dl).

The Cold Water Treatment of Burns.—This is useful First Aid for burns of the hands, arms, and legs. The part is immediately immersed in cold tap water (about 15°C.) for at least 2 minutes. Pain and exudation are reduced to a remarkable extent, and mortality is lessened. The chief disadvantage may be the increased risk of bacterial contamination, but, intelligently applied, this method is of special value in areas where medical and special burns-treatment facilities are sparse.

[1] Eusol = *E*dinburgh *U*niversity *SOL*ution. It must be freshly prepared.

SKIN GRAFTING

Skin grafting, by free grafts or pedicled flap, is necessary to obtain healing and limit deformity and disability when a large area has been lost by injury (e.g. burn), by disease (e.g. varicose ulcer), or by surgical excision of a neoplasm (e.g. malignant melanoma).

Free Skin Grafts.—These grafts provide the simplest method of restoring skin cover. They can be used when the raw surface is composed of healthy vascularised tissue (e.g. subcutaneous tissue, deep fascia, paratenon), or clean granulations. Ischæmia and infection prevent grafts from surviving.

1. *Split thickness grafts* are the most generally useful grafts. Though often suitable for permanent repair they have a tendency to shrink. The grafts originally popularised by Thiersch were very thin, but the grafts now commonly used consist of one-third to two-thirds of the thickness of the skin. They are usually taken from the thigh by means of a special knife (Blair or Humby pattern, fig. 119 and fig. 120). If a large area has to be covered (e.g. an extensive burn), the electric dermatome is useful. The Padgett dermatome, which necessitates the use of an adhesive, can be used to cut grafts from the abdomen or back. The graft may be affixed by sutures. Alternatively pieces of 'postage stamp' size are applied—the epithelium grows out from them to cover the intervening bare areas. The graft may be spread on paraffin tulle gras and laid or

FIG. 119.—A split skin graft, cut with a Blair knife. *(I. F. K. Muir, F.R.C.S., Aberdeen.)*

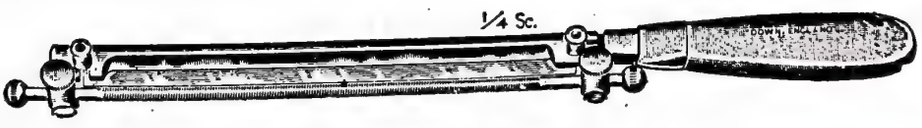

FIG. 120.—Humby's knife.

sutured on the area to be grafted. Light pressure is then exerted by either wool soaked in flavine emulsion or a piece of sterilised sponge covered by a crepe bandage. The donor site of the split skin graft is covered with a single layer of tulle gras and heals in two weeks by epithelialisation from the remaining deeper parts of the skin.

2. *Full Thickness Skin Graft* (Wolfe).—This graft consists of the full thickness of the skin to which *no* fat should be adherent. The criteria for the graft to take are more strict than in the case of the split skin graft but the Wolfe

Karl Thiersch, 1822–1895. Professor of Surgery, Erlangen (1854–1867), Leipzig, Germany (1867–1895). Described his method of Skin Grafting in 1874.
Vilray Papin Blair, 1871–1955. Professor of Clinical Surgery, Washington School of Medicine, St. Louis, Missouri, U.S.A.
Thomas Graham Humby, Contemporary. Formerly Plastic Surgeon, Barbados Genera Hospital, West Indies.
Earl Calvin Padgett, 1893—1946. Professor of Clinical Surgery, University of Kansas, Kansas, U.S.A.
John Reissberg Wolfe, 1824–1904. Ophthalmic Surgeon, Glasgow, Scotland. Described Full Thickness Skin Graft in 1885.

graft shows no tendency to contract, and is of better colour and texture than the split skin graft. It is therefore useful for defects of the face (example: when excising a rodent ulcer from a lower eyelid), when the graft may be taken from the posterior surface of the ear.

Pedicle Flaps.—Free grafts will not 'take' (i) on cartilage, open joints, bare cortical bone, or bare tendon, (ii) if the vitality of the recipient area has

(*A*) (*B*) (*C*)

FIG. 121.—A large rodent ulcer involving the upper lip, the side of the nose, and the antrum has been excised leaving the facial deficiency (A), in which post-operative biopsies show no residual growth. The upper lip and the side of the face are reconstructed by a flap graft (B), and the residual deficiency made good by a prosthesis, (C), which is held in place by a pair of spectacles. (*I. F. K. Muir, F.R.C.S., Aberdeen.*)

been depressed by scarring or irradiation, (iii) if the defect involves a cavity (example : full thickness excision of lip or cheek (fig. 121)). In any of these circumstances the repair must be by means of a flap of skin with some subcutaneous tissue, which remains attached to the body by one of its margins through which it retains a blood supply (i.e. by a pedicle or stalk) until it has united in its new position. Once it has attained its own blood supply the original attachment can be severed and the flap adjusted.

FIG. 122.— A cross leg flap. The legs are held together by a plaster cast.

(*a*) *Local flaps:* These are turned on their own blood supply (fig. 121).

(*b*) *Direct flaps:* If the donor site can be brought into approximation with the recipient area, the flap can be transferred at one stage and the division completed at a second stage. Examples are from one finger to another (cross finger flap, fig. 228), from the calf of one leg to cover a defect on the opposite shin (cross leg flap, fig. 122), or from abdomen to hand.

(*c*) *Indirect flap:* In some circumstances it may be impossible to bring the donor area and the recipient area

into proximity and the flap must first be attached to an ' intermediate carrier site ', thus tissue can be moved from the abdomen to the face or to the lower

FIG. 123.—A tube pedicle flap. The skin tube was raised on the lateral abdominal wall. In the course of months the wrist was used as the intermediate source of its blood supply before final separation from the abdomen and application to the scarred and ulcerated leg.

leg, using the wrist as the ' carrier '. In order to eliminate raw areas it is convenient to stitch the flap into the form of a tube, i.e. a tube pedicle flap (fig. 123).

CHAPTER 8

ARTERIES. GANGRENE

ARTERIAL SURGERY—BASIC CONSIDERATIONS AND PRINCIPLES

THE first section of this chapter deals with those aspects which can be regarded as the essentials of arterial surgery.

The Effects of Arterial Occlusion

When the arterial pathway to any part of the body is occluded, necrosis or gangrene will ensue unless there is an alternative pathway to bypass the circulation around the obstructed vessel. An alternative pathway is present for most organs and is known as the ' collateral circulation '. Provided the collateral circulation is adequate necrosis and gangrene will be avoided.

The effects of arterial occlusion depend principally on: (1) The anatomical arrangement of arteries; and (2) The speed of the occlusion. The various possibilities are shown in Fig. 124. Anatomically the best collateral path-

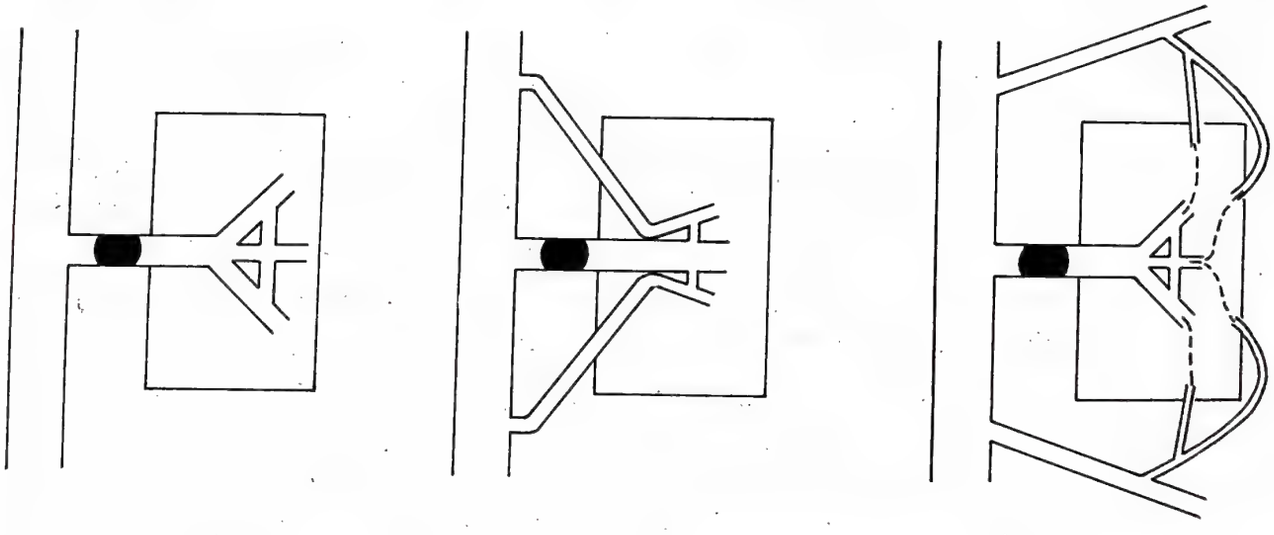

FIG. 124.—The effect of an arterial occlusion without and with a collateral circulation. A. Organ necrosis occurs with sudden or slow occlusion. B. Temporary ischæmia with sudden occlusion, no ischaemia with slow occlusion. C. Probable organ necrosis with sudden occlusion; but with slow occlusion the organ survives with greatly reduced reserve.

ways are through muscles. Therefore collateral circulation around an iliac artery obstruction is good, whereas the absence of muscle around the knee joint results in poor collateral circulation around a popliteal artery occlusion.

Other factors which modify the effect of arterial occlusion include pump failure (coronary artery disease, etc.), and occlusion of collateral channels (e.g. by extension thrombosis, p. 142, or progressive atheroma).

John Hunter, 1728–1793. Surgeon, St. George's Hospital, London. His collection of anatomical specimens forms the nucleus of the Hunterian Museum at the Royal College of Surgeons of England. Hunter was the first to demonstrate the formation of collateral circulation. He tied the external carotid artery of a stag from Richmond Park. The stag's antler fell off, but later another one grew in its place. On re-opening the original wound, Hunter found that while his ligature was intact, a collateral circulation had been established.

Clinical Features of Ischæmic Disease[1]

Ischæmic disease may affect any organ whose blood supply becomes compromised. The most commonly affected organs are, the heart (coronary thrombosis, angina pectoris), the lower extremities (intermittent claudication, gangrene), the brain (stroke), the kidneys (renovascular hypertension), and the intestine (mesenteric vascular accidents). Arterial disease of the lower limbs is common and frequently amenable to surgical treatment.

The following description applies principally to arterial disease of the lower limbs but the principles of management, may, suitably modified, be applied to similar arterial lesions affecting other organs.

Symptoms of Ischæmic Disease

The major symptoms of arterial occlusion of the lower extremity are:— intermittent claudication, rest pain, coldness, numbness and paræsthesiæ, colour changes, ulceration and gangrene.

Intermittent Claudication.—The blood supply to the muscles, which, except in the most advanced cases, is adequate at rest, becomes inadequate during exercise. On walking a certain distance (claudication distance), the patient experiences a cramp-like pain, which causes him to stop. After a minute or two, perhaps while he looks into a shop window, the pain passes off, allowing him to go on, only to return once more after he has walked a similar or slightly shorter distance. The claudication distance depends on the available blood supply, which in turn depends on the site and extent of the arterial obstruction and the efficiency of the collateral circulation. The general health of the patient (heart failure, anæmia), the speed of walking, hills and wind and ambient temperature all affect claudication distance.

Intermittent claudication is commonest in the calf (femoro-popliteal obstruction) but may occur in the buttock and thigh (aorto-iliac obstruction).

Mild Ischæmia.—Some patients with arterial occlusion have such good collateral vessels that they remain symptom free.

Other causes of pain in the leg on walking must always be considered. To do this it is helpful to review all the anatomical components of the leg (bones and joints, veins, muscles and nerves). Thus pain may be due to arthritis, deep vein thrombosis, torn muscles, or that due to a prolapsed intervertebral disc (e.g. sciatica).

The pain of spinal nerve root origin, often known as *neurospinal claudication*, due to a prolapsed disc, may appear to come on with exercise, but it rarely disappears on rest. By the end of the day it becomes particularly tiresome. Answers to the questions 'Do you get the pain while watching television in the evening?' or 'Do you get the pain in bed, especially when turning over?' are usually in the affirmative. Neurospinal claudication and arterial occlusions sometimes coexist, when the differential diagnosis of the cause of pain may be particularly difficult.

---

[1] Ischæmia = a lacking of blood flow.

Claudius (Tiberius Claudius Drusus Nero Germanicus), 10 B.C.–A.D. 54. Emperor of Rome (A.D. 41–54). Was deformed by a disease contracted in childhood (possibly Poliomyelitis), and walked with a limp. Claudicare = to limp. Claudicatio = limping (Latin).

Rest Pain.—As arterial insufficiency in a leg becomes more severe, a time comes when the limb blood supply becomes inadequate at rest. This may occur gradually or may be precipitated by a local infection (paronychia, cellulitis). When this stage is reached the patient begins to suffer continuous pain in the *foot* of the affected leg.

Rest pain is severe, relentless and continuous. It prevents sleep and dominates the patient's waking hours. A typical sufferer sits in bed, hip and knee flexed, clutching the painful foot with both hands, staring into space, and unable to concentrate on normal waking activities. Some relief may be obtained by hanging the foot and leg down, and some patients sleep in a chair, or hang the foot over the side of the bed, or they get up many times at night and pace the bedroom. Analgesics usually are of no avail. Untreated, the patient becomes withdrawn and anorexic and loses weight; he may beg for an amputation.

Rest pain should not be confused with acute night cramps, common in the age group affected by arterial disease, and of doubtful relevance to arterial insufficiency.

Coldness, numbness and paræsthesiæ.—Coldness of the affected limb is a common symptom of ischæmia of any severity. Subjective numbness and ' pins and needles ' are common in patients with ischæmia of moderate severity, although usually there is no objective neurological abnormality.

(a) (b)

FIG. 125.—Colour changes with (a) elevation and (b) dependency (see text).

Colour changes (fig. 125).—Moderate or severely ischæmic limbs become blanched on elevation and develop a bluish-purple discolouration on dependency (Buerger, p. 150). The angle of elevation at which blanching first occurs gives a good rough guide to the degree of ischaemia.

Ulceration and gangrene.—Ulceration occurs with severe arterial insufficiency and usually presents as a painful superficial erosion between toes

or in a web space. Alternatively small, shallow, indolent non-healing ulcers may occur on the dorsum of the feet, on the shins, and especially around the malleoli. The blackened mummified skin and tissues of frank gangrene are unmistakeable (p. 154).

Impotence.—Impotence due to failure to achieve an erection is a common symptom in male patients with bilateral internal iliac artery occlusion. Such occlusions may occur in isolation or in association with an aortic occlusion (Leriche syndrome).[1]

Appearance of the Ischæmic Limb

MILD	May be normal
MODERATE	Postural colour change pallor on elevation dusky cyanosis on dependency Loss of hair Wasting Indolent ulcers
SEVERE	ACUTE ISCHÆMIA Dead white pallor White with greyish purple blotching Gangrene
	CHRONIC ISCHÆMIA Fixed discolouration—red or red purple Œdema Gangrene

Signs of Ischæmic Disease

Appearance.—Examples of severe chronic ischæmia and severe acute ischæmia are shown in Figs. 126 and 127 respectively, but it should be

FIG. 126.—Severe chronic ischæmia.

FIG. 127.—Severe acute ischæmia.

appreciated that in mild cases the feet may look relatively normal. Beware of the dead white limb which then becomes mottled! This is a sign of impending gangrene, not a sign of improved circulation.

[1] Leriche's syndrome. René Leriche (1879–1955) described Leriche Syndrome in 1940.

Loss of hair, a time-honoured clinical sign, is due to friction of socks and trousers far more often than to ischæmia.

Temperature.—Ischæmic limbs are cool to the touch and noticeably cooler than a contralateral normal limb.[1] Severely ischæmic feet are usually cold but sometimes paradoxically may feel warmer than the non-involved foot. There is often an element of inflammation in these instances.

Sensation and movement.—These are only affected in the severely ischæmic limb. Acutely ischæmic limbs are frequently paralytic and without sensation. These are ominous physical signs and such a limb has a poor prognosis in the absence of active treatment. Severe chronic ischæmia does not produce paralysis, but hyperæsthesia is common, especially in those areas of skin on the borderline of gangrene. Gentle handling of such limbs is essential.

The combination of rest pain, colour changes, œdema and hyperæsthesia, with or without ischæmic ulceration, is frequently referred to as 'pregangrene'.

Arterial pulsations.—Arterial pulsations below an occlusion in a main artery are usually absent or, in the presence of good collaterals, diminished. In arterial occlusion with a highly developed collateral circulation, or main artery stenosis, the distal pulses may be normal to palpation. The following physical sign is then useful:

The 'disappearing pulse'.—Where peripheral pulses are apparently normal, exercising the patient to the point of claudication may unmask the effect of an arterial obstruction, by causing the previously palpable pulse to disappear. After a minute or two following exercise the disappearing pulse reappears. Under these circumstances exercise produces vasodilation below the obstructing lesion. The arterial inflow, reduced by the lesion, cannot keep pace with the increasing vascular space, arterial pressure falls, and the pulse disappears.

In patients with vascular symptoms it is standard practice in each case to feel the pulsations in the radial arteries, the carotid arteries, the abdominal aorta, the femoral arteries in the groin, the popliteal arteries behind the knee, the posterior tibial arteries behind the medial malleoli and the dorsalis pedis artery on the dorsum of the foot. Diminution of a pulse can best be appreciated by comparing it with the pulse in the other limb, provided that this pulse is normal.

Expansile arterial pulsation with a mass may indicate an aneurysm (p. 135).

Arterial bruits.—In addition to palpating pulses a vascular examination should include auscultation of the subclavian arteries in the supraclavicular fossæ, the carotid arteries behind the angle of the mandible, the abdominal aorta and the femoral arteries in the groin. A systolic bruit over an artery is due to turbulence, and often indicates a stenosis of the artery. Systolic bruits are conducted distally. Thus a bruit at the angle of the mandible without any supraclavicular bruit frequently means a carotid artery stenosis. Where, however, a bruit is heard at both sites, its origin may be more proximal, e.g. aortic valve, aortic arch, brachiocephalic or subclavian arteries. Under these circumstances the carotid artery may prove quite normal. The patient with renal artery stenosis shown in Fig. 128 had a bruit over the renal artery.

[1] The acutely ischæmic limb tends to take on the temperature of the surroundings and may feel quite warm under the bedclothes.

A Continuous Machinery Murmur over an artery may indicate an arterio-venous fistula (p. 140).

Venous Refilling.—The limb should be elevated for thirty seconds and then laid flat on the bed. Normal refilling occurs within seconds. Reduced venous filling is often present in the severer forms of arterial insufficiency but is also common in vasospastic disease (p. 151) and in cold weather.

Harvey's Sign[1].—If the two index fingers are placed firmly side by side on a vein, and the finger nearer the heart is moved so as to empty a short length of vein, the release of the distal finger will allow the speed of venous refilling to be observed.

Increased venous return and even varicosities of the veins may be seen in arterio-venous fistulæ (p. 140).

The Relationship of Clinical Findings to the Site of Disease

By associating the symptoms and signs found in a case of arterial disease it is usually easy to determine the site of the major arterial obstruction.

Relationship of Clinical Findings to Site of Disease

AORTO ILIAC OBSTRUCTION (LERICHE p. 125)	Pulses all absent in both limbs
	Claudication in both buttocks, thighs and calves
	Impotence common
ILIAC OBSTRUCTION	Unilateral absence of all pulses
	Unilateral claudication in thigh and calf and sometimes buttock
FEMORO-POPLITEAL OBSTRUCTION	Unilateral absence of pulses below femoral
	Claudication in calf and sometimes foot
DISTAL OBSTRUCTION	Ankle pulses absent
	Claudication in calf and foot

Double Blocks.—The presence of secondary obstructions can usually be inferred. Thus a patient with signs of iliac artery obstruction, but with rest pain and pre-gangrene of the foot, must have a secondary obstruction since collateral circulation around an isolated iliac artery obstruction is usually excellent. The severe symptoms would indicate a secondary obstruction probably in the femoral or popliteal arteries. However, if it is important to determine the site of a secondary obstruction more sophisticated investigations are required.

The Investigation of Arterial Disease

General Investigations.—The general examination and investigation of a case of arterial disease needs to be comprehensive. It should be appreciated that atherosclerosis is a generalised disease and the patient may also suffer from ischæmic heart disease, renal impairment, cerebro-vascular disease, hypertension, etc. Atherosclerosis is also a common accompaniment of diabetes, which always needs to be excluded. A previous history of peptic ulceration is also common.

---

[1] William Harvey (1578–1657), Physician, St. Bartholomew's Hospital, London. First described circulation of the blood in his course of lectures at the Royal College of Physicians of London in 1616. Harvey's book *Exercitatio Anatomica de Motu Cordis et Sanguinis in Animalibus* was not however published until 1628. The sign of venous refilling should be eponymous, as it was this observation on the direction of blood flow in the veins that confirmed Harvey's views that the blood moved in a circle.

Patients with arterial disease also frequently suffer from age related diseases, e.g. prostatic obstruction, and habit related diseases, e.g. chronic bronchitis or carcinoma of bronchus. Urine examination, chest X-ray, E.C.G., urea and electrolytes, blood count, etc., will therefore be among the appropriate investigations.

Special Investigations.—It is important to realise that it is unnecessary to submit every patient suffering from arterial disease to a series of special investigations.

Plain X-ray exposures will show the presence and extent of arterial calcification. Flecks of calcium may outline an aneurysm. Plain X-ray films, *per se*, are generally of limited value in helping the surgeon to formulate his opinion and treatment policy.

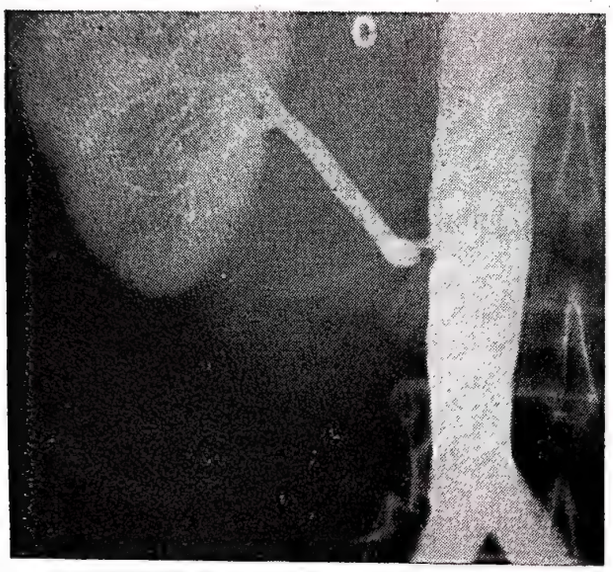

FIG. 128.—Renal artery stenosis. Arteriogram by retrograde femoral catheterisation.

Arteriography (figs. 128, 129).—This procedure furnishes information concerning the state of the arteries—constrictions, obstructions, or dilatations, and to some extent the state of a collateral circulation. The vascular pattern of tumours may also be studied. Arteriography should be restricted to those patients in whom surgical treatment is being considered, or in whom a diagnosis cannot otherwise be made. The occasional hazards of arteriography include thrombosis, and arterial dissection, and very occasionally arterial rupture. Paraplegia, or even a fatality, may result from aortography (see trial injection, below).

The following methods are employed:

(i) *Retrograde Percutaneous Catheterisation.*—Under a local or general anæsthetic, and with operating theatre aseptic ritual, a special needle and cannula (fig. 129) are inserted into the artery. A suitable length of flexible guide wire is threaded through the cannula, which is withdrawn so that a polythene catheter can be passed over the guide wire and into the vessel. The common femoral artery is the usual route in most instances including aortic arch, renal, mesenteric, iliac and femoro-popliteal arteriograms. The right brachial artery is preferred by some radiologists for coronary arteriograms.

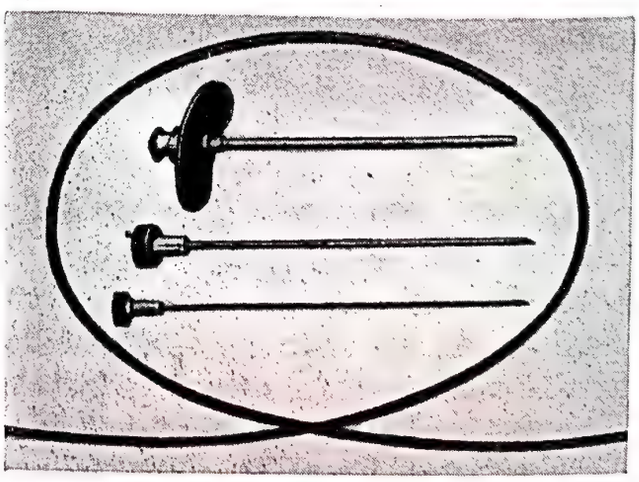

FIG. 129.—Seldinger needle and guide wire for introducing an arterial catheter.

(ii) *Direct Percutaneous Arterial Puncture.*—This may be used for carotid arteriograms, and for demonstrating the abdominal aorta (translumbar route) when the femoral arteries are occluded, or if the retrograde method cannot produce the necessary information (fig. 130).

A trial or test injection of 5 to 10 ml. of 45 per cent. Hypaque must be made in order (*a*) to exclude iodine sensitivity (Chap. 44) (cf. intravenous cholangiography) and (*b*) to ascertain that the tip of the catheter or the point of the needle is in the correct place. A dissecting aneurysm can occur if the bevel of the needle is partly in the wall of the artery. To prevent this hazard a special needle without a bevel but with a side hole may be employed.

If the result of the test injection is satisfactory, the whole volume (30 ml.) of the contrast medium is injected rapidly as a 'bolus', and serial X-ray exposures are made to obtain radiographs of the length of the arterial tree under examination. In the case of the leg, the examination must extend from the lower part of the abdominal aorta to the ankle, as a second obstruction may be present.

FIG. 130.—Translumbar aortography. Atherosclerotic stenosis of both common iliac arteries prevented proper visualisation by retrograde catheterisation.

(iii) *Use of Doppler Ultrasonic Blood Velocity Detector* (figs. 131 and 132).

This apparatus works on the Doppler principle. An ultrasonic signal is beamed at an artery and the reflected beam picked up in a receiver and converted to an audible signal. The pitch of the signal received varies with the velocity of blood flow. The audible signal reflects the character of the pulse wave and is modified by stenosis or a proximal arterial obstruction and will be lost entirely over the site of an obstruction. With practice it is possible to map out obstructions and stenoses from the character of the signal over arteries at various sites.

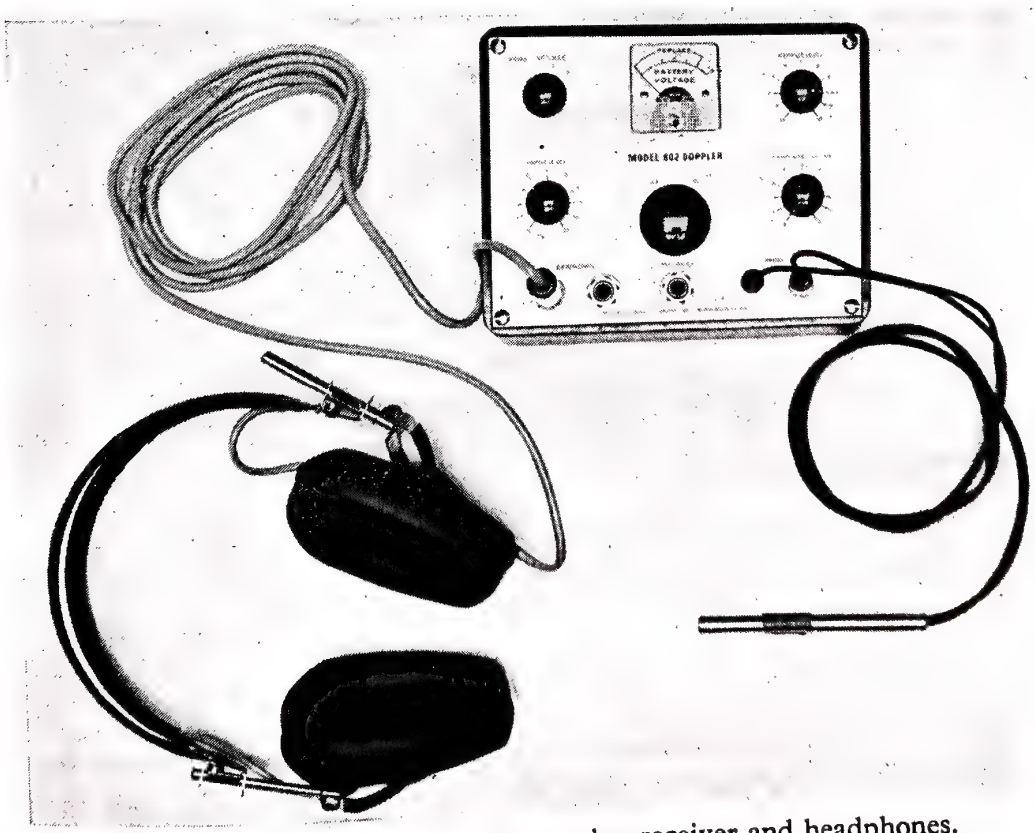

FIG. 131.—Doppler apparatus—probe, receiver and headphones.

Christian Johann Doppler, 1803–1853. Austrian Physicist.

FIG. 132.—Doppler probe.

Use as a Stethoscope. The detector may also be used as a stethoscope, when, in conjunction with a standard inflatable cuff, it is possible to measure the blood pressure at sites where the arterial pulse cannot be palpated. The detector is placed over the posterior tibial artery and the arterial signal found. The cuff is placed around the ankle and inflated until the signal disappears. This level is the ankle systolic blood pressure. With the detector still in the same place, the blood pressure at other points in the limb may be measured by altering the cuff site.

The ankle systolic blood pressure is greater than the brachial (arm) systolic blood pressure in normal individuals by 5–15 mmHg (0·67–2 kPa). Therefore the 'pressure index' $\left(\frac{\text{ankle blood pressure}}{\text{arm blood pressure}}\right)$ is normally greater than one. A 'pressure index' of less than one indicates some degree of arterial obstruction between the left ventricle and the ankle. The lower the pressure index the greater the degree of obstruction. When the ankle blood pressure falls below 30 mmHg (4·0 kPa), the measurements become difficult and gangrene of the extremity is imminent.

(iv) *Blood lipids and glucose tolerance.*—Abnormal levels of blood cholesterol, triglycerides and lipoproteins are found in about 60% of all patients with atherosclerotic peripheral arterial disease. A proportion of these patients, while not actually diabetic, also have impairment of glucose tolerance. The significance of these biochemical abnormalities in aetiology, management and prognosis is at present uncertain.

(v) *Other methods of special investigation.*—Measurement of blood flow (strain gauge plethysmography; ^{133}Xe, etc.); measurement of walking distances using a treadmill; and measurements of blood flow or ankle systolic blood pressure after exercise are useful research tools for assessing treatment methods. They are not necessary for ordinary clinical practice.

MANAGEMENT OF ARTERIAL DISEASE

A. Conservative Methods

Conservative methods of treatment are directed towards two aims: (1) Relief of symptoms; (2) Reduction in the rate of progression of atherosclerosis.

1. **Relief of Symptoms.**—Conservative methods are rarely capable of more than some improvement in claudication distance. Mild rest pain may occasionally be helped. Moderate or severe rest pain will not be relieved. Small ischæmic ulcers may be healed. Larger necrotic lesions are very rarely influenced.

Vasodilator methods.—Vasodilator methods have no significant effect on muscle vessels, probably including most collateral vessels, but are effective in dilating skin and sub-cutaneous vessels. For this reason, vasodilator methods do not improve intermittent claudication but usually have a beneficial effect on ischæmic ulcers and trophic changes. They may also help the mildest forms of rest pain.

(i) *Oral Vasodilator drugs.*—These are usually administered as first line treatment immediately after an acute arterial obstruction. At this time the claudication is at its most severe and spontaneous improvement may be expected as collateral circulation improves. This improvement is attributed both by physician and patient to the vasodilator drug, which thereby acquires a completely undeserved reputation. Some patients are helped by alcohol by mouth (sherry, brandy, whisky, etc.) but probably not always because of the vasodilator effect. The drink is frequently administered as a 'night cap'.

(ii) *Intra-arterial Vasodilator drugs.*[1]—Tolazoline hydrochloride ('Priscol') and papaverine sulphate are of very short action and limited usefulness. Reserpine ('Serpasil') is longer acting and in a dose of 1 mg is often helpful in obtaining relief in an acute exacerbation of vasospastic disease (p. 151).

(iii) *Paravertebral injections of the Sympathetic Chain.* ('Chemical Sympathectomy').—This is an alternative to surgical sympathectomy. It is also sometimes used as a method of assessing the likely effect of this operation. Injection can be given on more than one occasion. The procedure is contraindicated if anticoagulants are in use.

Technique.—For the leg this implies the injection of 1% lignocaine beside the bodies of the second, third, and fourth lumbar vertebræ. Fig. 133 shows how to position the patient (a lumbar-puncture position is used for patients who cannot sit up). Fig. 134 shows how a long (15 cm.) needle is inserted, firstly to seek the side of the vertebral body and, secondly, to pass alongside it. Then 1% lignocaine (10–20 ml.) is injected. The effect of the injection (warmer feet and improved venous filling) may last for two or three days. Further injections may be given, but a permanent effect more easily achieved if 5 ml. of 5% phenol solution in water is injected (chemical sympathectomy). Care is needed to avoid penetrating the aorta or the vena cava.

FIG. 133. — Sitting position for a paravertebral injection. The patient rests his head and arms on a pillow.

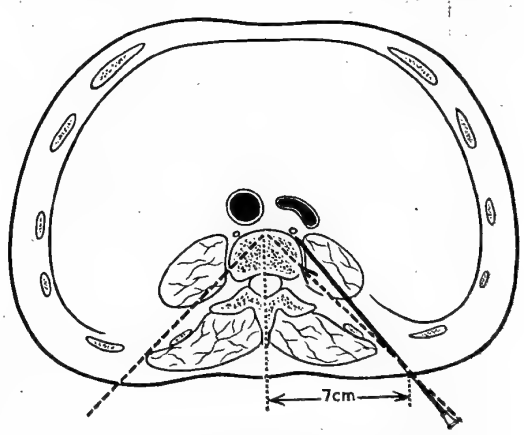

FIG. 134.—Lumbar paravertebral injection.

Precision injection.—With the patient in the lumbar puncture position, the employment of an X-ray T.V. image intensifier, used in two planes, assists greatly in the accurate positioning of the needles.

[1] The reader is referred to the book *Annapurna*, by Maurice Herzog (*Jonathan Cape, Ltd.*), who experienced intra-arterial and paravertebral injections for the treatment of frostbite.

For the arm a shorter needle is introduced vertically to the skin, 4 cm. lateral to the spines of the second, third and fourth thoracic vertebræ. The needle seeks the back ends of the ribs, and is then passed over or under them for another 1 cm. while the bolus of lignocaine is injected. Special care is needed to avoid puncturing the lung and thereby causing a pneumothorax.

(iv) *Reflex heating.* The affected limb is nursed exposed to room temperature, while the trunk and remaining limbs are warmed by an electric pad or blanket. Reflex vasodilatation of the exposed limb usually results, and may be a helpful adjunct, especially in acute ischæmia where improvement may be expected as collateral circulation develops.

Cooling the exposed limb with a fan as often practised may reduce local metabolism but will counteract the effect of reflex heating. Direct heating or freezing of an ischæmic limb should never be employed.

(v) *Buerger's position* (fig. 135). The head of the bed is raised 15 cm. The hydrostatic congestion is associated with a slight increase in blood flow and may afford some relief to rest pain.

(vi) *Buerger's Exercises* (fig. 136).—The leg is elevated for two minutes, and lowered beside the bed for two minutes. Elevation and lowering are repeated for séances of about thirty minutes, twice or thrice daily. Elevation can be readily obtained by putting a chair on the bed. Their value is probably only that of giving the patient something to do!

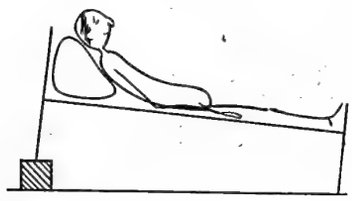

FIG. 135.—Buerger's position.

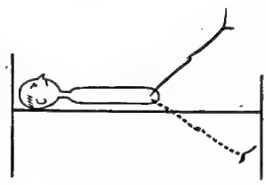

FIG. 136.–Buerger's exercises.

Protection of Ischæmic Parts.—In the severely ischæmic limb, steps must be taken to prevent gangrene occurring in the areas likely to be subject to pressure (e.g. the heel, p. 155). All cases of peripheral vascular disease need careful chiropody; gangrene often follows the trauma of a badly cut toe nail.

Muscular Activity.—In the past it has been customary to restrict the walking distance to within the claudication distance or to advise a slowed pace of walking. Recent work in Scandinavia has shown that exercise training to improve general physical fitness and promote muscular activity in the involved limbs is associated with an increase in claudication distance of 100% or more in most patients. Similar improvements in angina pectoris can be obtained by exercise training.

Pain Relief.—Pain relief for intermittent claudication is not required since the occurrence of pain remains within the patient's control. Relief of rest pain is difficult and may require strong analgesic drugs which frequently fail to give complete relief. Simple drugs such as 'Distalgesic' should be tried first. Stronger analgesics such as oral dihydrocodeinone (' D.F. 118 ') 30 mg or intramuscular pentazocine (' Fortral ') 30–60 mg, are often required. Since the pain will be relieved either by reconstructive surgery or amputation, the use of strong analgesics causing dependence such as morphine and pethidine should be avoided if possible.

Heel Raise.—Raising the heel of the shoes has been advocated to diminish the load on the gastrocnemius muscle but usually has little useful effect.

Other Forms of Drug Treatment

(i) **Low molecular weight dextran**—given intravenously this is helpful in the temporary acute ischæmic phase. It may also be valuable in vasospastic disease (p. 151).

(ii) **Anticoagulant drugs.**—Agents such as ' Dindevan ' or ' Warfarin ' given in the long term to reduce the incidence of thrombosis may be used but are of unproven value.

(iii) **Fibrinolysis.**—Fibrinolytic agents such as streptokinase may be useful, especially in acute recent arterial thrombosis, but the effect is capricious, sometimes dramatically reopening blocked arteries and at other times a complete failure.

(iv) **Alpha-tocopherol (Vit. E.).**—often given for intermittent claudication in the past, there is now some evidence that its long term administration may be of some help in increasing claudication distance. The effect may not appear for 6 months.

2. **Reduction in the Rate of Progression of the Disease.**—Many failures in direct arterial surgery for atherosclerosis are due to progression of the disease. The risk factors for atherosclerosis include diabetes, hypertension, raised serum lipids (cholesterol and triglycerides), smoking, obesity, and lack of exercise. Although there is little evidence yet that significant reduction in rate of deterioration can be achieved some effort should probably be directed to the control of the risk factors.

Smoking.—Tobacco smoking should be strongly discouraged and every effort made to get the patient to stop smoking. Symptomatic peripheral vascular disease due to atherosclerosis is very rare in non-smokers (Eastcott).

Obesity.—Overweight patients should be encouraged to lose weight and weight increase on stopping smoking must be avoided.

Lipid abnormalities.—Serum lipoproteins contain cholesterol and triglyceride. β lipoproteins are cholesterol rich and pre-β lipoproteins are triglyceride rich. The commonest abnormalities in peripheral vascular disease are Frederickson Type II hyperlipoproteinæmia (raised β lipoproteins) and Type IV hyperlipoproteinæmia (raised pre-β lipoproteins). Low cholesterol diet or drugs such as ' Atromid S ' or cholestyramine are useful for Type II abnormalities. Weight reduction will frequently correct Type IV abnormality, but ' Atromid S ' is also useful.

Diabetes and hypertension.—should be treated by standard methods.

Exercise training.—has been discussed (p. 132).

B. Operative Methods

1. **Direct arterial surgery** is used either to restore the continuity of blood flow, or to provide an alternative channel (by-pass).

Arterial Repair.—For closure of a simple wound or arteriotomy after embolectomy, a continuous suture is employed, using 0000 silk or polypropylene on a 16 to 20 mm. atraumatic needle. A patch of vein or Dacron is frequently used for repairs in order to prevent narrowing the lumen of the vessel (fig. 137). If possible, small sections of the long saphenous vein should not be used as it may be required for by-pass grafting at a later date.

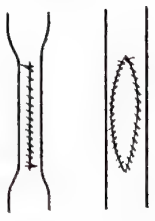

FIG. 137.—Where arterial suturing may reduce the lumen, a vein patch (right) is useful.

Artery By-pass Grafting (figs. 138 and 139).—*Veins* are commonly used for by-pass grafting of peripheral vessels, especially the femoro-popliteal artery segments. The long saphenous vein is usefully placed for by-passing a femoro-popliteal obstruction. A suitable length of long saphenous

Harry Hubert Grayson Eastcott, Contemporary. Surgeon, St. Mary's Hospital, London.

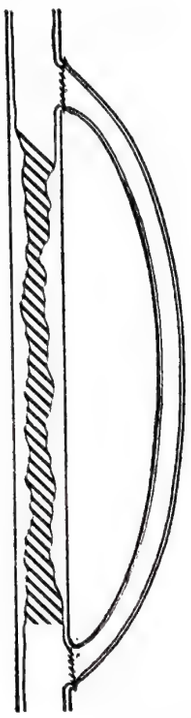

FIG. 138.—By-pass grafting.

vein is excised, after the careful ligation of all its tributaries with fine silk. The vein is then distended with warm heparinised saline or Hartmann's solution, reversed to prevent obstruction of blood flow due to its valves and sutured end to side to the patent artery above and below the occlusion (see p. 146).

Synthetic grafts of knitted or woven Dacron or Teflon are used mainly for aortoiliac-replacement (fig. 147). They are less suitable for peripheral work, as those of small calibre tend to thrombose more easily than vein grafts. As they are crimped in concertina fashion, they require to be stretched before insertion. Very little blood oozes through the interstices of the woven variety. After insertion, these grafts are incorporated by an invasion of fibroblasts, and within the lumen they become lined with pseudoendothelium of uncertain origin.

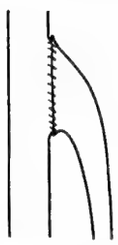

FIG. 139.—End of graft widened and sutured as a 'sucker foot' to the side of the parent artery.

Thrombo-endarterectomy ('disobliteration' or 'rebore') is described on p. 149.

Embolectomy and thrombectomy are described on p. 143.

2. **Indirect Surgery.—Sympathectomy.**—This is employed (a) for the treatment of vasospastic conditions (p. 151), (b) in Buerger's disease and other cases of peripheral arteritis (p. 150) and (c) in those cases of atherosclerosis where the disease is restricted to the most distal vessels, e.g. plantar or digital arteries, or where its vasodilator effect in improving skin lesions, e.g. small ischæmic ulcers, is required. Lumbar sympathectomy should not be used unless properly indicated. The techniques are described on p. 153.

DISEASES OF ARTERIES

Injury

Injuries to arteries usually take the form of *division*, *rupture*, or *contusion*.

Division occurs in penetrating wounds. A classical example is 'butcher's thigh', which is a penetrating wound in the femoral triangle, due to the knife slipping while boning meat. Any of the femoral arteries may be severed, sometimes with an immediate fatal result. *Rupture* of an artery can be caused by severe trauma, e.g. the popliteal, in the case of a dislocated knee. *Contusion* of the arterial wall also follows violence (e.g. a severe blow).

Clinical Effects of Injury.—Primary arterial hæmorrhage is usually obvious (p. 65), but the effects of a closed rupture or contusion may be less apparent. In cases of rupture there will be a swelling which may pulsate

(pulsating hæmatoma). Contusion usually causes a local thrombus (fig. 140) if a main artery is involved. In all three forms of injury the life of the limb may be threatened by ischæmia.

Late Effects of Injury.—An arteriovenous fistula may be caused by a penetrating wound. A false aneurysm may follow penetration or rupture, while a saccular aneurysm may follow contusion (fig. 141).

Treatment includes arresting hæmorrhage (p. 70), and reconstruction of the artery (p. 133), interposition of a vein graft, or thrombectomy (p. 143), as the case may be. The possibility of injury to other structures (e.g. nerves) must not escape the surgeon's notice, as these also will require appropriate treatment. In cases where a main artery has to be ligated to save life, or reconstruction is impossible, or when a local thrombosis becomes extensive, the limb will become severely ischæmic. Gangrene may occur or a group of muscles may necrose (e.g. Volkmann's ischæmia, Chap. 21). However, the rapid opening up of an efficient collateral circulation especially in the young, may save a limb from amputation. In the case of the leg there will be a period of intermittent claudication which disappears slowly over a matter of a few months. Conservative measures, as outlined on p. 130, are generally employed, and where the blood flow is satisfactory, arteriography will show if artery grafting is likely to be successful.

FIG. 140. — Thrombosis of the popliteal artery caused by a contusion. The foot was gangrenous. (Actual size.)

FIG. 141. — Saccular palmar aneurysm in a hæmophiliac, due to the repeated trauma of striking a nail-removing tool with his palm. (Actual size.)

Aneurysm

An aneurysm is a sac filled with blood in direct communication with the interior of an artery.

Aneurysms may be:—

- True { fusiform, saccular, dissecting.
- False
  - Arteriovenous (fistula), congenital and acquired.

A *true aneurysm* is due to dilatation of an artery, whereas a *false aneurysm* is a sac lined by condensed cellular tissue which communicates with the artery through an opening in its wall.

A *fusiform aneurysm* (the commonest type), is one in which the lumen is more or less equally expanded. The artery wall is usually weakened by severe atheroma and hypertension. In syphilis, the media of the arch of the aorta may be weakened by endarteritis of the vasa vasorum (figs. 142, 144). In a *mycotic*[1] *aneurysm*, the artery wall is weakened by infection, either in the form of a local abscess, or because an infected embolus has come to rest at that point.

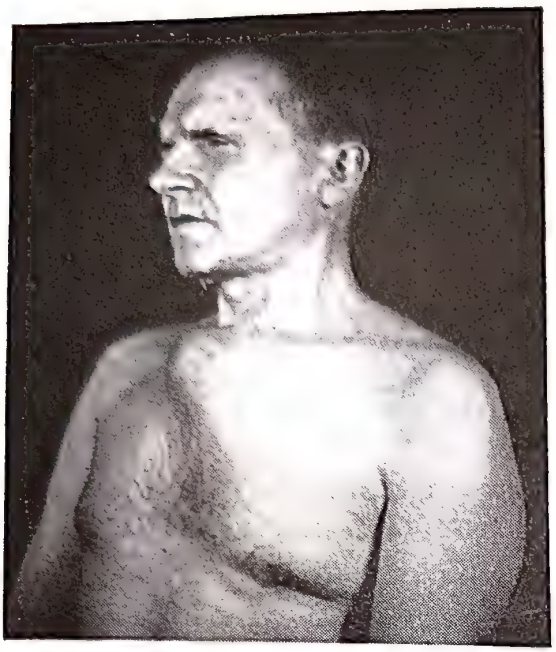

FIG. 142.—Aortic aneurysm which has eroded the sternum. *See Fig. 144.*

A *saccular aneurysm* is due to stretching of part of the arterial wall and commonly follows injury to superficial arteries (figs. 141 and 142).

Clinical Features of an Aneurysm. (*a*) *Intrinsic.*—A swelling exhibiting expansile pulsation is present in the course of an artery. The pulsation diminishes if proximal pressure can be applied, and the sac itself is compressible,[2] filling again in two or three beats if proximal pressure is released. A thrill may be palpable, and auscultation sometimes reveals a bruit.

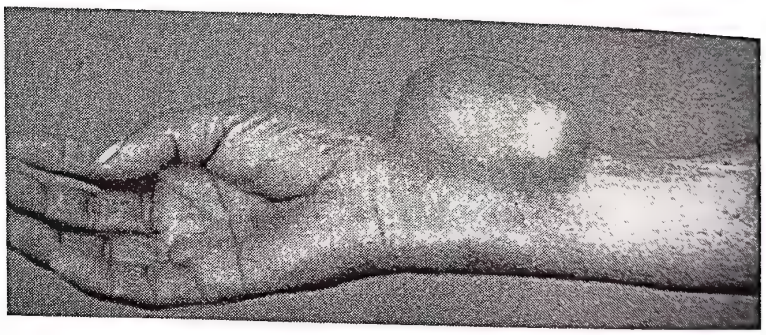

FIG. 143.—Saccular aneurysm of the radial artery. (*Professor A. K. Toufeeq, F.R.C.S., Lahore, Pakistan.*)

(*b*) *Extrinsic.*—Neighbouring or distal structures are affected. Thus pressure on veins or nerves causes distal œdema or altered sensation. In the popliteal fossa pressure eventually will cause gangrene. Bones, joints, or tubes (such as the trachea or œsophagus), are sometimes affected, but structures which are resilient, such as the intervertebral discs, often withstand prolonged pressure.

Differential Diagnosis.—1. *Swelling Under an Artery.*—An artery may be pushed forwards, e.g. the subclavian by a cervical rib, and thus rendered prominent. Careful palpation distinguishes this condition.

2. *Swelling Over an Artery.*—Transmitted pulsation is liable to be mistaken for that caused by expansion. However, posture may diminish pulsation; thus a pancreatic cyst examined in the genupectoral position falls away from the aorta, and consequently pulsation is less definite.

---

[1] 'Mycotic' is a misnomer, as the disease is not due to a fungus but to bacterial infection.
[2] Large aneurysms are frequently full of mural thrombus and may not be compressible.

3. *Pulsating tumours*, such as bone sarcoma, osteoclastoma, and a metastasis, especially from a hypernephroma.

4. *An Abscess.*—Before making an incision into a swelling believed to be an abscess, e.g. of the chest wall (fig. 144) in the groin, in the axilla, or in the popliteal fossa, it is essential to make sure that it does not pulsate! This mistake has been made many times.

FIG. 144. — An aortic aneurysm about to rupture. (*Raymond Helsby, F.R.C.S., Liverpool.*)

5. *A serpentine artery* (e.g. innominate).

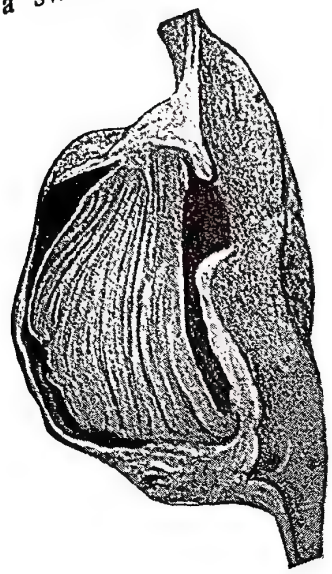

FIG. 145.—Aneurysm of the aorta. Extensive clotting in the sac. (*R.C.S. Museum.*)

Natural Terminations.—1. *Spontaneous Cure* (Consolidation).—This sometimes occurs in small peripheral saccular aneurysms. In large aneurysms mural thrombus is common but this does not prevent progression to rupture (fig. 145).

2. *Extension and Rupture.*—This occurs either slowly as a leakage, or suddenly, in which case death may follow if a large vessel is involved (fig. 144).

3. *Infection.*—Usually arises from organisms in the blood-stream. Signs of inflammation supervene and, if untreated, suppuration and rupture follow.[1]

Treatment.—This is surgical. The scope of the operation required may be indicated by arteriography, which will show the state of the arteries above and below the lesion but due to the presence of mural laminated blood-clot, the aneurysmal dilatation is seldom visualised. Fig. 146 is designed to itemise the procedures which are available:—

Hunterian Ligation (fig. 146A).—This operation was designed by Hunter for the treatment of popliteal aneurysm, but the principle can be applied to the treatment of other limb aneurysms, when a simple and quick measure is needed.

The ligature must be placed above the main collateral nearest the aneurysm (e.g. above the descending geniculate artery). In this way the blood flow through the aneurysm is not immediately cut off. The collateral circulation is given time to open up before consolidation occurs.

Exclusion and By-pass Grafting (fig. 146B).—Excision is not always necessary. It may be undesirable, as neighbouring vital structures may be damaged. The excluded aneurysm thromboses, and shrinks into a fibrous mass.

Excision and Grafting (fig. 146C).—Veins, or knitted or woven Dacron tubes, are used. The graft can be inserted 'end to end' or 'end to side'.

[1] Salmonella organisms may sometimes be isolated from ruptured aortic aneurysms.

Excision of the sac and arterial reconstruction (Matas' reconstructive aneurysmorrhaphy) fig. 146D, is a very useful procedure for small saccular aneurysms of important arteries (e.g. femoral or popliteal).

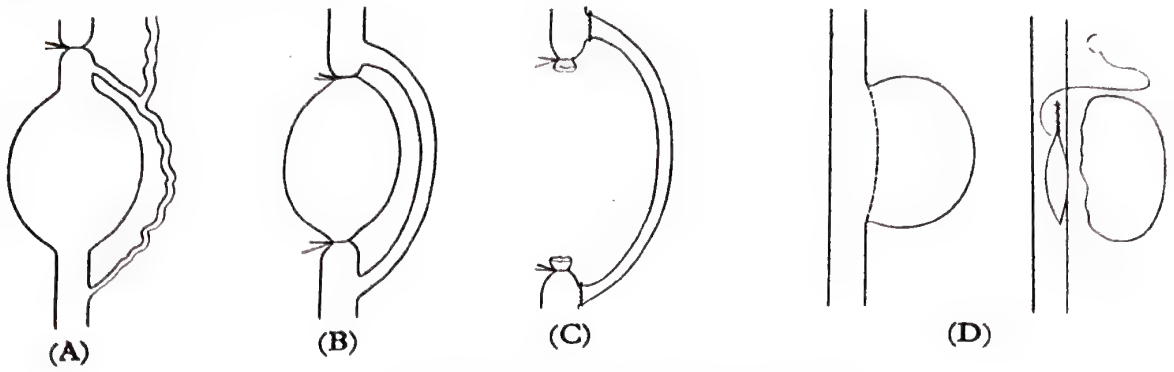

FIG. 146.—Operations for aneurysm.

(C) Excision and graft.
(D) Reconstruction (Matas).

Ligation and Excision.—Aneurysms of secondary arteries are treated by ligation of the proximal and distal vessels. Excision is not obligatory, save in special anatomical or physiological circumstances (fig. 141).

Abdominal aortic aneurysms are usually amenable to surgery. The patient complains of abdominal or back pains, and may be aware of the pulsatile abdominal mass. Left alone, the average expectation of life before rupture is about three years. When the aneurysm ruptures, the patient presents with abdominal pain and hæmorrhagic shock. The diagnosis may be difficult, as the clinical features may mimic some other abdominal emergency (e.g. perforated diverticulitis, acute pancreatitis, etc.). Emergency surgery has a high mortality, due usually to an unstable cardio-vascular system or renal failure resulting from prolonged hypotension. Modern intensive care wards have improved the prospects. Elective surgery, with a mortality of 5%, is therefore advised in otherwise fit patients, and when the aneurysm is believed to lie below the level of the renal arteries (usually the case).

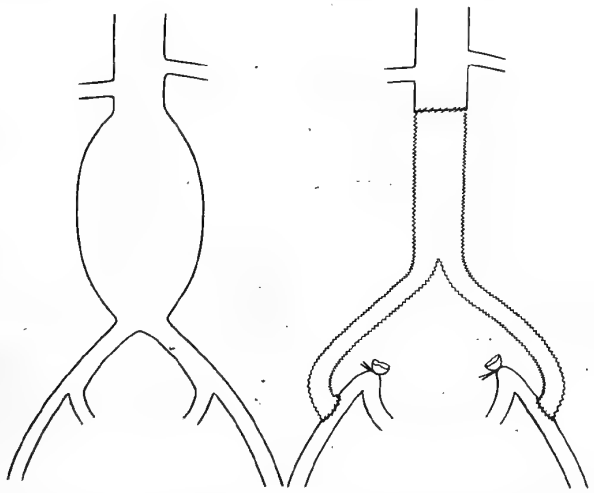

FIG. 147.—Grafting for an abdominal aneurysm. The remains of the aneurysm are omitted for the sake of clarity.

Exposure is through a long mid-line, a curved transverse,[1] or a flank incision, the latter using an extraperitoneal approach. The aorta is curiously amenable to encirclement with the finger and the application of a clamp just

[1] Post-operative wound dehiscence and incisional hernia are less common if a transverse incision is employed.

Rudolph Matas, 1860–1957. Professor of Surgery, Tulane University, New Orleans, Louisiana, U.S.A. (1894–1923). Introduced Endo-Aneurysmorraphy in 1888.

below the renal arteries.[1] The aneurysm may simply be excluded or evacuated and obliterated by suturing. The aneurysm is opened and evacuated, and a Dacron bifurcated graft is inserted (fig. 147). The walls may be wrapped round the graft.

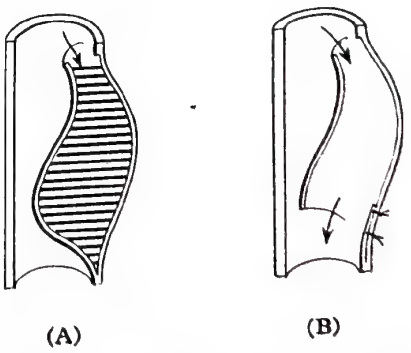
Dissecting aneurysms are frequently rapidly fatal and occur in the ascending aorta (65%) or near the origin of the left subclavian artery (35%). The patients are hypertensive, usually markedly so, and the dissection results from a spontaneous tear in the intima which allows blood to insinuate itself between the inner and outer layers of the media in an aorta where medial degeneration has occurred, e.g., in hypertension and in Marfan's syndrome. The dissection may spread proximally into the aortic valve ring, resulting in acute aortic incompetence (ascending aortic tears) or distally. The distal dissection may be extensive reaching even into the iliac and femoral vessels where obstruction of the true lumen may mimic embolism or thrombosis. Alternatively, death may occur from external rupture. The diagnosis is frequently difficult because symptoms vary considerably depending on which arteries are obstructed. The dissection itself causes severe pain—anterior chest pain suggesting myocardial infarction and/or pain in the back (chest and/or lumbar region). The combination of severe chest and back pain in a markedly hypertensive patient is suspicious of a dissecting aneurysm, and the diastolic murmur of aortic incompetence may help to clinch the diagnosis. Chest X-ray may show an expanded aortic shadow and emergency aortography will usually demonstrate the double lumen.

Conservative Treatment of Dissecting Aneurysms (Wheat).—The mortality from dissecting aneurysms in the acute stage has been significantly reduced by vigorous conservative measures. These are now the treatment of choice for the acute stage after dissection. The aim is to reduce the systolic blood pressure quickly to levels of 100–110 mmHg (13·3–14·6 kPa).[2] This is achieved using trimetaphan (Arfonad) in an intravenous drip of 1–2 mg per ml. The rate of the drip is adjusted to produce the desired level of blood pressure. Simultaneously reserpine 1–2 mg is administered i.m. or i.v. and guanethidine 50 mg commenced twice daily. The trimetaphan drip is gradually withdrawn as the blood pressure comes under the control of the other drugs. The urine output and peripheral pulses are monitored.

Surgical Treatment of Dissecting Aneurysms.—The 're-entry operation' (fig. 148B) consists of incising the artery and opening a 'window' in the false sac so that blood can flow freely back into the true lumen so relieving obstructive symptoms.

Resection of the aorta at the site of the tear, with grafting, carries a very high mortality in the acute stage, but has a place in management once a patient has been stabilised by conservative treatment. Cardio-pulmonary bypass (Chap. 39) will usually be required and replacement of the incompetent aortic valve may also be necessary.

Aorto-duodenal fistula is an uncommon but eminently treatable complication of abdominal aortic replacement surgery. It should be suspected whenever hæmatemesis or melæna occurs in the months or years after operation. A successful outcome is only achieved by prompt operation, separating aorta from duodenum, closing the holes, and also interposing some omentum.



(A) (B)

FIG. 148.—Dissecting aneurysm. (A) The dissection may obstruct the lumen. (B) The re-entry operation.

False aneurysms are traumatic in origin, and the extravasated blood is enclosed in a sac of condensed cellular tissue. Fig. 149 is a typical example, and the caption recounts the method of repair.

[1] The encirclement of the aorta with the finger below the renal arteries was demonstrated by Sir Astley Cooper, Surgeon, Guy's Hospital, London, and President of the Royal College of Surgeons of England 1827.

[2] Hypotensive therapy for aneurysms was in fact used empirically in the 18th century by employing absolute bed-rest, starvation and blood letting.

Myron W. Wheat, Jr., Contemporary. Professor of Thoracic Surgery, University of Florida College of Medicine, U.S.A.

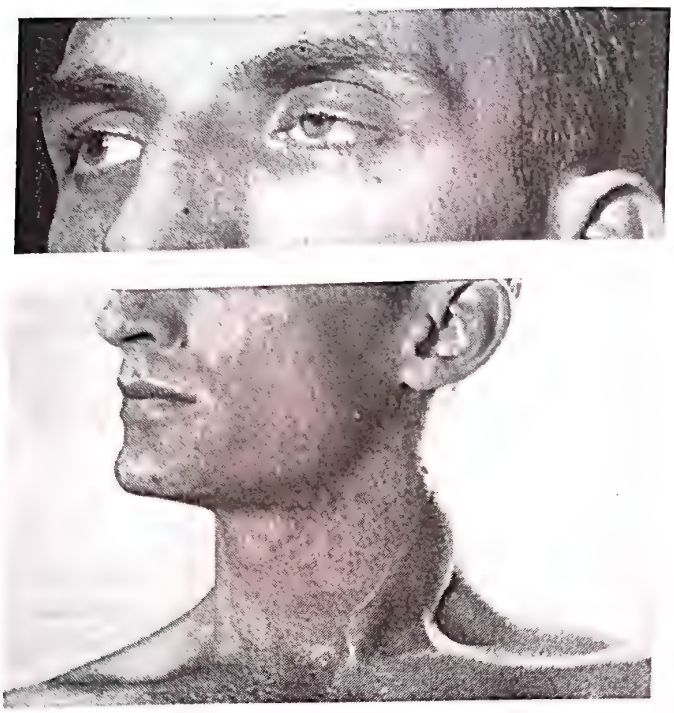


FIG. 149.—A false, and rapidly extending aneurysm of the common carotid caused by a stab wound. Note (above) the ptosis, myosis, and enophthalmos of a Horner's syndrome, due to concomitant severance of the cervical sympathetic nerve.

The scales of justice hung in the balance while the carotid artery was repaired and the sac evacuated (not excised), with a good result.

Arteriovenous Fistula.—Communication between an artery and a vein (or veins) may be either a congenital malformation, or acquired by the trauma of a penetrating wound or a sharp blow (fig. 150). Such a communication has both a structural and a physiological effect.

The *structural effect* of the arterial blood flow on the veins is characteristic, as they become dilated, tortuous, and thick walled (arterialised), and they also make the lesions diffuse and so render surgical procedures difficult. This is specially the case with the congenital variety.

Physiological Effect.—The combination of a leak from the high pressure arterial system and an enhanced venous return and venous pressure result in an increase in pulse rate and cardiac output. The pulse pressure is high if there is a large and persistent shunt. Left ventricular enlargement and, later, cardiac failure will occur. A congenital fistula in the young may cause overgrowth of a limb. In the leg, indolent ulcers may result from relative ischæmia below the short circuit.

Clinically, a pulsatile swelling may be present if the lesion is relatively superficial. On palpation, a thrill is detected and auscultation reveals a buzzing continuous bruit. Dilated veins may be seen, in which there is a rapid blood flow. Pressure on the artery proximal to the fistula causes the swelling to diminish in size, the thrill and bruit to cease, the pulse-rate to fall[1] and the pulse pressure to return to normal.

FIG. 150.—Arteriovenous fistula of inferior orbital vessels, caused by a cricket-ball.

Arteriography confirms the lesion, which is noteworthy for the speed with which venous filling occurs. It is often difficult to pinpoint the actual site of the fistula.

Treatment.—*Congenital* lesions are usually stationary. Excision is ad-

[1] Known variously as Nicoladoni's (1875) or Branham's sign (1890).

Johann Friedrich Horner, 1831–1886. Professor of Ophthalmology, Zürich, Switzerland. Described the syndrome which bears his name in 1869. The effects produced by section of the cervical sympathetic chain had been noted previously by François Pourfour Du Petit (1664–1741) in 1710.
Carl Nicoladoni. 19th century Surgeon, Vienna.
H. H. Branham. 19th century Surgeon, U.S.A.

vocated only for severe deformity or recurrent hæmorrhage. It is often wise to enlist the aid of a plastic surgeon in order that proper ablation and reconstruction can be effected. Ligation of a 'feeding' artery is of no lasting value.

The *acquired* lesions tend to be progressive, and operation is indicated. The vessels are separated, and, if possible, repaired by suturing, any intervening sac being excised. Failing this, ligation of the involved artery and vein is required both above and below the lesion (quadruple ligation). Vein or Dacron grafts may be required.

EMBOLISM AND THROMBOSIS

An embolus is a body which is foreign to the blood-stream, and which may become lodged in a vessel and so cause obstruction.

Simple emboli are due to blood-clot, vegetations from cardiac valves, or fragments from an atheromatous plaque. In the heart, mitral stenosis or auricular fibrillation predisposes to their formation, which is also encouraged if fibrillation is treated with quinidine. An endocardial mural thrombus, following a myocardial infarct, accounts for about one third of cases.

In some situations the results of embolism are characteristic, e.g. :

BRAIN.—The middle cerebral artery is most commonly affected, resulting in hemiplegia, temporary or permanent.

RETINA.—Occlusion of the central artery causes a momentary flash of light, followed by total and permanent blindness.

MESENTERIC VESSELS.—Causing engorgement and possibly gangrene of the corresponding loop of intestine.

SPLEEN.—Commonly affected, with local pain and enlargement.

KIDNEYS.—Resulting in pain in the loin and hæmaturia.

LUNG.—Pulmonary embolism (Chap. 38) is a catastrophe which may fatally interrupt convalescence after operation.

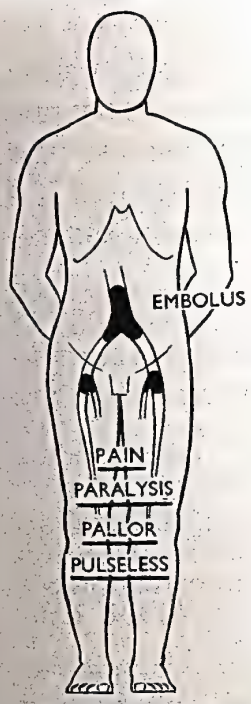

FIG. 151.—The symptoms and signs of embolism.

LIMBS.—An embolus is arrested at the bifurcation of a main vessel (fig. 151), causing *pain*,[1] *pallor*, *paresis*, *loss of pulsation*, and *anæsthesia*, followed by acute ischæmia, sometimes progressing to gangrene but often going on to recovery with varying degrees of chronic ischæmia. The more distal in the limb an embolus lodges, the more likely is gangrene to occur. Popliteal emboli lead to gangrene much more commonly than femoral or iliac emboli. Aortic bifurcation saddle emboli usually cause bilateral gangrene. In the arm emboli usually lodge at the brachial artery bifurcation and may cause gangrene of the hand.

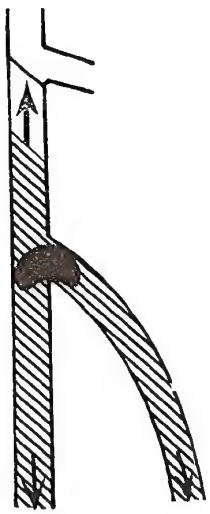

FIG. 152.—Extension-thrombosis subsequent to the arrest of an embolus.

[1] In some cases of peripheral embolism pain is absent and the incident may pass unnoticed by a bedridden patient until gangrene is obvious.

The danger of extension thrombosis (consecutive or secondary thrombosis) is present immediately after an embolus becomes arrested. The presence of the embolus and the consequent stasis of blood favours the formation of blood-clot which, in a matter of hours, extends proximally as far as the nearest branch and distally down the main vessels and its branches (fig. 152). Should a collateral circulation not open up, the peripheral stasis, and therefore the thrombosis, extends still further, and gangrene occurs.

Other types of acute arterial thrombosis are conveniently mentioned here, because clinically they mimic an embolus, and they are equally complicated by extension-thrombosis. Trauma causes arterial contusion (p. 134), which results in a local thrombus. The popliteal, external iliac, and axillary arteries (fig. 153) are specially susceptible. In axillary artery thrombosis, extension-thrombosis rapidly descends to obstruct the bifurcation of the brachial artery, a fact of great practical importance (see embolectomy). Acute arterial thrombosis, and this dangerous sequel, may also occur in an artery affected by atheroma (e.g. coronary thrombosis, cerebral thrombosis, femoral thrombosis, p. 145).

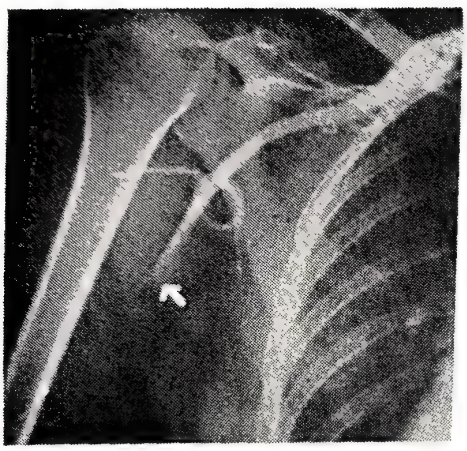

FIG. 153.—Arteriogram showing axillary artery thrombosis in a woman following trauma to the axilla over the headboard of a bed during the second stage of labour.

Treatment. — *Conservative treatment* is employed (*a*) if the embolism is mild and signs of recovery of the circulation are evident (loss of pain, return of movement), (*b*) in cases where the limb is showing early gangrene—too late for embolectomy! (*c*) in rare instances the patient may be unfit for operation (heart failure, etc.). This is now a very rare contraindication since operation may be performed under local anaesthesia and sedation. *Embolectomy* is advised if a main artery is involved, and, generally speaking, within ten hours of the onset of the emergency.

Conservative treatment consists of (1) anticoagulant therapy, (2) treating any cardiac failure or arrhythmia, and (3) employing those vasodilator and other conservative measures which are described in the section on basic principles (p. 130).

Anticoagulant Therapy

Heparin.—This substance is present in body tissues, especially the liver and lung. It is produced by the mast cells, and prolongs the clotting time of blood. Heparin is much the most effective anticoagulant for treating acute thrombo-embolism but must be given intravenously, usually in four-hourly doses of 5000–10 000 units (50–100 mg.), via an indwelling needle or polythene cannula.

Overdosage leads to hæmorrhage, but the effect can immediately be neutralised by an intravenous injection of protamine sulphate. Each ml. of a 1 per cent. solution neutralises 1000 units of heparin.

Synthetic Anticoagulants.—Phenindione B.P. (e.g. Dindevan) and dicoumarol[1]

[1] Dicoumarol was originally discovered in spoiled clover causing hæmorrhagic disease in sheep.

derivatives (e.g. Warfarin or Marevan) depress the blood level of the prothrombin complex. They exert a full effect thirty-six to forty-eight hours after starting therapy, and for twenty-four hours after stopping. A loading dose is given in divided doses (loading dose of phenindione is 200 to 300 mg., Warfarin 30 to 50 mg.). The prothrombin level is estimated on the third day, and the amount given is then revised if necessary. Control is effected by estimation of the prothrombin time, which should be prolonged to two to three times the normal. The interval between estimation may be lengthened when a stable dose is found. These drugs may be useful for long-term administration to reduce incidence of further episodes of thrombo-embolism. They are much less effective for managing the acute episode.

Overdosage is shown by hæmorrhage, especially hæmaturia. Vitamin K_1 (Phytomenadione B.P., *not* the analogue) very quickly reverses the effects of synthetic anticoagulants. It is usually enough to give 10 mg. by mouth, but if bleeding persists, it should be administered by intravenous injection.

Contraindications to the use of anticoagulants include pregnancy, hepatic or renal deficiency, hypertension, or when there is a risk of hæmorrhage, e.g. in cases of peptic ulceration. Atromid should not be given concomitantly.

Combined Anticoagulant Therapy.—Heparin is injected for its rapid effect, and at the same time phenindione is started. When it is judged that the synthetic compound has exerted a full effect, the heparin is discontinued and clotting is controlled by prothrombin estimations (which, incidentally, are not valid within six hours of giving heparin).

Many surgeons prefer to rely upon heparin only, for four to six days before using the synthetic compounds, especially in cases of embolism.

Fibrinolysins.—Fibrinolytic agents (e.g. streptokinase) are useful and may lyse an acute thrombus or embolus without resorting to surgery. They are more effective in acute thrombosis than in embolism and are usually given in an intravenous infusion. Infusion intra-arterially through a catheter whose tip is close to the obstruction is more effective but carries a higher complication rate from hæmorrhage and infection. Infusion of fibrinolysins through a catheter in the right ventricle or pulmonary artery may be very effective in certain cases of severe pulmonary embolism. Certain forms of venous thrombosis (e.g. ilio-femoral) may also be treated. Heparin should not be used concomitantly with fibrinolysins.

Embolectomy and Thrombectomy

Local or general anæsthesia is used, dependent upon the patient's general condition and the scope of the proposed operation. The artery, bulging with clot, is exposed and held up by slings of fine rubber tubing. Through a longitudinal or transverse incision the clot begins to extrude and is removed, together with the embolus (fig. 154). Arterial clamps are applied as bleeding occurs, special note being made of the degree of retrograde bleeding (back bleeding). *Fogarty Catheterisation.* This is the most effective method of removing proximal and distal extension thrombus and also allows an embolus or thrombus to be removed from a vessel remote from the arteriotomy. The Fogarty catheter is like a ureteric catheter, with a balloon tip, and is introduced until it is deemed to have passed the limit of the thrombus. The balloon is inflated and the catheter withdrawn slowly, together with the

FIG. 154.—Aortic embolectomy. The extension-thrombosis extended proximally up to the renal, and distally into the iliac arteries.

Thomas J. Fogarty, Contemporary. Surgeon, University of Oregon Medical School, Portland, U.S.A.

clot. The procedure is repeated until bleeding occurs. The method is valuable in patients with an aortic bifurcation embolus, since the clot and embolus can be extracted by insertion of balloon catheters via the common femoral arteries in the groin and the patient is saved from a laparotomy. Post-operatively, anticoagulant therapy is commenced. *Other special measures* may sometimes be required to extract extension thrombus: (a) application of a spiral rubber bandage from below upwards, (b) retrograde flushing with heparinised Hartman's solution (1,000 units in 150 ml.).

In *axillary artery thrombosis*, it is often necessary to expose and even open the brachial artery at the elbow to be sure that it is free of clot or another embolus.

Papaverine sulphate (1% solution) painted on to the arteries may help to relieve post-operative spasm (Kinmonth).

Air Embolism

Venous.—Air may be accidentally injected into the venous circulation (e.g. artificial pneumothorax), or accidentally sucked into an open vein. Thus venous air embolism occasionally complicates operations on the neck or axilla if a large vein is inadvertently opened, or it may be an accessory cause of death following a cut throat. The risks associated with intravenous infusion are reduced by the use of a drip chamber containing a spherical plastic float which plugs the exit when the fluid falls to a dangerous level (fig. 80).

When air enters the right auricle it is churned up, and the foam enters the right ventricle and causes an air-lock in the pulmonary artery, which may end in right-sided heart failure.

Treatment.—Trendelenburg's position encourages air to pass into the veins of the lower half of the body, and the patient is placed on the left side so that air will float into the apex of the ventricle, away from the pulmonary artery. Oxygen is administered to counteract anoxæmia, and to assist in the excretion of nitrogen. In serious cases the right ventricle should be aspirated by a needle passed upwards and backwards from below the left costal margin. If this fails, the heart is rapidly exposed for aspiration under direct vision.

Air may occasionally enter the left side of the heart, e.g. at open heart surgery, following puncture of a pulmonary vein during artificial pneumothorax or through a patent foramen ovale (paradoxical embolism). It may from there embolise coronary or cerebral arteries. Treatment is along similar lines to venous air embolism.[1]

Fat Embolism.—This condition, which is more common than generally supposed, usually follows severe injuries with multiple or major fractures. Cases have also been recorded following convulsive therapy. The fat may be derived from bone marrow or adipose tissue but recent work suggests that it is metabolic in origin, perhaps by aggregation of chylomicrons. Symptoms are evident a day or so after injury, and two more or less distinct types, cerebral and pulmonary, are recognised. In the cerebral type, the patient becomes drowsy, restless, and disorientated (delirium tremens may be suspected). Subsequently he is comatose. the pupils become small and pyrexia ensues. The pulmonary type is ushered in with cyanosis, which increases in intensity, and signs of right heart failure. White froth may occur at the mouth and nostrils. It may be mistaken for broncho-pneumonia or left ventricular failure.

One of the earliest signs may be emboli in the retinal arteries, which cause striate hæmorrhages and 'fluffy' patches of exudate. The sputum should be examined for fat droplets, and fat may be excreted in the urine. A fall in the hæmoglobin value of the blood is a constant sign. Petechial hæmorrhages often occur.

Treatment consists of oxygen, early heparinisation, and intravenous low molecular-weight dextran (Rheomacrodex, p. 77). Intravenous 5 per cent. dextrose solution with 5 per cent. alcohol is supposed to increase the emulsifying power of the blood and reduce the size of fat globules. Hypothermia may be of use.

Other forms of emboli include *Infective emboli* of masses of bacteria or infected clot, which may cause mycotic aneurysms (p. 136), pyæmia, or infected infarcts, *Parasitic emboli* due to the ova of *Tænia echinococcus*—and *Filaria sanguinis hominis* (p. 44), and emboli of *malignant cells* (e.g. hypernephroma, Chap. 54).

[1] Air embolism is also a risk following Fallopian tube insufflation, and following illegal abortion. The air may travel to the brain via the paravertebral veins.

John Bernard Kinmonth, Contemporary. Professor of Surgery, St. Thomas's Hospital and University of London.
Gabriele Fallopio, 1523–1562. Professor of Anatomy, Surgery and Botany, Padua, Italy.

Caisson and Decompression Disease.—These similar conditions may affect divers, those who work in compressed air chambers, or who ascend in open aeroplanes to above 25,000 feet (7 620 m). If decompression is too rapid, bubbles of nitrogen are set free in the tissues and blood-stream, and occlude small vessels. Symptoms include pain in the muscles or joints, which may be excruciating (the ' bends '), and neurological disturbances; if the spinal cord is affected the patient suffers from weakness of the legs and sphincters. In severe cases, the lungs may be affected, and the patient complains of tightness of the chest and a dry cough (the ' chokes '). Caisson disease requires recompression and gradual decompression. The high altitude flyer is relieved by gradual descent. Inhalation of oxygen assists the excretion of nitrogen. If the spinal cord is not permanently damaged the prognosis is good, but hypertrophic changes may persist in the ends of long bones.

ATHEROSCLEROTIC OBSTRUCTION

The reader is advised to refer to the section on basic considerations and principles of arterial surgery (pp. 122–133) in conjunction with the following.

The Legs.—Patients with atherosclerotic obstruction of the arteries to the legs comprise the majority of cases of peripheral vascular disease. It is to be remembered that the condition is part of a generalised disease, so that while the patient may present with symptoms in the legs, there may be manifestations in the coronary, carotid, or cerebral vessels. The patient is usually fifty years old or over, but a ' pre-senile ' variety may occur in early adult life, which must be distinguished from Buerger's disease (p. 150). Non-smokers are rarely affected. The incidence in males is much greater than that in females but this is changing. The increasing number of females may be associated with the increase in the smoking habit among women.

The symptoms are described on p. 123. They are caused by ischæmia, so they occur when the lumen of the artery (aorta, iliac, femoral, or popliteal) becomes severely diminished, or finally obstructed. As stenosis and occlusion occur, the collateral circulation usually has time to develop, and any episode of worsening of symptoms may be followed by a phase of improvement. Eventually, even the ostia of the collateral branches become obstructed, and should further thrombosis occur, rest pain and gangrene will follow (about 10 per cent. of patients). Sixty per cent. of the patients ultimately die from coronary thrombosis, 12 per cent. from congestive cardiac failure, and 12 per cent. from cerebral thrombosis or hæmorrhage.

The signs are described on p. 125 and the relationship of these clinical findings to the sites of disease are given on p. 127.

Arteriography (p. 128) is essential to show the exact site and the extent of the obstruction, as well as the presence of multiple lesions. It should, however, be performed only if surgical treatment is indicated.

The treatment policy depends upon (1) the degree of disability, (2) the general condition of the patient, and (3) the feasibility of an operation as shown by arteriography.

(1) *The Degree of Disability.*—Rest pain and early gangrene are severe degrees of disability, and demand an attempt to salvage the leg. The disability of claudication is, however, very variable. Some patients with a walking distance of fifty yards may be content to restrict their activities within such a limit. Others, such as business executives, keen walkers, golfers,

and gardeners complain that a distance of 300 to 400 yards (275–365 m) is intolerable, and they are reluctant to sacrifice either position or enjoyment.

(2) *The General Condition of the Patient.*—The absolute contraindications to operation are heart failure, severe bronchitis and emphysema, open tuberculosis, and advanced malignant disease. A recent coronary thrombosis or cerebral thrombosis (within 6 months), are temporary contraindications. Special care is required if a patient has an active peptic ulcer, since the stress occasioned by the operation (or even the arteriogram) may cause it to bleed. The ulcer requires priority treatment.

(3) *The Feasibility of Direct Arterial Surgery* to restore an adequate circulation depends upon the evidence given by arteriography of the site and extent of the obstructive disease. There should be no major stenosis proximal to the proposed upper limit of operation (e.g. in the iliac arteries when femoro-popliteal reconstruction is completed). There should preferably be a good 'run off' below the distal limit of reconstruction. Obstruction to the calf arteries below a femoro-popliteal reconstruction will reduce the success rate of the operation in both short and long term. Salvage of a gangrenous limb may be achieved by vein by-pass grafting into a short patent segment of popliteal artery even when all the calf arteries are seen to be occluded distally. Vein grafting into isolated calf arteries e.g. posterior tibial artery near the ankle or peroneal artery in mid-calf, may be tried when the popliteal artery is completely occluded to hope to avert a major amputation; it should be noted that these are salvage operations and *should not* be performed for intermittent claudication alone. Gangrene and loss of limb may result if the operation should fail.

Profundaplasty.—A patent profunda femoris artery will provide an adequate 'run off' for operation on an iliac artery occlusion even in the presence of a concomitant femoro-popliteal occlusion. If it be stenosed at its origin, it can be widened by the insertion of a patch of vein, a procedure which will usually salvage a threatened limb. In those cases in which it proves insufficient, femoro-popliteal reconstruction may be performed later.

Conservative Treatment as outlined on page 130 is advised if the disability is mild, and/or the general condition of the patient is poor. It is also advised when an operation is not technically feasible or following the failure of a previous operation.

Operation

Aortic or Aortic-iliac Occlusion.—Thrombo-endarterectomy or Dacron by-pass grafting are both effective procedures. Thrombo-endarterectomy may be used for short localised lesions and Dacron by-pass grafts for more extensive blocks. A knitted Dacron bifurcation graft is a commonly used prosthesis. End-to-end or end-to-side anastomoses may be used but the latter are usually the simpler, and more convenient. The distal anastomoses should be to the external iliac arteries within the pelvis if possible, but if these arteries are involved by disease the distal anastomoses can be made to the common femoral arteries below the inguinal ligaments or even direct to the profunda femoris arteries.

Femoro-popliteal Artery Occlusions.—Vein by-pass grafting or thrombo-endarterectomy are suitable. Modern practice usually prefers vein by-pass grafting for their management, utilising thrombo-endarterectomy for short localised obstructions of 2–3 cm or longer blocks when a suitable vein is not available. Whichever method is used its distal limit should not be behind the knee-joint since arteriotomies at this point usually fail rapidly. When the distal limit of the reconstruction is above the knee-joint an 8–10 mm Dacron prosthesis may be used for by-pass grafting instead of a vein. When the distal anastomosis is below the knee-joint vein by-pass grafting is much superior to either thrombo-endarterectomy or Dacron prosthetic grafting. Vein grafting should always be used if the distal anastomosis must be made to one of the calf arteries.

Aorto-iliac Endarterectomy.—The abdomen is opened by an incision (p. 138), the intestines are eviscerated into a polythene bag, the aorta and iliac arteries are exposed and lifted up by slings of fine rubber tubing so that the clamps can be applied. The aorta is incised, and after any red jelly-like mural thrombus has been extracted, the inner atheromatous layer is peeled out, leaving an outer layer of media and adventitia. This procedure is carried down the iliac vessels until a satisfactory lumen and 'bleed-back' is obtained. Should an intraluminal thrombus extend up to the level of the renal arteries (as in Leriche's syndrome, p. 125), it is milked or scraped out while pressure from a thumb occludes the aorta and protects the renal vessels. The arteriotomies are closed with a continuous 000 polypropylene suture after carefully tacking down the divided intima with one or two interrupted 0000 sutures at the lower limit of the reconstruction. *As a precaution against extension thrombosis* (p. 142) below the clamped-off iliac arteries many surgeons give intravenous heparin 2,500–5,000 units just before clamping the aorta. It is also a wise precaution to pass a Fogarty catheter (p. 143) down the distal arteries to remove any extension thrombus which may have formed, just prior to closure of the arteriotomies. The midline incision in the abdomen is best closed by interrupted non-absorbable sutures.

Aorto-iliac By-pass (p. 133).—The abdomen is opened and the aorta and iliac arteries dissected as above. Heparin 2,500–5,000 units is given i.v. and the aorta and iliac arteries cross-clamped. The aorta is opened at a convenient point below the renal arteries, by a 5 cm longitudinal incision. After removal of mural thrombus a suitably sized (usually 16 × 8 mm) knitted Dacron bifurcation graft is selected. The stem of the graft is stretched and divided so that the bifurcation of the graft will correspond with the bifurcation of the patient's aorta when the graft is inserted—this avoids any 'concertina-effect' from too long a graft. The cut in the stem of the graft should be made obliquely to produce a 'comfortable lie' and is sutured end-to-side with a continuous 000 silk or polypropylene suture to the aortic incision. Knitted grafts are porous and at this point the graft should be 'clotted' by releasing the aortic clamp sufficiently to fill it with blood. Disease-free segments of the external iliac arteries are selected and each is opened by a 1·5–2 cm longitudinal incision. When the graft and its proximal anastomosis are fully blood-tight, each limb of the graft is stretched and divided obliquely, so that the completed anastomoses are not under tension. The limbs of the graft are taken retro-peritoneally and anastomosed to the iliac arteriotomies by a 0000 continuous suture. On the left side this will necessitate taking the graft behind the sigmoid mesocolon. Fogarty catheterisation (p. 143) of the distal vessels may be performed just prior to completion of the anastomoses. If the external iliac arteries are diseased the limbs of the graft may be taken behind the inguinal ligament and anastomosed to the femoral arteries in the groin, which will have been displayed through separate inguinal incisions.

Femoro-popliteal vein by-pass grafting.—The patient is positioned and the incision made according to fig. 155 so as to expose the long saphenous vein, the femoral artery and its branches in the groin, and the popliteal artery below the obstruction (either above or below the knee). Once the limits of the arterial occlusion have been confirmed the long saphenous vein is divided at the sapheno-femoral junction. A suitable length of

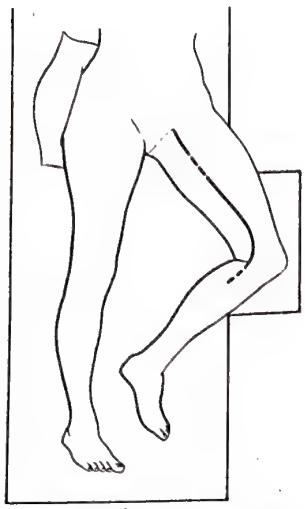

FIG. 155. — Position and incision for femoro-popliteal artery operations.

vein is then removed taking care to dissect and tie each tributary with fine silk ligatures. The graft should preferably be 5 cm or so longer than the length of the arterial obstruction to allow for wastage when fashioning the ends for anastomosis. The vein is fully distended to its maximal diameter using warm heparinised Hartmann's solution. A good vein will be 5 mm or more in diameter—veins smaller than 4 mm diameter give poor long-term results. 2,500–5,000 units of heparin is given i.v. and the common femoral and profunda femoris arteries cross-clamped. The common femoral artery is opened by a 2–3 cm longitudinal incision opposite the mouth of the profunda femoris artery. This should be inspected since stenosis of its ostium is common and not always visible on the standard views taken at arteriography (Martin). Ostial stenosis should be treated by progressive dilatation or by a local endarterectomy. The distal end of the long saphenous vein is cut obliquely and anastomosed to the femoral arteriotomy with a 0000 silk or polypropylene suture. Special care must be taken not to narrow the vein at this point or early graft failure will result. The graft is laid subcutaneously and its reversed proximal end bevelled and sutured to a 2–3 cm longitudinal arteriotomy in a disease-free area of popliteal artery. A good back-bleed should be present. If the distal anastomosis is made below the knee joint it is best to tunnel the graft through the popliteal fossa alongside the occluded popliteal artery. The knee should be straightened when measuring

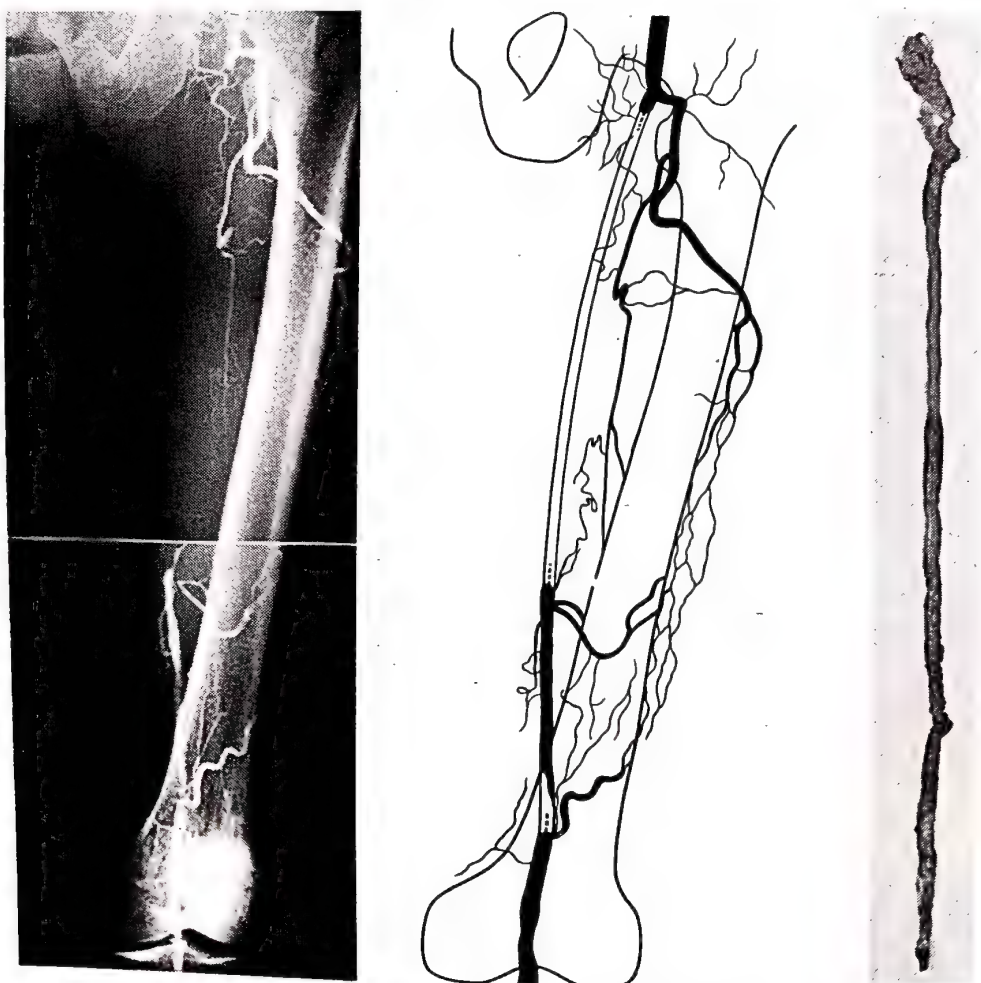

FIG. 156.—Thrombo-endarterectomy (' disobliteration ' or ' rebore ') from the common femoral to the popliteral artery. The sites of arteriotomy are indicated by dotted lines. The core was removed through these arteriotomies.

Peter Guy Cutlack Martin, Contemporary. Formerly Surgeon, Hammersmith Hospital, London.

the length of graft required since a short graft under tension will result in early failure.

Femoro-popliteal thrombo-endarterectomy (disobliteration or rebore).—The artery is opened by longitudinal incisions at the upper and lower limits of the obstruction. The 'core' is dissected out, separated and removed. This is achieved by placing an endarterectomy loop over the lower end and pushing this upward along the diseased segment to emerge at the upper arteriotomy (fig. 157). Several arteriotomies may be required. The distal intima must be tacked down with interrupted sutures. The arteriotomies are usually closed with vein patches (p. 133). Short blocks of 2–3 cm are removed through a single arteriotomy by direct dissection.

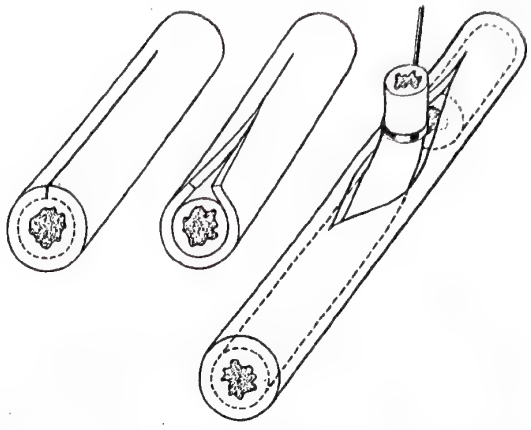

FIG. 157.—Commencement of disobliteration. An incision through the outer layer of media discloses a plane of cleavage and the core of atheroma and thromus. The core is then threaded through the endarterectomy loop.

Results of Operation.—The long term results of aorto-iliac reconstructive surgery are excellent. They are usually only marred by progressive disease producing femoro-popliteal occlusions at a later date. Femoro-popliteal surgery is less successful. The immediate post-operative success rate for vein by-pass approaches 90%. Many cases fail in the first eighteen months after operation and at the end of five years the success rate is usually only 50–60%. The results of thrombo-endarterectomy are less good in both short and long term and Dacron by-pass gives the poorest result with five year success rates of only 20–30%. The rather poor long term results of femoro-popliteal surgery emphasise that these operations should only be used for clear indications.

Other Arterial Operations

(i) *Femoro-femoral crossover graft* is useful for relieving an iliac artery occlusion when the other iliac artery is patent with a strong femoral pulse. An 8 mm Dacron graft is tunnelled subcutaneously above the pubis and anastomosed end-to-side to the common femoral arteries on each side. Blood from the patent iliac system is then carried through this graft to vascularise the ischæmic limb.

(ii) *Axillo-femoral graft*—useful for salvaging a pre-gangrenous limb in a poor risk patient with bilateral iliac obstruction. A long 8 mm Dacron graft is tunnelled subcutaneously, from an end-to-side anastomosis with the axillary artery proximally, to reach the femoral artery of the involved limb in the groin where the distal anastomosis is made. The axillary artery will carry a sufficient volume of blood to maintain the circulation in the arm and re-vascularise the lower limb. The short term results are usually good and in these patients with their poor general condition, the poorer long term result is usually less important.

(iii) *Hitch-hike femoro-popliteal-tibial graft.*—A Dacron graft connects the common femoral artery to a rebored section of the upper popliteal artery. A vein graft connects the rebored section to arteries below the knee.

Adjuncts to Direct Arterial Surgery

(i) Lumbar sympathectomy in conjunction with direct arterial surgery, especially if the 'run-off' is poor. The other indications for sympathectomy are considered on p. 134.

(ii) Reserpine 1 mg by intra-arterial injection at the completion of the operation to promote vaso-dilatation and increased flow through the reconstruction during the first 2–3 days after operation.

(iii) Blood-flow estimations (by flowmeter), or on-table arteriography at the completion of the operation are useful techniques for ensuring that there have been no errors of surgical technique before the wound is closed.

(iv) Conservative amputation of gangrenous digits at the same time as direct arterial surgery.

Major Gangrene (see p. 154) will require a radical amputation (p. 156) but arterial surgery may sometimes be justified to enable a more distal amputation to be performed.

Other Sites of Atherosclerotic Obstruction.—The principles of arterial surgery can be applied to other arteries which are stenosed by the disease.

Carotid stenosis causes transient, recurrent, and progressive 'strokes' (hemiplegia). On the contralateral side to the stroke, a carotid arteriogram will show either a local stenosis at the origin of the internal carotid artery, or a complete obstruction of that artery up into the skull, to where the ophthalmic artery enters as a collateral. Only a local stenosis is suitable for the disobliteration and vein-patch operation. Special measures may be necessary to prevent cerebral damage occurring while the clamps are in place; postural hypertension (operating with the patient tilted head down) can be used, but a temporary polythene by-pass may be required.

Vertebral artery stenosis, causing basilar artery 'strokes' of giddiness and impairment of vision, may be demonstrated by arch arteriography (p. 128). Operation by widening of the lumen by vein-patch graft without removing the stenosis is sometimes performed.

Subclavian artery stenosis causes pain and a feeling of coldness in the arm and hand. Small patches of thrombus and atheroma break off as emboli, and occlude the arteries of the forearm, hand, and fingers. Resection and grafting, or disobliteration, may be performed.

Subclavian Steal Syndrome.—If the first part of the subclavian artery is obstructed, the vertebral artery provides collateral circulation to the arm, and its flow is reversed, as is demonstrated by arteriography. The cerebral circulation is diminished, hence the term 'steal'. Clinical features include syncopal attacks, visual disturbances, and diminished pulse and blood pressure on the affected side. A Dacron by-pass of the affected part of the subclavian artery, or thrombo-endarterectomy (rebore), relieves the symptoms. To avoid opening the chest the graft is usually taken from the common carotid artery of the affected side and anastomosed to the easily accessible third part of the subclavian artery.

Mesenteric Artery Stenosis.—Post-cibal central abdominal pain in a patient with atherosclerosis elsewhere may be shown by an arteriogram (lateral view) to be due to stenosis of the origin of the superior mesenteric artery. Usually the collateral circulation via the inferior mesenteric artery or cœliac artery has already been obstructed. The pain occurs so soon after food that the patient is afraid to eat. This classical syndrome is however a very rare cause of post-cibal pain. A by-pass graft is led from the aorta to the superior mesenteric artery, distal to the stenosis.

Renal artery stenosis may be responsible for some cases of hypertension (fig. 128). If the function of the kidney is satisfactory, the stenosis may either be disobliterated or by-passed (fig. 158).

Coronary artery disease.—See Chapter 39.

ARTERITIS

Thrombo-angiitis Obliterans (Buerger's disease):

This is a condition characterised by occlusive disease of the small and medium size arteries (plantars, tibials, radial, etc.), thrombophlebitis (fig. 168) of superficial or deep veins, and Raynaud's phenomena occurring in male patients in a young age group (usually under the age of 30 years). Usually one or two of the three manifestations are present and occasionally all three.

Leo Buerger, 1879–1943. Professor of Urologic Surgery, New York Polyclinic Medical School, New York, U.S.A. Described Thrombo-Angiitis Obliterans in 1908.

The condition does not occur in women or non-smokers. It is not, as used to be stated, more common in Russian Jews. Cases are seen in different races all over the world. Histologically, localised inflammatory changes occur in the walls of arteries and veins leading to thrombosis.

The usual symptoms and signs of arterial occlusive disease will be present. Progression to gangrene of toes and fingers is common.

Arteriography sometimes shows a characteristic 'corrugation' of the femoral arteries as well as the distal arterial occlusions and helps to distinguish the condition from pre-senile atherosclerosis.

Other forms of arteritis (e.g. polyarteritis nodosa) must be excluded.

Treatment.—The treatment is total abstinence of smoking, i.e. 'You can have your cigarettes or your legs, but you can't have both'! This will arrest the disease but not, or course, reverse established arterial occlusions. Reduction in smoking is not sufficient to prevent the otherwise relentless progression of this disease. Established arterial occlusions must be treated along the usual lines. Direct arterial surgery is not usually applicable and sympathectomy is the most useful surgical procedure. It often results in the healing of ischæmic ulcers and improvement in skin nutrition, with relief of pain. Amputations, conservative if possible, may be required.

Bilateral adrenalectomy and steroid therapy has been popular on the continent of Europe for many years. Striking successes are claimed in half of the cases.

Other types of arteritis are encountered in rheumatoid arthritis, diffuse lupus erythematosis, and polyarteritis. Treatment is similar. *Diabetes* is discussed on p. 158. *Temporal arteritis or occipital arteritis*, which is a local collagen disease causing headache and sometimes retinal vessel changes, may be relieved when the tender thrombosed artery is excised for biopsy purposes. *Takayasu's arteriopathy* (obliterative arteritis of females, pulseless disease) causes narrowing and obstruction of major arteries and usually pursues a relentless course (fig. 158).

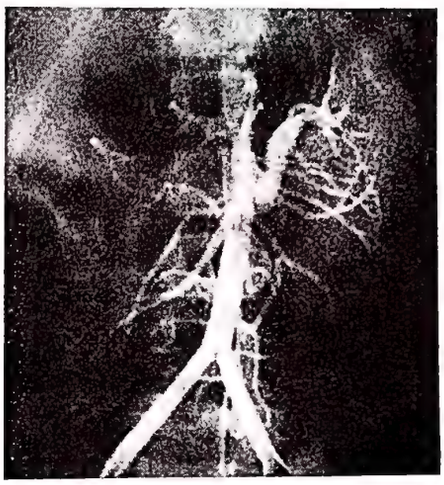

FIG. 158.—A by-pass vein graft from the aorta to the left renal artery in a little girl with bilateral renal artery stenosis, causing hypertension. The subclavian and other arteries were also occluded by Takayasu's arteriopathy (see text).

Cystic Myxomatous Degeneration.—Instances of an accumulation of clear jelly (like a synovial ganglion) in the outer layers of a main artery have been reported, e.g. the popliteal artery. The lesion so stiffens the artery that pulsation disappears, and claudication occurs when the limb is flexed (as on walking up stairs). Arteriography shows a smooth narrowing of an otherwise normal artery, and a sharp kink, or buckling, when the knee is flexed. Decompression, by removal of the myxomatous material, is all that is required, but the 'ganglion' may recur and require excision of part of the arterial wall and a vein-patch repair.

VASOSPASTIC CONDITIONS

Raynaud's disease usually occurs in young women, and affects the upper extremities more than the lower. The peripheral pulses are normal. The condition is attributable to abnormal sensitivity in the direct response of the arterioles to cold. When cooled, these vessels go into spasm, and as

M. Takayasu, 1871– . A Japanese Ophthalmologist who studied in Tokyo, St. Thomas's Hospital, London and Breslau. (Conjoint M.R.C.S., L.R.C.P., 1896). Published paper on Takayasu's Disease in 1908.

Maurice Raynaud, 1834–1881. Physician, Hôpital Lariboisière, and Professor Agrégé, Paris. Published his thesis 'De L'Asphyie Locale et La Gangrène Symetrique des Extrémités' in 1862.

a result the part becomes blanched and incapable of finer movements. The decreased blood flow causes an accumulation of metabolites in the capillary circulation. The capillaries dilate and become filled with slowly flowing deoxygenated blood, the part therefore becomes swollen and dusky. As the attack passes off, the arterioles relax, oxygenated blood returns into the dilated capillaries, the hands become red and a burning sensation or pain is produced by increase in tissue tension. Thus the condition is recognised by the characteristic sequence of blanching, dusky cyanosis and red engorgement. Eventually, in a minority of patients, obliterative changes may occur in the peripheral vessels, superficial necrosis occurs, the tips of the fingers undergo dry gangrene, and the distal parts of the terminal phalanges are absorbed. Early cases of Raynaud's disease must be distinguished from chilblains and vascular disturbances which are sometimes associated with the costoclavicular (cervical rib and the scalene) syndrome (Chap. 32).

Treatment.—*Conservative.*—Protection from cold, avoidance of pulp and nail-bed infections, and the use of vasodilator drugs are part of the conservative regimen that is advised for mild cases.

Peacock's regime consists of oral administration of small doses of triiodothyronine (5 μg t.d.s.) and reserpine (p. 131) and may help some cases. Severe persistent attacks may sometimes occur in cold weather. These can usually be relieved by hospitalisation and either (i) intra-arterial injection of reserpine (1 mg in 10 ml normal saline by slow injection into the brachial artery) or (ii) intravenous infusion of low molecular weight dextran (500 ml per day for 5 days). Heparin may enhance the effect of the dextran (Walder).

Sympathectomy.—The immediate results of sympathectomy are good, but after a few months the susceptibility to cold returns, although cyanosis is not so severe as before the operation, and subjective symptoms are less marked. This partial relapse is an indication that the underlying cause of Raynaud's disease is not in the sympathetic system, but is due to some abnormality in the smaller arteries and arterioles; sympathectomy apparently raises the threshold at which spasm occurs. From the practical point of view preganglionic section of the thoracic sympathetic chain can be recommended as a palliative procedure in Raynaud's disease, especially if performed before the onset of ulceration and absorption of the terminal phalanges.

Raynaud's Phenomenon.—Peripheral vasospasm also occurs secondarily to other organic diseases such as atherosclerosis, collagen diseases—especially scleroderma, Buerger's disease, cervical rib, etc. It also follows the use of industrial tools, e.g. pneumatic road drills and chain saws, which vibrate at certain frequencies. Also, in the arm, atherosclerotic stenosis of the subclavian artery (p. 150), scleroderma, Buerger's disease (p. 150), or cervical rib and the scalene syndrome (Chap. 32) may be responsible. Treatment is directed primarily to these causal lesions, though the conservative measures outlined above are often helpful. Sympathectomy may occasionally be required but it is not very helpful in scleroderma.

Raynaud's phenomena may also occur secondarily to atrophic changes in a limb, e.g. *after poliomyelitis, following trauma*, e.g. arthrodesis of a peripheral joint, crushing

Joseph Henry Peacock, Contemporary. *Professor of Surgical Science, Bristol University, England.*
Dennis Neville Walder, Contemporary. *Professor of Surgical Science, Newcastle-upon-Tyne, Tyne and Wear.*

injuries, etc., in cases of *severe chilblains* (perniosis) and *following frostbite*. The mechanism of the cold sensitivity in these cases is obscure but in most instances good results follow sympathectomy.

Acrocyanosis may be confused with Raynaud's disease, but this condition is painless and is not paroxysmal. It occurs in young females, and the cyanosis of the fingers, and especially the legs, may be accompanied with paraesthesia and chilblains. In severe cases sympathectomy may be necessary, and gives good results.

Sympathectomy

Preganglionic Cervico-dorsal Sympathectomy.—(*a*) *Supraclavicular Method*—Through a supraclavicular incision, the clavicular part of the sternomastoid, the posterior belly of the omo-hyoid, and the scalenus anterior muscles are divided, the phrenic nerve being displaced inwards. The subclavian artery is exposed, and the thyro-cervical trunk is divided. The subclavian artery is depressed and the supra-pleural fascia is divided, so that the dome of the pleura can be displaced downwards. The stellate ganglion is identified as it lies on the neck of the first rib (fig. 159). The sympathetic trunk is traced downwards and divided below the third thoracic ganglion.

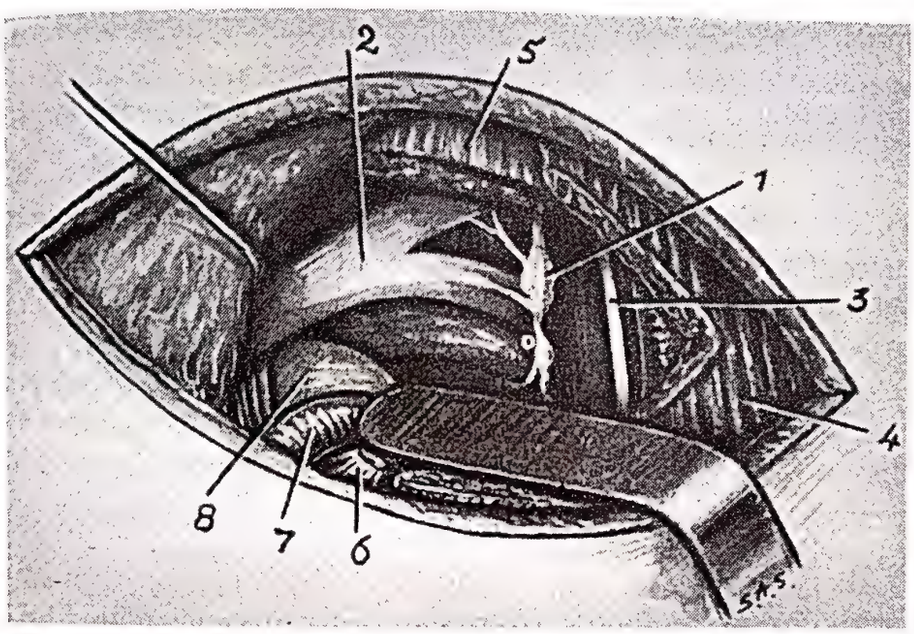

FIG. 159.—Exposure of the right cervicodorsal sympathetic chain from the front.

1. Stellate ganglion.
2. Lower trunk of brachial plexus.
3. Phrenic nerve displaced inwards.
4. Partially divided sternomastoid muscle.
5. Divided scalenus anticus muscle.
6. Divided posterior belly of the omo-hyoid.
7. Subclavian artery displaced downwards.
8. Dome of the pleura.

All rami communicantes associated with the second and third ganglia and the nerve of Kuntz, a grey ramus running upwards from the second thoracic ganglion to the first thoracic nerve, are meticulously divided.

(*b*) *Transthoracic Method.*—This gives a greater exposure and facilitates the removal of the sympathetic chain from the fifth ganglion up to the lower fringe of the stellate ganglion. It tends to give better results than (*a*), and can be employed when (*a*) has failed. In women where cosmetic effects are a consideration, the approach can be made via an axillary incision through the third space (Hedley Atkins). The sympathetic chain is easily seen and after dividing the pleura, it is dissected out, care being taken to avoid damage to the intercostal vessels, which may cause tedious haemorrhage. Care should also be taken, when making and suturing the approach wound, to avoid damage to the nerve to serratus anterior, giving rise to 'winging' of the scapula.

Lumbar Sympathectomy.—Using a transverse loin incision, an extra peritoneal approach is used in which the colon and peritoneum, to which the ureter clings, are

Albert Kuntz, 1879–1957. Professor of Anatomy, St. Louis, Missouri, U.S.A.
Sir Hedley John Barnard Atkins, Contemporary. Past President, The Royal College of Surgeons of England. Emeritus Professor of Surgery, Guy's Hospital, London.

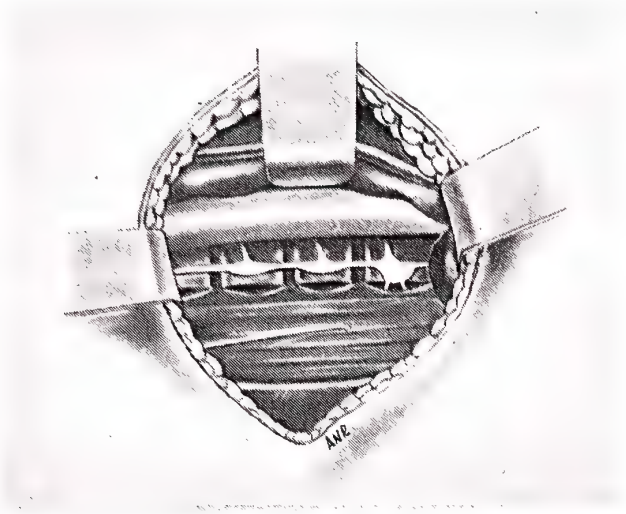

FIG. 160.—Left lumbar sympathectomy. The central retractor is holding back the peritoneum and ureter to expose the aorta and the psoas muscle, between which lies the sympathetic chain. Note that the second lumbar ganglion, adjacent to the lower pole of the kidney, has connecting rami to the spinal cord. The genitofemoral nerve is seen emerging through the fibres of the psoas.

stripped inwards so as to expose the inner border of the psoas muscle (fig. 160).

The sympathetic trunk lies on the sides of the bodies of the lumbar vertebræ, and on the right side is overlapped by the vena cava. Lumbar veins are apt to cross the trunk superficially. The sympathetic trunk is divided on the side of the body of the fourth lumbar vertebra, and is traced upwards to be divided above the large second lumbar ganglion, which is easily recognised by the number of white rami which join it. Care should be taken not to mistake small lymph nodes, lymphatics, the genitofemoral nerve or the occasional tendinous strip of the psoas minor for the sympathetic chain.

Occasionally both sides are done at one session.

GANGRENE

Gangrene implies death with putrefaction of macroscopic portions of tissue. It is commonly seen affecting the distal part of a limb, the appendix, a loop of small intestine, and sometimes organs such as the gall-bladder, the pancreas, or the testis. Note that the term 'necrosis' applies mainly to the death of groups of cells, though it is extended to include bone, i.e. a 'sequestrum'. A 'slough' is a piece of dead soft tissue, e.g. skin, fascia, or tendon.

VARIETIES OF GANGRENE ACCORDING TO CAUSE

1. Secondary to arterial obstruction from disease,[1] e.g. thrombosis of an atherosclerotic artery; embolus from the heart in auricular fibrillation or after coronary thrombosis; arteritis with neuropathy in diabetes; Buerger's disease; arterial shut-down in Raynaud's disease, and ergotism; the effect of intra-arterial injections—thiopentone and cytotoxic substances.

2. Infective: Boils and carbuncles, gas gangrene, gangrene of the scrotum.

3. Traumatic:

(*a*) *Direct*, such as crushes, pressure sores, and the constriction groove of strangulated bowel.

(*b*) *Indirect*, due to injury of vessels at some distance from the site of gangrene, e.g. pressure on the popliteal artery by the lower end of a fractured femur.

4. Physical, e.g. burns, scalds, frostbite, chemicals, irradiation and electricity.

5. Venous Gangrene (p. 161).

[1] A classical mnemonic (aid to memory) for these causes is the word 'RESTED', signifying: Raynaud, Ergot, Senile, Thrombosis, Embolism, Diabetes.

CLINICAL FEATURES OF GANGRENE (Figs. 126 and 127)

A gangrenous part lacks arterial pulsation, venous return, capillary response to pressure (colour return), sensation, warmth, and function. The colour of the part changes through a variety of shades according to circumstances (pallor, dusky grey, mottled, purple) until finally taking on the characteristic dark brown, greenish black, or black appearance which is due to the disintegration of hæmoglobin and the formation of iron sulphide.

Clinical Types.—Dry gangrene and moist (wet) gangrene.

Dry gangrene occurs when the tissues are desiccated by gradual slowing of the blood-stream, and typically occurs as a result of atherosclerosis, e.g. senile gangrene. The affected part becomes dry and wrinkled, discoloured from disintegration of hæmoglobin, and greasy to the touch.

Moist gangrene occurs when venous as well as arterial obstruction is present, when the artery is suddenly occluded, as by a ligature or embolus, and in diabetes. Infection and putrefaction are always present, and the affected part becomes swollen, discoloured, and the epidermis may be raised in blebs. Crepitus may be palpated, due to infection by gas-forming organisms. Moist gangrene is manifest also in such conditions as acute appendicitis and strangulated bowel.

SEPARATION OF GANGRENE

Separation by Demarcation.—A '*zone of demarcation*', between the truly viable and the dead or dying tissue, appears first. It is indicated on the surface by a band of hyperæmia and hyperæsthesia. Separation is achieved by the development of a layer of granulation tissue which forms between the dead and the living parts. These granulations extend into the dead tissue, until those which have penetrated farthest are unable to derive adequate nourishment. Ulceration follows, and thus a '*final line of demarcation (separation)*' forms which separates the gangrenous mass from healthy tissue.

In dry gangrene, if the blood supply of the proximal tissues is adequate, the final line of demarcation appears in a matter of days and separation begins to take place neatly and with the minimum of infection (so-called separation by aseptic ulceration). Where bone is involved complete separation takes longer than when soft tissues alone are affected, and the stump tends to be conical as the bone has a better blood supply than its coverings.

In moist gangrene there is more infection, and suppuration extends into the neighbouring living tissue, thus causing the final line of demarcation to be higher than in dry gangrene (separation by septic ulceration). This is why dry gangrene must be kept as dry and aseptic as possible, and every effort should be made to convert moist gangrene into the dry type.

Vague Demarcation. Spread of Gangrene.—In many cases of gangrene from atherosclerosis and embolism, the line of final demarcation is very slow to form or does not develop. Unless the arterial supply to the living tissues can be improved (pp. 122–133), the gangrene will spread to adjacent tissues or toes, or will suddenly appear as 'skip' areas further up the limb. Signs of skipping should always be carefully looked for.

Black patches suddenly appear, perhaps on the other side of the foot, on the heel, on the dorsum of the foot, in front of the ankle, and in the calf. *Infection*, being another cause of the spread of gangrene, may spread upwards beyond the line of separation along the lymphatic vessels or cellular tissue into healthy parts, and extensive inflammation then results. Except in diabetic gangrene without concomitant atherosclerotic obstruction, these forms of spread do not usually respond to efforts to save the limb, and an above-knee amputation is then necessary. To attempt local amputation in the phase of vague demarcation is to court failure, as gangrene reappears in the skin-flaps (die-back).

TREATMENT OF GANGRENE

General Principles.—*A limb-saving attitude* is needed in most cases of symptomatic gangrene affecting hands and feet. The surgeon is concerned with how much can be preserved or salvaged.[1] With arterial disease, so much depends upon there being a good blood supply to the limb above the gangrene, or whether a poor blood supply can be improved by such measures as direct arterial surgery (p. 133) or interruption of the sympathetic nerve supply (p. 134). A good or improved blood supply indicates that a conservative excision is likely to be successful and a major amputation may be avoided. *A life-saving amputation* is required for a badly crushed limb, rapidly spreading symptomatic gangrene, and gas gangrene.

General treatment includes that of cardiac failure, atrial fibrillation, and anæmia, in order to improve the tissue oxygenation. A nutritious diet, essential in all forms of gangrene, and the control of diabetes when present, are additional items of care. Pain, especially night pain, may be difficult to relieve. Non-addictive drugs should be used whenever possible.

Local Treatment.—(*a*) *Care of the affected part* includes keeping it absolutely dry. Exposure, and the use of a fan may assist in the desiccation and may relieve pain. *The limb must not be heated.*

(*b*) *Protection of local pressure areas*, e.g. the skin of the heel or the malleoli, otherwise fresh patches of gangrene are likely to occur in these places. A bed-cradle, padded or Sorbo rings, foam P.V.C. blocks, or a 'sheepskin', (Acrilan)[2] are useful preventive aids.

(*c*) *Minor Surgical Toilet.*—Careful observation of a gangrenous part will show whether the lifting of a crust, or the removal of hard or desiccated skin, will assist in demarcation, the release of pus and the relief of pain.

Amputations of the Leg for Gangrene.—These may be conservative, radical (definitive) and semi-conservative (compromise), and as stated above, the indications depend upon the blood supply of the part of the limb immediately adjacent.

[1] Sir William Fergusson (1808–1877), Surgeon, Royal Infirmary, Edinburgh, later Professor of Surgery, King's College Hospital, London, said that amputation is 'one of the meanest, and yet one of the greatest operations in surgery: mean, when resorted to where better may be done—great, as the only step to give comfort and prolong life'.

[2] A sheepskin or a large pelt made of washable fibre ('Acrilan' pad made by Northpads, London). The air pockets in wool make it specially resilient to pressure, so these pads may be used wherever areas need protection. The idea stems from cattle and sheep ranches where saddle-sores on horses are prevented by the interposition of a sheepskin.

(*a*) *Conservative.*—There need be no undue haste to remove a dry, painless, gangrenous toe when the final line of demarcation is satisfactory. A diabetic or frostbitten part can in theory be left to separate. An excision through the line of demarcation is usually performed when separation is proceeding well. These wounds are left open to heal by granulation (fig. 161). If bone and tendons are to be sectioned at a higher level, this can be done through the cuff of skin and soft tissue. Special flaps are not fashioned in conservative amputations unless a portion of a foot or the forefoot is to be removed. A trans-metatarsal amputation (fig. 162) is only possible when there is

FIG. 161.—Conservative amputation for diabetic gangrene.

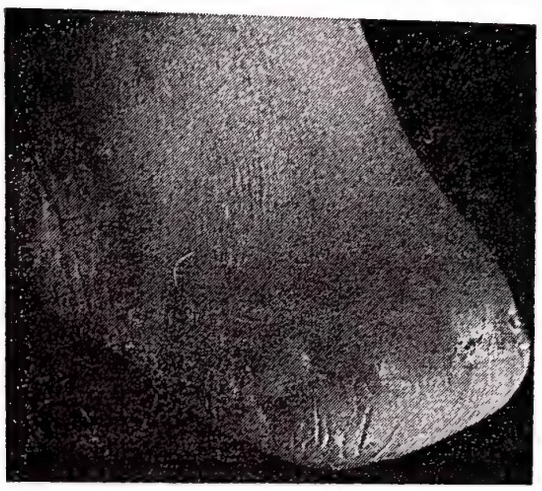

FIG. 162.—Trans-metatarsal amputation for diabetic gangrene of the toes.

a viable long plantar flap extending almost to the base of the toes. This must be wrapped round the severed forefoot and sutured to the dorsal skin. A long dorsal flap cannot withstand the subsequent trauma from a shoe.

(*b*) *Radical* (*Definitive*).—Where conservative amputation is impossible because of failure of demarcation, spread of gangrene, failure of direct rtraeial salvage surgery or sympathectomy, a mid-thigh amputation is the classical method of treatment. There is no statutory length of the stump; it is, in fact, essential to amputate high enough to ensure that the wound will heal soundly. This usually means a bony stump of some 15 to 20 cm. below the greater trochanter. Equal anterior and posterior flaps of skin and subcutaneous tissue and deep fascia are used. The muscles are divided just below the level of bone section (quadriceps divided with the knee flexed, and hamstrings with the knee extended). A tourniquet is not used to control hæmorrhage in atherosclerotic and embolic gangrene as there is surprisingly little bleeding owing to the obstructed main vessels. The sciatic nerve is cut cleanly across. It should not be ligated, though usually there is brisk bleeding from the artery to the nerve, which requires a ligature.

After sawing across the bone the leg is removed and full hæmostasis is secured. The *myoplastic* technique consists of suturing a flap of periosteum across the severed bone, and separating the muscles into anterior, posterior, medial and lateral bunches. The anterior and posterior groups are sutured to each other across the bone end and the medial and lateral groups to each other across these. A subcutaneous catgut suture may be inserted and the skin closed by a subcuticular suture of catgut or Dexon. The stump should be drained, the 'Readivac' suction method being convenient.

(*c*) *Semi-conservative* (*Compromise*) *Amputations.*—In many cases amputations below the knee, through the knee, or supracondylar (Stokes-Gritti) will heal well. The functional result of these amputations is usually much better than the classical above knee amputation. Classically, below knee amputations were performed with equal length anterior and posterior skin flaps, and through knee and supracondylar amputations with a long anterior skin flap. It is now realised that in atherosclerotic limbs the posterior skin has a much better blood supply, and long posterior skin flaps are now used to close all three types of amputation with greatly improved results.

Sir William Stokes, 1839–1900 (*see p. 95*). *Rocco Gritti, 1857–1920. Surgeon, Milan.*

After-care.—The stump is immobilised between sandbags for forty-eight hours, and there should be adequate sedation for pain. Thereafter the patient is encouraged by a programme of promotion to a full and active participation in the community. This programme entails exercises, sitting up in a chair, getting up on crutches, and finally the measurement for, fitting of, and rehabilitation with, an artificial limb (prosthesis). Early dressing and the removal of the drain require sedation, and an assistant to hold the limb gently but firmly between his hands. When the wound of an above- or below-knee amputation has healed, the patient holds his limb himself while he is taught how to bandage the stump in such a way as to mould it into the cone-shape necessary for fitting the prosthesis. Removal of the sutures on the fourteenth day depends upon satisfactory healing, and if there is any doubt on this score, they should be left in for three or even four weeks. Catgut or Dexon sutures have the advantage of not requiring removal.

Complications.—*Early*, include the following: reactionary hæmorrhage, which requires return to the theatre for operative hæmostasis; a hæmatoma, which requires evacuation; infection, usually from a hæmatoma. Any abscess must be drained. Depending upon the sensitivity reactions of the organisms cultured, the appropriate antibiotics are given. Gas gangrene can occur in a mid-thigh stump—the organisms coming from contamination by the patient's fæces (p. 28).

Wound dehiscence and gangrene of the flaps are due to ischæmia, and a higher amputation may well be necessary. Fat embolism (p. 144) is another but uncommon sequel, occurring within the first two days.

Late.—Pain is usually the presenting symptom. It may be due to: unresolved infection, e.g. a sinus, osteitis, bone necrosis and sequestrum formation; a bone spur; a scar adherent to bone; an amputation neuroma from the outgrowth of nerve fibrils which become attached to skin, muscle or fibrous tissue; a phantom limb.

Phantom Pain.—Patients frequently remark that they can feel the amputated limb and sometimes that it is painful. The surgeon's attitude should be one of reassurance that these feelings will disappear. He should on no account foster the subject and talk about phantom-limb pain in front of the patient, as it is very refractory to treatment once it is established.

Other late complications include ulceration of the stump (pressure effects of the prosthesis or increased ischæmia). Rarely, an ulcer is artefacta (fig. 66). Some patients are troubled by cold and discoloured stumps, especially during the winter.

ASPECTS OF CERTAIN VARIETIES OF GANGRENE

Ergot, a cause of gangrene among dwellers on the shores of the Mediterranean Sea and the Russian steppes who eat rye bread infected with *Claviceps purpurea*, also occurs in migraine sufferers, who, for prophylactic reasons, unwittingly take ergot preparations over a long period. Overdosage can also occur following the ergot treatment of post-partum hæmorrhage. The fingers, the nose and ears may be affected.

Diabetic gangrene is due to three factors. These are (i) trophic changes resulting from peripheral neuritis, (ii) atheroma of the arteries resulting in ischæmia, and (iii) excess of sugar in the tissues which lowers their resistance to infection (fig. 163) including fungal infections.

The neuropathic factor impairs sensation, and thus favours the neglect of minor injuries and infections, so that inflammation and damage to tissues are ignored. Muscular involvement is frequently accompanied by loss of reflexes, and deformities. In some cases the feet are splayed and deformed (neuropathic joints). Thick callosities develop on the sole, and are the means whereby infection gains

FIG. 163.—Early diabetic gangrene.

entry, often following amateur chiropody. Infection involving fascia, tendon, and bone can spread rapidly upwards via subfascial planes.

Clinical examinations and investigations include those on the urine and blood for diabetes. Palpable dorsalis pedis and posterior tibial pulses, and the absence of rest pain and intermittent claudication, imply that there is no associated major arterial disease (atherosclerosis). A bacteriological examination is made of any pus. An X-ray will reveal the extent of any osteomyelitis.

TREATMENT.—The diabetes must be brought under control by diet and the appropriate drugs (e.g. Insulin, Tolbutamide, etc.). The gangrene is treated on the lines already described on the previous pages, the accent being on conservatism if there is no major arterial obstruction. A rapid spread of infection requires drainage of the area by incision and the removal of any obviously dead tissue. This may often involve free and extensive laying open of infected tissue planes. Adequate surgical drainage of pus and the control of infection due to bacteria and fungi may then be followed by rapid healing.

TRAUMATIC GANGRENE

(i) **Direct traumatic gangrene** is due to local injury, and may arise as a result of crushes, pressure (as in the case of splints or plasters), or bedsores.

Gangrene following severe injury, e.g. a street accident in which a heavy vehicle passes over a limb, is of the moist variety (p. 155) and removal without delay is usually indicated. Amputation may be performed as close to the damaged part as will leave the most useful limb.

Bedsores (*syn.* decubitus ulcers) are either acute or chronic. The acute or *trophic* variety is associated with disease or injury of the spinal cord, and often progresses with alarming rapidity in spite of every care and attention.

The chronic or *postural bedsore* is predisposed to by five factors—pressure, injury, anæmia, malnutrition, and moisture. Prophylactic treatment is of the utmost importance. Thus pressure over bony prominencies is counteracted by a two-hourly change of posture and protection by foam P.V.C. blocks, or a ' sheepskin ' (footnote, p. 156). A water-bed or a ripple bed is sometimes desirable. Injury due to wrinkled drawsheets and maceration of the skin by sweat, urine, or pus is combated by skilled nursing.

A bedsore is to be expected if erythema, which does not change colour on pressure, appears. The part must be kept dry. An aerosol silicone spray may be used. Actual bedsores may either be treated by lotions (p. 60) or by exposure to keep them as dry as possible, and the appropriate antibiotic given systemically. The hæmoglobin of the patient should be maintained at a normal level by transfusions of packed cells if need be. If the patient is young and otherwise healthy, excision of the dead tissue and flap pedicle skin grafting (page 120) is often successful.

(ii) **Indirect traumatic gangrene** is due to interference with blood-vessels:—

(*a*) From pressure by a fractured bone in a limb, or by strangulation (fig. 164) (strangulated hernia, Chap. 52).

(*b*) Thrombosis of a large artery, following injury.

(*c*) Ligation of the main artery of a limb, as after division by injury.

FIG. 164.—Indirect traumatic gangrene of a new-born infant's finger, accidentally caused by a thread of cotton.

The likelihood of gangrene depends upon the sufficiency of the collateral circulation (p. 122).

Treatment directed to the cause, e.g. closed or open reduction of a fracture together with direct arterial surgery for the damaged vessel, will usually prevent the onset of gangrene. The limb must be kept cool, so as to reduce metabolism to the minimum (p. 132). When gangrene is slow to develop, a line of demarcation will indicate the level of vitality. If moist gangrene occurs and spreads rapidly, amputation may be needed to save the patient's life.

PHYSICAL AND CHEMICAL CAUSES OF GANGRENE

Frostbite is due to exposure to cold, especially if accompanied by wind or high altitudes (e.g. explorers and airmen). It is also encountered in the elderly or the vagrant during cold spells (fig. 165). Pathologically, there is damage to the vessel walls, which is followed by transudation and œdema. The sufferer notices severe burning pain in the affected part, after which it assumes a waxy appearance and is painless. Blistering, and then gangrene, follows.

Treatment.—Frostbitten parts must be warmed *very gradually*. Any temperature higher than that of the body will be detrimental. Many frostbitten limbs have been either stewed or roasted in ignorance, and gangrene thereby encouraged. The part should be wrapped in cottonwool and kept at rest. Friction, e.g. rubbing with snow, may damage the already devitalised tissues. Warm drinks and clothing are provided and powerful analgesics are required to relieve the pain which heralds the return of circulation. Paravertebral injection of the sympathetic chain (p. 131) may be helpful in relieving associated vasospasm. Amputations should be conservative (p. 157). Hyperbaric oxygen (p. 80) is effective.

Trench foot is due to cold, damp, and muscular inactivity, and is predisposed to by tight clothing, such as garters, puttees, or ill-fitting boots. Prophylaxis is therefore of paramount importance. Numbness is followed by

FIG. 165.—Frostbite in Fulham, London. An elderly patient, living without sufficient food or heating. Conservative amputations were successful.

pain, which is excruciating when boots are removed. The skin is mottled like marble, and in severe cases blisters containing blood-stained serum develop, and moist gangrene follows. The pathology is similar to that of frostbite, and the treatment is the same.

Ainhum (fig. 166), a disease of unknown ætiology, usually affects male Negroes, (but some females), who have run barefoot in childhood. Besides Central Africa there are reports from Central America and the East. A fissure appears at the level of the interphalangeal joint of a toe, usually the fifth. The fissure becomes a fibrous band, which encircles the digit and causes necrosis. The treatment is either early Z-plasty or, later, amputation.

FIG. 166.—Ainhum (see text).
(Dennis Morrissey, F.R.C.S., Birmingham.)

Intra-arterial injection of thiopentone is an occasional accident when a high division of the brachial artery results in one of its two terminal branches, usually the ulnar, passing superficially downwards in the antecubital fossa. Pulsation of the vessel, and the withdrawal of bright red blood should prevent this calamity.

Injection causes immediate and severe burning pain and blanching of the hand, usually accompanied by an interjection from the patient! The needle should be left in position, and 5 ml. of 1 per cent. procaine and/or 2 per cent. papaverine sulphate, or 1 mg reserpine injected in order to obviate vascular spasm. Dilute heparin solution (p. 142) may also be given intra-arterially if the needle is in position. If the needle is not in position, and the facilities are available, the artery may be exposed, opened, and any clots flushed out with dilute heparin solution. Then vein-patch repair (p. 133), and/or peri-arterial papaverine, or intra-arterial fibrinolysins (p. 133) and intravenous low molecular weight Dextran (p. 77) may be employed. Brachial block must also be performed, and repeated if necessary. Even so, gangrene of one or more fingers may occur.

Chemical Gangrene.—Carbolic acid is the most dangerous, as anæsthesia masks the pain which occurs before the onset of gangrene. *Carbolic compresses should never be used*, for fingers have been lost by application of compresses even as dilute as 1:80. The gangrene is due to local arterial spasm. In addition there is danger of severe systemic effects from absorption of the carbolic. Local bicarbonate soaks should be applied. Later, excision of the slough and skin grafting are necessary.

VENOUS GANGRENE

A rare condition, due to extensive thrombosis in peripheral veins, there being normal arterial pulsations. It may occur in the toes and forefoot without any apparent cause, though it may be a manifestation of visceral neoplasm (Trousseau's sign, p. 162). It also occurs in peripheral thrombosis due to polycythæmia vera (fig. 167).

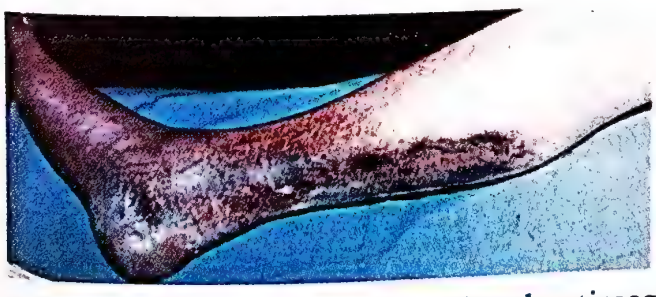

FIG. 167.—Venous gangrene due to polycythæmia vera. Conservative amputation was not possible in this case (see Treatment).

Treatment.—The limb is elevated and anticoagulant therapy commenced (p. 142). Low molecular weight Dextran i.v. to reduce the viscosity of the blood may be helpful. Conservative surgery is performed when the final line of separation appears. It may be found that the gangrenous tissue is relatively superficial and that the deeper layers are pink and viable. Skin grafting may be helpful in this conservative approach to treatment.

CHAPTER 9

VEINS

VENOUS THROMBOSIS

Thrombosis of veins is predisposed to by:

(1) Change in the vessel wall with damage of the endothelium, e.g. inflammation or injury.

(2) Diminished rate of blood flow, as occurs during and after operations, and in debilitating conditions, such as typhoid fever.

(3) Increased coagulability of the blood, such as occurs in infective conditions, or after hæmorrhage. Some such blood change may be the explanation of Trousseau's sign—thrombosis of veins in association with visceral carcinoma.

The results of thrombosis are as follows:

(1) *Locally*.—The clot may organise into fibrous tissue, or the vein later becomes recanalised. Calcification sometimes follows, resulting in the formation of a phlebolith, so commonly seen in pelvic veins. Suppuration can occur, forming a localised abscess, or giving rise to pyæmia.

(2) *Distally*.—Œdema may occur, the degree depending on the size of the vessel affected. The venous collateral circulation is soon established, as evinced by widespread varicosity of the superficial veins.

FIG. 168.—Spontaneous thrombophlebitis in Buerger's disease.

(3) *Proximally*. — Thrombosis may extend upwards to larger veins, and portions of clot are liable to become detached. The resultant emboli may cause pulmonary infarcts (Chap. 38). If the portal drainage area is affected with infected clot, foci of infection will riddle the liver (pylephlebitis, Chap. 43).

Superficial Vein Thrombosis (Thrombophlebitis).—Commonly varicose veins are affected, or a vein which is cannulated for transfusion (p. 91). There is pain, and the vein is a tender hard cord. The skin may appear dusky and inflamed. Spontaneous thrombophlebitis, which may be sporadic and migratory (thrombophlebitis migrans), brings to mind such diseases as Buerger's disease in a young man, a visceral carcinoma, polycythæmia, and polyarteritis (fig. 168). Some cases are idiopathic. The symptomatic treatment is by compression

Armand Trousseau, 1801–1867. Physician, Hôtel-Dieu, and Professor of Medicine, Paris. Noted this sign as his own death warrant, as it confirmed his suspicion that he had a carcinoma of the stomach.
Leo Buerger, 1879–1943 (see p. 150).

with a supportive crepe bandage or as described on p. 168. A short course of penicillin (1 mega unit twice daily for four days) and indomethacin (25 mg. thrice daily) are often of value.

As the thrombus is adherent to the wall of the vein, an embolus is unusual. However, a thrombus which spreads rapidly up the long saphenous vein may require emergency saphenous ligation in the groin.

Deep Vein Thrombosis (Phlebothrombosis) follows childbirth, operations, muscular violence, local trauma of any kind, immobility, and any debilitating illness. Spontaneous thrombosis may also be indicative of the presence of a visceral neoplasm (see superficial vein thrombosis).

Postoperative thrombosis, virtually unknown in Singapore, is believed to occur more frequently with the arrival of snow and ice.

The thrombus may commence in a venous tributary of a main vein, where there are eddying currents around a valve. It extends in a serpentine fashion into the main deep vein where the relatively faster stream may cause a portion to break off and so cause a pulmonary embolus (Chap. 38). The pelvic and calf veins are more commonly implicated than others. Occlusion of a length of the deep femoral vein will cause painful congestion and œdema of the leg. If in addition there is an associated lymphangitis, the swelling will increase and is likely to be protracted (e.g. ' white leg '—phlegmasia alba dolens). Extensive deep vein thrombosis of the iliac and pelvic veins may cause a ' blue leg ' (phlegmasia cærulea dolens) in which either venous gangrene or areas of infarction may threaten part of or the whole of the limb (page 161).

Prophylaxis.[1]—*Before operation.* When possible, grossly over-weight patients should reduce weight. Those over forty, rendered immobile during a period of in-patient investigation or other treatment, are less at risk if they have a spell of 2–3 weeks activity at home before readmission for operation. Patients with cancer are particularly at risk.

During operation it is essential that the venous return from the lower limbs is not impeded in any way. Pressure of the calf on the operating table *must* be prevented by elevating the heel on a sandbag or sorbo-rubber pad. At the end of an operation it is a good plan to elevate and massage the legs.

Prophylactic anticoagulants.—Subcutaneous heparin, 5 000 units, is given 2 hours before operation and continued 8 hourly for 7 days. It is of value in major surgical cases providing the operation does not involve leaving raw bleeding areas. It is contraindicated where a small postoperative hæmorrhage in a restricted area would be disastrous. Intravenous heparin may be used in cases where there is a high risk of thrombosis and a low to medium risk of bleeding (Browse).

Dextran ' 70 ' inhibits platelet adhesion. A useful regimen is to give 500 ml i.v. during the operation, and 500 ml in the following 24 hours.

Mechanical methods of prophylaxis include:—(i) *Graduated static compression* of the leg using specially constructed elastic stockings (Kendall's thrombo-embolic deterrent). These exert diminishing pressure on the leg from the ankle upwards to the thigh. Other methods of maintaining a satisfactory flow of blood in the deep veins include (ii) *Electrical stimulation* of the calf muscles and (iii) *Pneumatic compression.*

[1] When there is no urgency, female patients on the ' pill ' should stop this method of contraception for one month before surgery.

Norman Leslie Browse, Contemporary. Professor of Vascular Surgery, St. Thomas's Hospital, London.
Kendall Company, Chicago, Illinois, U.S.A.

After operation conditions which predispose to a sluggish circulation such as immobility of the lower limbs, dehydration, and delayed venous return should be avoided by massage, leg movements, continued use of graduated compression stockings, adequate hydration, and early ambulation. Patients should not be allowed to sit out of bed with their legs dependent. In fact, patients are often more mobile in bed than in a chair.

Detection of Thrombosis.—Phlebothrombosis is often symptomless,[1] but there may be a complaint of pain in the affected calf. Any unexplained elevation of temperature or pulse-rate should arouse suspicion of thrombosis, especially when occurring towards the end of the first post-operative week. In all cases the calves should be examined daily for tender areas of induration. Tenderness may be elicited along the course of the posterior tibial and peroneal veins. Slight swelling of the calf muscles is another important sign. Homans' sign—pain in the calf or dorsiflexion of the foot may be present but it is rather unreliable.

The Doppler principle (p. 129) is a useful and simple aid (Sonic-aid) in the diagnosis of deep vein thrombosis. The sensing probe, placed over the femoral vein in the groin normally transmits a venous hum (like wind in telegraph wires) and pressure on the calf, or calf muscle contractions, changes the hum into a roar, due to increased blood flow. If there is a thrombosis of the deep vein between calf and groin the roar does not occur. A deep venogram is used sometimes to show the site and extent of the obstructing thrombus (pp. 170, 171). Browse believes a venogram to be essential to diagnosis and to the formulation of the correct treatment policy. However, caution should be exercised in patients who are inveterate clotters, as venous gangrene has been known to occur after this investigation.

Treatment of Deep Vein Thrombosis.—(*a*) *Anticoagulants, Bandage and Rest.*—Opinion is divided as to the best method. At one extreme, the whole limb is bandaged with a supportive crepe, 'blue-line' or other elastic bandage, heparin is given for eight days, and the patient is kept mobile. At the other extreme the limb is also bandaged, but the patient remains in bed until the elevated temperature and the local signs abate, and anticoagulants are not used unless a small pulmonary embolus has occurred. A middle course is to employ anticoagulants, combining heparin and phenindione (or Warfarin) (p. 142), and to continue with them for three to six weeks, taking care to tail-off slowly at the end of the course to prevent a 'rebound' of thrombosis.

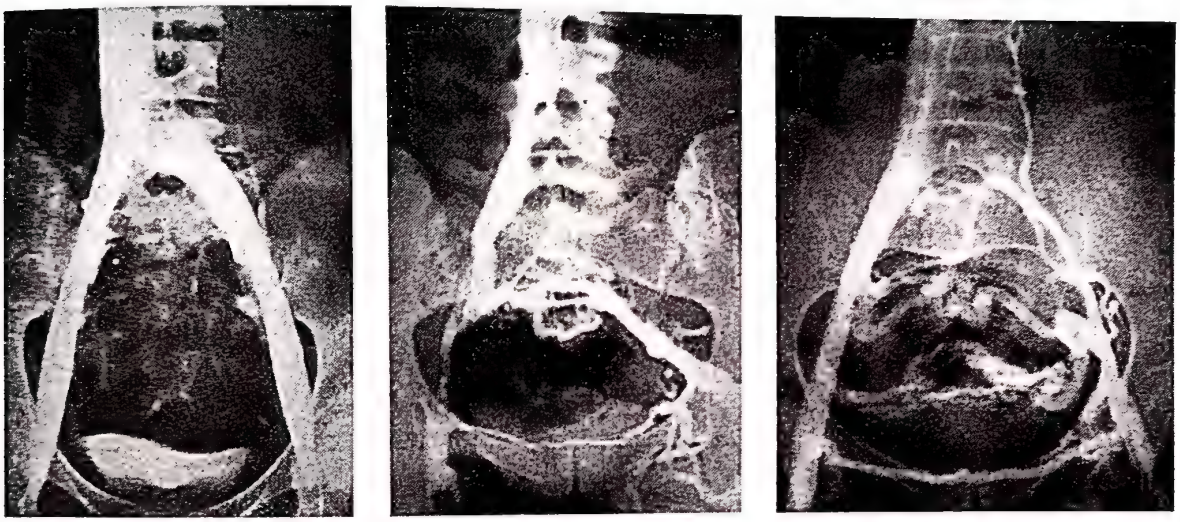
(*b*) *Treatment based on venography.*—(i) *Fixed thrombus.*—If the thrombus is fixed to the vein wall, anticoagulants are given. Heparin 40,000 units per day for 7 days are given, if possible, by continuous infusion. Warfarin is begun (p. 143) and continued for 6 months. (ii) *Free thrombus.*—If the thrombus is loose at the top it should be either removed or 'fixed'. Removal is achieved by thrombectomy, using a Fogarty balloon venous

[1] Studies, using isotope-labelled fibrinogen, have indicated that symptomless thrombosis is relatively common.

John Homans, 1877–1955. Professor of Clinical Surgery, Harvard Medical School, Boston, Massachusetts, U.S.A. Described this sign in 1941.

catheter (p. 143), or by streptokinase (providing there is no bleeding and no heparin is given). Fixation is achieved in reality by blocking the vein. A ligature suffices for the superficial (not main) femoral vein. For the vena cava ligation, or the introduction of a filter, may be carried out. One such filter is the Mobin-Uddin umbrella, introduced in a capsule, under X-ray control, via the neck and internal jugular vein into the inferior vena cava.

Iliac Vein Compression (Cockett) (fig. 169 (*a*), (*b*) and (*c*)). Good venograms of the iliac and pelvic veins, and the cava, may be obtained by injection of Hypaque (diatrizoate) into the femoral vein, or into the bonemarrow via the greater trochanter (per-trochanteric venogram). In some patients with swelling of a leg (see lymph-œdema, p. 175), the left common iliac vein or the cava is compressed by the over-riding aortic bifurcation. In addition thrombosis in, or a stricture of, the vein may be present. Operations involving the mobilisation of the aortic bifurcation, or direct venous disobliteration, are still under trial.



(*a*) (*b*) (*c*)

FIG. 169.—Iliac vein obstruction. (*a*) The defect which is often seen on iliac venograms even without symptoms is representative of an average degree of iliac compression.
(*b*) The venogram in the acute stage of an iliac thrombosis following iliac compression. This patient had an embolus a few days prior to this X-ray. The whole of the left common iliac vein has disappeared and there is a large bulge in the vena caval bifurcation which is probably the smooth edge of the residual clot.
(*c*) Iliac obstruction in the chronic phase, with a block at the upper end of the left common iliac vein, and the typical, quite profuse, collateral circulation across to the right side.
(F. B. Cockett, F.R.C.S., London.)

Axillary Vein Thrombosis.—Thrombosis of the axillary vein is not uncommon, and can occur after unaccustomed use of the corresponding arm (e.g. distempering a ceiling). The vein is damaged by the excessive movement that occurs between the clavicle and the first rib.[1] ' Spontaneous ' thrombosis may be due to a pyjama sleeve becoming twisted around the axilla during heavy slumber, with consequent compression of the vein. The thrombosis

[1] Henry of Navarre, 1553–1610 (King Henry IV of France, 1589–1610), led his army into the battle of Ivry (1590), shouting 'Rally round the white plume of Navarre'. He used his sword to such good effect that he could not use his arm for six weeks, and probably had an axillary vein thrombosis.

Kazi Mobin-Uddin, Contemporary. Cardiovascular Surgeon, Marion, Ohio, U.S.A.
Frank Bernard Cockett, Contemporary. Surgeon, St. Thomas's Hospital, London.

results in painful congestien and œdema of the arm (fig. 170). As a collateral venous circulation develops, the symptoms subside; this takes about three months. The extent of the thrombosis can be limited if heparin and phenindione anticoagulant therapy is given in the early stages. Fibrinolytic therapy may restore the circulation if given in the first 2 or 3 days (p. 143).

FIG. 170. — Infra-red photograph showing collateral venous circulation following thrombosis of the axillary vein. (*Max Pemberton, F.R.C.S., Enfield, London.*)

VARICOSE VEINS

A vein is stated to be varicose when it is dilated and tortuous. The condition commonly occurs in connection with the veins of the leg, but also the spermatic, œsophageal, and hæmorrhoidal veins may be affected. The three last conditions are dealt with elsewhere.

Ætiology.—Varicose veins are part of the penalty we pay for the adoption of the erect posture. Animals do not suffer from this condition.

The Venous Pump.—In the human, the return of venous blood from the lower limb to the heart requires a pump equipped with non-return valves. The pumping action is provided by the muscles. Their tone and contractions, acting within the strict confines of the encircling deep fascia, squeeze or milk the blood in the direction insisted upon by the valves, i.e. towards the heart. Therefore a congenital paucity of valves, muscle weakness and wasting, or deep fascia stretching, will impair the function of the pump. On standing, the whole weight of the column of blood from the legs to the heart is exerted on the valves (up to pressures of 90 mmHg (12·0 kPa)), particularly on those guarding the communications between the superficial and deep venous systems of the leg (blood in the superficial system normally flows into the deep veins). The main valves affected are the sapheno-femoral lying at the junction of the long saphenous and common femoral veins (leading to dilatation of the long saphenous system), and the sapheno-popliteal (leading to dilatation of the short

FIG. 171.—The sites of communicating (perforating) veins between the deep and superficial (long saphenous) veins. The short saphenous vein has similar communications on the lateral side of the Achilles tendon.

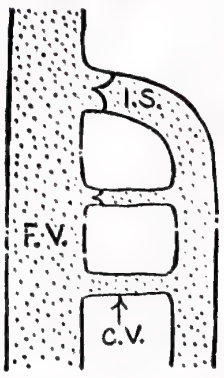


FIG. 172.—An incompetent communicating vein (C.V.), femoral vein (F.V.), long (internal) saphenous vein (I.S.).

saphenous system). However, varices may commence at the site of any incompetent communicating vein perforating the deep fascia, either alone or in conjunction with one of the above (fig. 171).

When these valves become incompetent, there is a high, intermittent pressure leakage of blood into the superficial system (fig. 172). The main superficial veins are partially protected by the superficial fascia and they possess muscular walls which in some cases prevent the varicosity which affects mainly the intercommunicating network of veins.

Varicosity is also predisposed to by any obstruction which hampers venous return, e.g. tumours and pregnancy, and by thrombosis of the deep veins. The predilection for females suggests a hormonal (? progesterone) factor.

Varicose veins occurring below the age of twenty may be due to congenital arteriovenous fistula, or an extensive cavernous hæmangioma (fig. 173).

FIG. 173.—Varicose veins of the legs and trunk in an extensive cavernous hæmangioma. Arteriography did not reveal an arteriovenous fistula.

In severe cases of varicose veins the blood volume is increased. It is reduced by operation, so there is a reduction of symptoms and an improvement of ability to perform physical work.

Symptoms occur in connection with varicose veins only when there is a retrograde flow, and they depend on the extent of the back pressure. The commonest is a tired and aching sensation, felt in the whole of the lower leg, and especially in the calf, towards the end of the day. Sharp pains, when present, are localised to the site of the varices, and are especially noticeable in grossly dilated thigh veins. The ankle may swell towards evening, or the skin of the leg may itch. Some patients suffer from cramp in the calf shortly after retiring to bed; this is due to a sudden change in the calibre of the communicating veins which stimulates the muscles between which they pass.[1]

Examination.—The condition may be widespread in both legs, or a single varix is sometimes present. If this is situated close to the saphenous opening, it is called a 'saphena-varix',[2] and it is readily distinguished from a femoral hernia on account of the characteristic thrill when the patient coughs, or if the vein below is tapped with a finger.

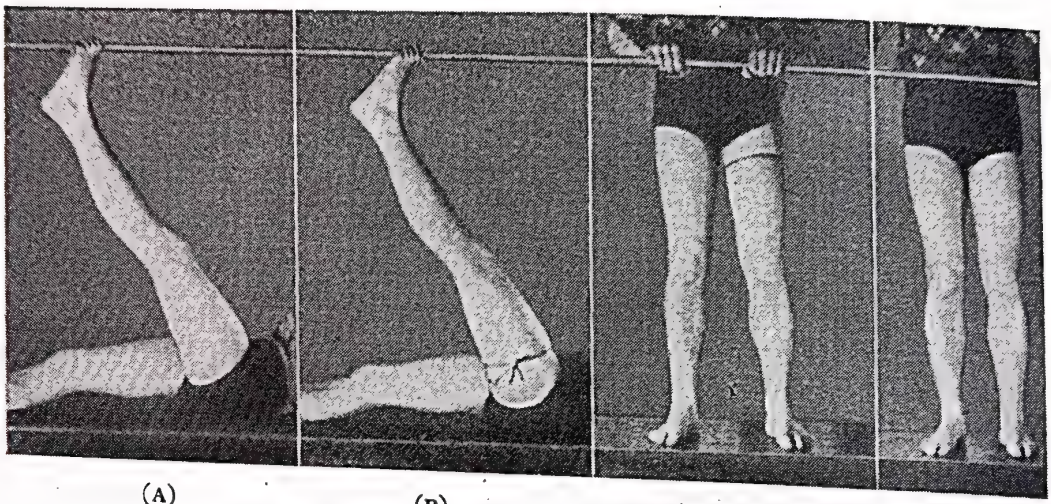
The examination of the varices is most important, for upon it depends the success, or failure, of treatment. The aim is to locate the site of the incom-

[1] Quinine dihydrochloride (200 mg), taken on retiring, is often efficacious in relieving night cramps. Hexopal 500 mg has also helped some patients.

[2] The word 'saphenous' is of Arabic derivation and means 'seen easily'.

petent superficial-deep valves (fig. 171), remembering that if an incompetent valve is present the venous flow is retrograde, so that veins when emptied fill from above; normally they fill from below. The examination, based upon the test described by Brodie (1846) and Trendelenburg (1890), involves what has aptly been described as ' the intelligent use of the tourniquet '.

Brodie-Trendelenburg Test.—Briefly, the patient lies upon his back and raises his leg to empty the veins (fig. 174A). A venous tourniquet is applied just below the saphenous opening (fig. 174B), and he stands up (174C). The constriction is then released (174D). If the sapheno-femoral valve is incompetent, the veins fill immediately from



(A) (B) (C) (D)

FIG. 174.—The Brodie-Trendelenburg test (see text). *(Dr. S. M. Rivlin, London.)*

above; if not, the veins fill slowly from below. The veins may fill rapidly from above, even though the tourniquet has not been released; this means that the varices are in communication with a perforating vein (one is commonly present in the lower third of the thigh), or the sapheno-popliteal junction is incompetent. In this case, the tourniquet test must be repeated, with application at successively lower sites on the thigh and leg, until the point of origin is shown by prevention of the abnormal direction of flow.

Morrissey's test for sapheno-femoral incompetence. Elevate the leg about 30° and allow veins to empty. Get the patient to give a forcible cough and watch for the retrograde venous pressure wave in the saphenous vein, which confirms the valvular incompetence.

Treatment.—(i) **Palliative treatment** is required for varicose veins in pregnancy, and for patients who do not wish for, who are unfit for, or who are waiting for, operation. The veins are supported by elastic stockings or crepe or elastic bandages.

Rowden Foote describes how a patient with an aching leg used to obtain relief by employing the Brodie-Trendelenburg manœuvre. If he lay down, elevated his leg, and then pressed hard in his groin, the veins remained empty when he stood up, and the aching was relieved.

(ii) **Injection-Compression.**[1]—The use of sclerosants, like ethanolamine oleate[2] 5 per cent. (Ethanolamine BPC), or sodium tetradecyl sulphate 3 per

[1] A word of warning is necessary in this era of the contraceptive pill. Caution should be exercised before giving sclerosant injections to a woman practising this form of family planning. Deep-vein thrombosis and fatal thrombo-embolism have been reported.

[2] Strange to relate, Mother Nature has, from the days of the primeval swamp, provided this substance from ? platelets in the actual chemistry of thrombosis.

Sir Benjamin Collins Brodie, 1783–1862. Surgeon, St. George's Hospital, London.
Friedrich Trendelenburg, 1844–1924 (see p. 71).
Denis Martin Morrissey, Contemporary. Surgeon, Queen Elizabeth Hospital, Birmingham, England.
Robert Rowden Foote, Contemporary. Surgeon, Varicose Vein Dept., Harrow Hospital, Middlesex, England.

cent. (Sotradecol or Thrombovar) acts by damaging the intima of the vein so that a thrombosis, and later sclerosis, develops. Intimal damage will take place only whilst the sclerosant is able to act in sufficient concentration; as soon as it is diluted by the blood in the deep veins the effect is lost. If an excess of the sclerosant is injected at one site it may reach the deep veins in sufficient concentration to initiate a thrombosis before it becomes sufficiently diluted to render it harmless. *The minimum fully effective dose* for a sclerosant should always be known, and should not be exceeded at any one site. *Indications.*—Injection-Compression treatment is the treatment of choice for varicose veins confined to below the knee and for recurrent varicosities after operation. It is not an ideal cosmetic treatment because of the unpredictable staining which may occur.

Technique.—In order to make the venous occlusion permanent, injections must be given into an empty vein, so that wall adheres to wall with no intervening blood clot and thrombosis which will certainly recanalise. The needle is inserted into the vein with the patient sitting down, with the leg horizontal. A latex foam pad may be put over the site of the injection (not on to the skin directly), and along the length of vein (fig. 175), and it is maintained by pressure bandage and a stocking overall for six weeks from the last injection or until the pain has gone from the site (Fegan). Injections are also given at the site of the perforating veins as delineated by the Brodie-Trendelenburg test (above) and at the maximum site of tenderness.

The maximum dose at any one time and any one point is 1 ml. It is usual to commence treatment with a test dose of ½–1 ml. so that the extent of the local reaction may be gauged and the dose modified as necessary.

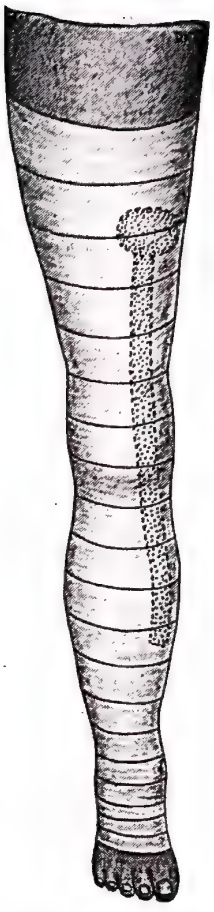


FIG. 175.—Bandage and pressure in the injection treatment of varicose veins (see text), and the ambulatory treatment of thrombophlebitis (p. 164).

(iii) Operations for Varicose Veins

Ligation Procedures.—The basic principle of the operative treatment of varicose veins is the ligation and division of those veins into which the high-pressure leak from the deep venous system has primarily occurred. Almost always this means ligation of the long saphenous vein where it enters the femoral vein (sapheno-femoral flush ligation). A flush ligation proximal to any tributaries is essential, otherwise a recurrence is inevitable (fig. 176).

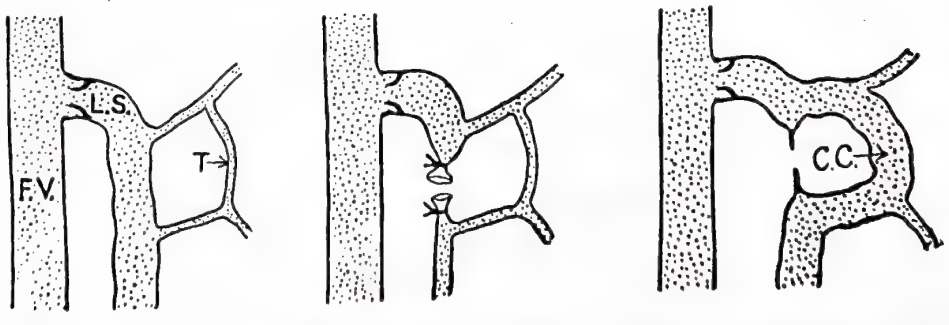

FIG. 176.—Tributaries (T.) must be ligated as well as the long saphenous vein (L.S.) flush with the femoral vein, otherwise a collateral circulation (C.C.) develops.

William George Fegan, Contemporary. Professor of Surgery, Trinity College, Dublin.

Should the short saphenous vein be the site of a high-pressure leak, it must be exposed in the popliteal fossa and ligated, proximal to any superficial tributaries, close to or flush with the popliteal vein.

In other instances of incompetent valves (or ' blow outs ') of the communicating veins (fig. 171), they must be ligated under the deep fascia (p. 172).

Technique.—An oblique incision is made just below the groin, commencing over the pulsation of the femoral artery and extending some 6 to 7 cm. medially. The proximal portion of the long saphenous vein is exposed and traced to the femoral junction, which may lie 1·25 cm deep to the fossa ovalis, *dividing and ligating all tributaries* encountered on the way. It is then tied flush with the femoral vein.

Stripping.—This procedure is ancillary to ligation, and is a method whereby the main veins of the superficial system (long or short saphenous) can be removed, in order that the remaining varicosities of the superficial network will thrombose and be permanently occluded. After juxta-femoral ligation of the long saphenous vein and ligation of its tributaries a metal stripper is introduced into the vein in front of the internal malleolus (fig. 177). Care must be taken to preserve the long saphenous nerve which is close to the vein. The stripper is threaded upwards to emerge from the proximal end of the vein, the leg is elevated, and the vein avulsed by traction. Bleeding is controlled by pressure bandages applied from below upwards as the stripper is withdrawn. The wounds are sutured, and the patient is ambulatory the following day. If advisable, an incision over the popliteal fossa permits stripping of the short saphenous vein, after it has been ligated at its entry into the popliteal vein. Care is also required to avoid stripping the sural nerve which is close to the vein behind the external malleolus.

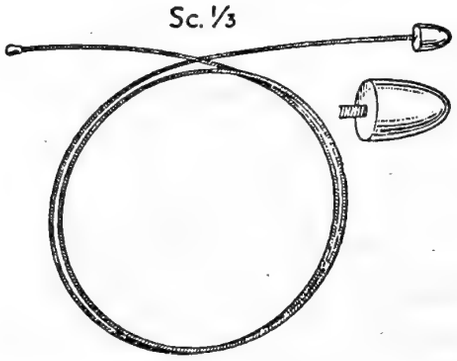

FIG. 177.—Myer's vein stripper.

Contraindications to Injection and Operative Treatment

(*a*) *Acute Infective Thrombophlebitis.*—At least three months should be allowed to pass, after this has completely subsided, before injecting.

(*b*) *Deep Thrombosis.*—Due to any cause or revealed by a history of prolonged confinement to bed with a painful swollen leg. Perthes' test is informative if doubt exists regarding the patency of the femoral vein:—The saphenous vein is occluded by a tourniquet applied immediately below the saphenous opening, and the patient walks 15 to 20 yards (13·5 to 18 metres). Normally, the veins below the constriction become less obvious, but if the communicating veins or the femoral vein are obliterated, these subcutaneous veins become engorged and the patient complains of ' bursting ' pain.

(*c*) *Pregnancy, pelvic tumours and the ' Pill '.* See footnotes pp. 163 and 168.

COMPLICATIONS OF VARICOSE VEINS

Thrombophlebitis of superficial veins reveals itself as a reddened, tender cord in the subcutaneous tissues. Ambulatory treatment is safe and convenient. Strips of foam rubber or P.V.C., the edges of which are bevelled, are laid over the inflamed vein (over a layer of bandage), and 2·5 cm above it a double thickness is placed transversely. The leg is then bandaged with an elastic bandage (fig. 175). The strapping is removed after a fortnight. This procedure gives immediate relief, and it need be renewed only if tenderness persists.

Eczema (chronic dermatitis) may follow minor trauma or the patient scratching his skin which itches due to extravasation and break-down of red-cells in the affected area. It may be an allergic manifestation resulting from ointment or strapping applied for treatment. The condition is treated by the application, twice daily, of an ointment containing zinc oxide and coal tar.

Georg Clemens Perthes, 1869–1927. Professor of Surgery, Tübingen, Germany. Described this test in 1895.

Venous ulcers[1] occur either in connection with varicose veins (fig. 178), or follow deep-vein thrombosis in which recanalisation of the deep vein has occurred, but the valves are either destroyed or incompetent due to damage. Venous stasis is the underlying cause of both types as it results in local tissue anoxia. It is important, firstly, to be sure that the ulcer is not an ischæmic ulcer due to atherosclerotic arterial obstruction, arteritis (p. 150), or syphilis (p. 39). Secondly, it is important to differentiate between these venous ulcers, for whereas a varicose ulcer responds promptly to ambulatory treatment or operation (see below), post-thrombotic ulcers are refractory to treatment, and may require bed-rest with possibly excision and skin grafting. Carcinomatous changes may occur in a chronic ulcer (fig. 46).

FIG. 178.—Venous ulcers with pigmentation of skin and talipes equinus deformity.

A deep venogram is particularly useful in difficult cases, as it will show the patency and the size of the lumen of the deep veins, the presence of valves, and the existence of high-pressure leaks in the calf:—

A fine rubber tourniquet is applied just above the malleoli to occlude the superficial veins. An injection of 20 to 30 ml. of 45 to 65 per cent. Hypaque (sodium diatrizoate) is given into a superficial vein of the foot, via a fine polythene cannula. (A test injection is, of course, given first, p. 129). The contrast medium is thus forced into the deep veins, and serial X-ray exposures are made of the whole leg. High-pressure conditions are simulated by tilting the patient into the semi-vertical position, or by his pinching the nostrils and endeavouring to expire forcibly.

Treatment.

(*a*) **Bisgaard method.** Almost any venous ulcer can be healed by elevation, bandaging, exercises, and massage. A physiotherapy department can be most helpful in applying the Bisgaard treatment, which consists of:

(1) Massage in elevation to the whole leg and particularly to soften the indurated area round the ulcer.

(2) Passive movements to maintain the mobility of the foot and ankle.

(3) Active movements to the calf muscles in elevation, and in standing (with bandages on).

(4) Teaching correct walking, placing heel down first and using the calf muscles to lift the heel of the back foot, giving 'spring' to the walk and therefore improving the venous pump (p. 166).

(5) A *firm* elastic (e.g. 'blue line') bandage is applied spirally from the base of the toes to the knee, so that movements in walking alternatively stretch and relax the bandage and produce an added pumping effect.

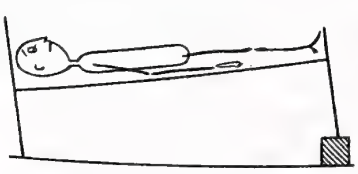

FIG. 179. — Sleeping with the foot of the bed raised.

(*b*) **Bandage and elevation.** Without facilities for Bisgaard treatment, reliance is placed upon the use of compression bandaging (e.g. wet 'Viscopaste' type, or a firm spiral of elastic bandage over a suitable dressing). Proper bandaging reduces the local œdema and aids the muscular component of the venous pump (p. 166). The patient should sleep with the foot of the bed raised (fig. 179) and periods of high

[1] *John Gay, 1812–1885. Surgeon, Great (now Royal) Northern Hospital, London. Was the first to use the term Venous Ulcer.*
Holger Bisgaard, 1881–1943. General Practitioner, Copenhagen. Published his method of treating varicose ulcers in 1939.

elevation of the leg are to be strongly encouraged (fig. 180). A 'wet' bandage cannot be wound spirally round the leg without the bias of the weave cutting into the skin. It must be applied in many encircling and overlapping strips. Often a piece of felt, with bevelled edges and cut to a size larger than the ulcer, is interposed in the bandage, over the ulcer, to reduce the local œdema which so often retards healing. A crepe bandage is put on over the 'wet' bandage. The patient is instructed to continue his usual work, and to wash off any discharge which may percolate through the bandage. Injection-Compression therapy may also be used as an ancillary treatment.

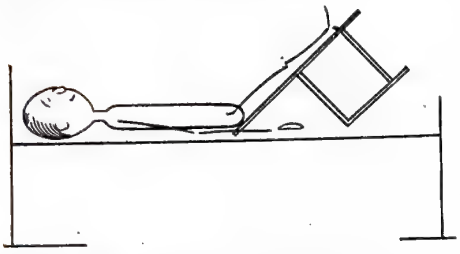

FIG. 180.—High elevation of the leg, using a chair.
(After Dickson Wright, F.R.C.S., London.)

The first application is removed after one week, and thereafter the bandage is renewed at fortnightly intervals until the ulcer is healed. The area of the ulcer should be measured at each visit, so that the decrease in size can be recorded.

(*c*) **Subfascial Ligation** (Cockett & Dodd Operation).—Most venous ulcers are due to incompetence of perforating veins on the inner side of the ankle (fig. 171). Therefore, when the ulcer has healed, the perforating veins should be identified and divided through an incision in the lower half of the leg 2·5 cm. behind the posterior border of the tibia. The veins, which may be enormously dilated, are best secured by exposing them beneath the deep fascia. If necessary the saphenous veins are also dealt with, as already described.

An indolent ulcer is sometimes best treated by excision and skin grafting (p. 119). In order to avoid œdema, pressure bandages must be worn for a few weeks after the operation.

Hæmorrhage from a ruptured varicose vein is usually profuse. Elevation of the leg and the application of a firm pad and bandage easily control the bleeding. *On no account* should a tourniquet be used (p. 70).

Calcification occasionally occurs in veins which have been varicose for many years.

Periostitis occurs in long-standing cases if the ulcer is situated over the tibia.

Equinus deformity may result from a long-standing ulcer. The patient finds that walking on the toes relieves the pain, and after some years the Achilles tendon becomes contracted (fig. 178). Cases usually respond to remedial exercises. The Bisgaard treatment (p. 171) should prevent this complication.

Harold Dodd, Contemporary. Emeritus Surgeon, Royal London Homœopathic Hospital, London.

CHAPTER 10

LYMPHATICS AND LYMPH NODES

Acute lymphangitis is caused by infection spreading from a wound in the drainage area of the involved lymphatic vessels. The infection is usually limited by the lymph nodes immediately proximal to the site of infection, where an abscess may form, but occasionally infection by-passes a group of lymph nodes and affects those at a higher level. Thus, in the case of an infected foot, the abscess may form in the external iliac lymph nodes instead of the groin, and because the wound itself has sometimes healed and been forgotten by the time the mass appears, it may be mistaken for an appendix abscess. Lymphangitis from hand infections is described on p. 193.

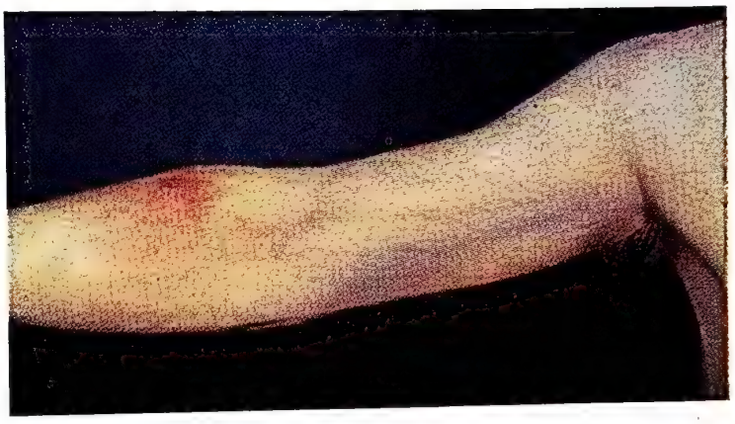

FIG. 181.—Acute lymphangitis of the arm. Red streaks and blushes extend from the infection on the forearm up to the axilla where the axillary lymph nodes are enlarged and tender.

Acute lymphangitis is characterised by the appearance of red blushes and streaks in the skin, corresponding to the inflamed lymphatics (fig. 181). The streptococcus is the common infecting organism. Toxæmia is often severe, and is greater when the more proximally the lesion has extended. Permanent lymphatic occlusion may follow acute lymphangitis, leading to persistent œdema.

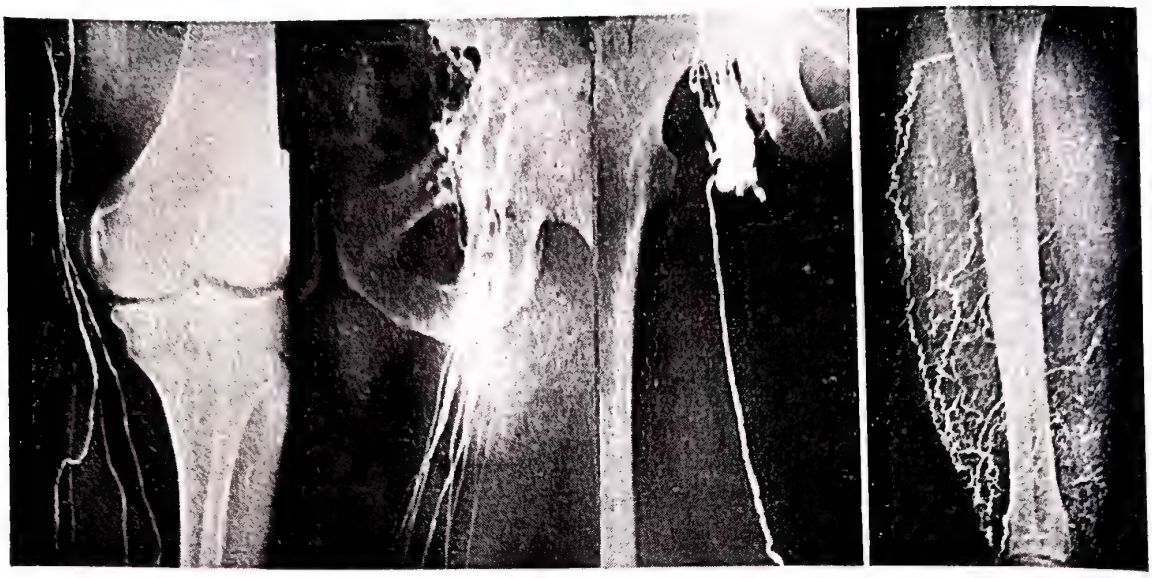
Treatment consists of bed rest, with the affected limb comfortably elevated, and giving cloxacillin, which usually causes rapid resolution. Only when suppuration is present and there are definite signs of pus should an incision be made.

Chronic lymphangitis may follow one attack, or more commonly, repeated attacks of acute lymphangitis, usually due to the hæmolytic streptococcus or staphylococcus pyogenes. Tuberculous lymphangitis also occurs and may be seen in the neck, when the lymph nodes are matted together, and in the groins when it may produce chronic lymphatic obstruction and elephantiasis.

Lymphangiography

This procedure has solved many of the problems concerning lymphatic œdema. Patent blue dye is injected into the web between the toes, thus showing up the lymphatics on the dorsum of the foot, which are exposed, cannulated, and then injected with a radio-opaque solution (ultra-fluid lipiodol) in order that the deeper main trunks in the leg may be visualised on X-ray (Kinmonth and Taylor). The method requires patience and practice (fig. 182).

John Bernard Kinmonth, Contemporary. *Professor of Surgery, St. Thomas's Hospital, London.*
Gerard William Taylor, Contemporary. *Professor of Surgery, St. Bartholomew's Hospital, London.*



(*a*) (*b*) (*c*) (*d*)

FIG. 182.—Lymphangiograms showing, (*a*) normal lymphatics at the knee, (*b*) normal lymphatics in the groin, (*c*) lymphatic hypoplasia, (*d*) distended subdermal lymphatics due to lymphatic obstruction. *(Professor John Kinmonth, F.R.C.S., London.)*

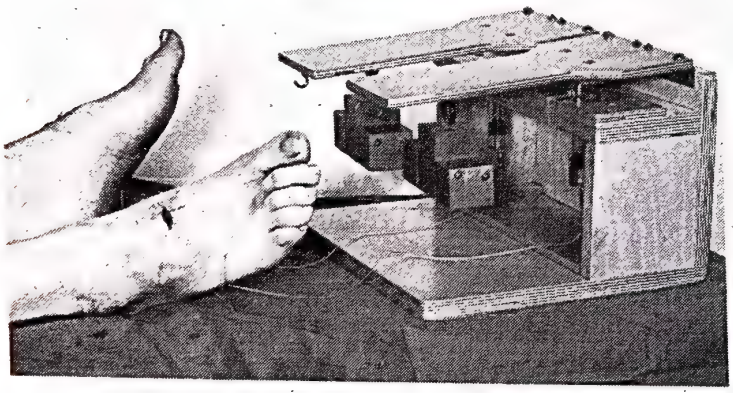


FIG. 183.—Pedal lymphangiogram: Blue dye is injected subcutaneously between the toes to outline the lymphatic vessels. A small incision is made on the dorsum of each foot and a 30E needle is passed into a vessel. Using an infusion pump, such as this (McIvor-Charing Cross), oily contrast medium is injected and is subsequently taken up by the phagocytes in the para-aortic, iliac and inguinal lymph nodes. *(Dr. James McIvor, F.D.S., F.F.R., London.)*

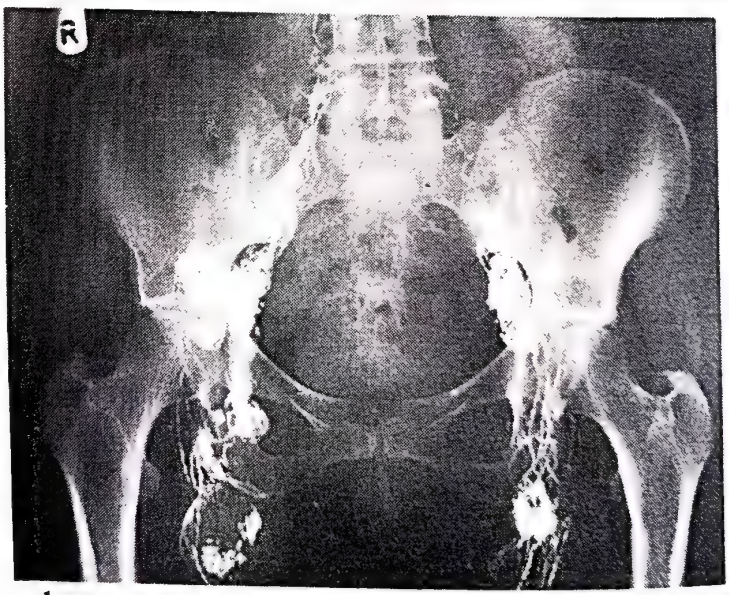

FIG. 184.—Central round filling defects in inguinal and iliac nodes on both sides typical of metastatic melanoma. *(Dr. James McIvor, F.D.S., F.F.R., London.)*

Lymphangiography has also become standard practice in the assessment of the extent of spread of cancer via the lymphatics (e.g. malignant melanoma and testicular tumours (fig. 184)).

LYMPHŒDEMA (and ELEPHANTIASIS)

Lymphœdema is caused by the accumulation of fluid in the lymphatics. In the limbs it affects mainly the subcutaneous tissues where there is an increase both in the stagnant lymphatic channels and in the supporting fat. The cause of the lymph stasis is either congenital or acquired.

(*a*) **Congenital malformations (primary lymphœdema,** fig. 185), which may be of three varieties:

(i) Aplasia—the main subcutaneous trunks fail to develop. The dermal lymphatic plexus is dilated.

(ii) Hypoplasia—the main subcutaneous trunks are few and underdeveloped.

(iii) Dilated and varicose lymphatic trunks —this may be associated with congenital arterio-venous fistula, and also with 'chylous reflux' (p. 176).

FIG. 185.—Primary lymphœdema of the right leg.

The congenital variety is either hereditary or familial (Milroy's disease). The œdema may be in one or both legs. It may start at birth (Lymphœdema congenita), or at puberty (L. præcox), or in adult life (L. tarda). It continues throughout life and does not of itself produce any constitutional disturbance.

(*b*) **Acquired obstruction (secondary lymphœdema).** The cause of this may be:

(i) Trauma, e.g. the removal of axillary lymphatics in radical mastectomy.

(ii) Repeated acute infection, as in those who go about barefoot.

(iii) Chronic infection, e.g. tuberculosis, filariasis[1] (p. 44) (fig. 186), and fungus infection.

(iv) Obstruction by malignant disease (fig. 187).

Whatever the cause, the stagnation in the lymph stream is usually followed by recurrent infection. Each such attack makes the obstruction worse until the limb becomes grotesquely swollen, the skin folded and wrinkled and, particularly in the leg, coarsened (like that of an elephant) with brown areas of dry undesquamated keratin. Ulceration eventually follows.

Differential Diagnosis.—*Bilateral* œdema of the legs always requires an examination to exclude cardiac, renal and metabolic (hypoproteinæmia) causes. *Unilateral* lymphœdema may be confused with that caused by deep vein thrombosis or compression, particularly of the iliac veins on the left side (fig. 153 and p. 163).

Treatment.—1. *Palliative.*—For the attacks of inflammation, prolonged bed-rest, elevation, and the appropriate antibiotic are important. Even in between attacks, the patient should sleep with the foot of the bed raised and may require to use elastic pressure—preferably of the spiral type (e.g. 'blue

[1] Sir Patrick Manson, 1844–1922, discovered elephantiasis was caused by filaria in 1877 while working in China. The organisms may be discovered microscopically in a nocturnal blood smear.

William Forsyth Milroy, 1855–1942. Professor of Clinical Medicine, University of Nebraska, Omaha, Nebraska, U.S.A. Described hereditary œdema of the legs in 1892.

FIG. 186. — Lymphœdema due to filariasis.

line' elastic bandage). Intermittent diuresis, induced by modern diuretic drugs, also is helpful.

2. *Surgery* is reserved for those with severe disability. The most useful of many surgical procedures is the removal of all the abnormal subcutaneous tissues and the covering of the exposed deeper tissues with a split skin graft (flaying operation). An improvement on this method is to bury the dermal part of the excess skin like a 'swiss-roll cake' along the whole length of the leg, so that the subdermal lymphatics may orientate themselves lengthwise

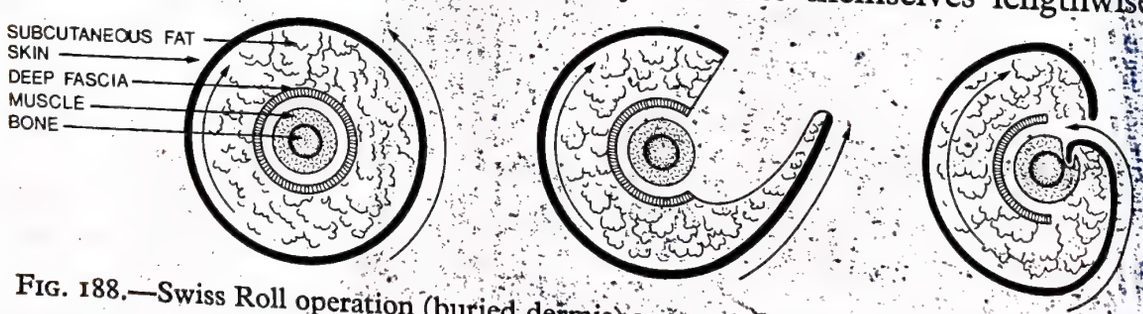

FIG. 188.—Swiss Roll operation (buried dermis) see text. (*N. Thompson, F.R.C.S., London*).

and thereby assist drainage (fig. 188). Other operations seeking to divert the lymph flow through the deep fascia by removing strips of it (Kondoleon's operation) or across the obstructed zone by a skin pedicle bridge, have failed. This is partly because the great mass of abnormally thickened subcutaneous tissue still remains.

3. *Microsurgery*.—This expanding field of operative surgery is beginning to be relevant to the treatment of lymphœdema. It is becoming possible to anastomose dilated lymphatics to veins (lymphovenous anastomosis), for example in the antecubital fossa in cases of œdema of the arm (O'Brien).

Chylous Reflux.—Lymphangiography has shown that in some cases of lymphœdema there is a backflow of milky chyle from the cisterna chyli, there being dilated

Emmanuel Kondoleon, 1879–1936. Surgeon in Athens.
B. McC. O'Brien, Contemporary. Director, Microsurgery Research Unit, and Assistant Surgeon, St. Vincent's Hospital, Melbourne, Australia.

lymphatics, resulting in cutaneous chylous vesicles and fistulæ on the limbs. Ligation and excision of the lymphatics on the posterior abdominal wall may cure the reflux, though lymphœdema persists. A few cases have hypoplastic lymphatics and hypoproteinæmia.

LYMPHANGIOMA

There are two types:

Capillary Lymphangioma.—Localised congenital anomalies may be composed of capillary-like lesions in the skin. They are brownish papules or wart-like excrescences. On examination with a lens, small vesicles can be seen, which are lymphatic nævi.

Cavernous lymphangioma is often associated with the preceding variety, and consists of masses of lymphatic cysts, particularly in the neck or axilla, the condition being termed a *cystic hygroma* (Chap. 32). A similar lymphangiectatic condition may affect the lips (macrocheilia) or the tongue (macroglossia) producing sometimes gross soft tissue enlargement.

LYMPH NODES

Acute Inflammation.—Lymph nodes, draining any area where there is acute infection, will also become inflamed. This has been discussed at the beginning of the chapter.

Chronic inflammation is either simple (pyogenic) or specific.

1. *Simple Lymphadenitis.*—Chronicity is present because of persistence of infection, such as occurs in recurrent tonsillitis or pediculosis capitis; or in inefficient treatment with antibiotics. The treatment is to remove the cause and attend to the general health of the patient.

2. *Specific Lymphadenitis*

(*a*) **Tuberculous lymphadenitis** is common in children and young adults, particularly those who have been in contact with open human tuberculosis or who drink infected milk. It also occurs in the aged. The cervical lymph nodes are most often seen to be enlarged, but the remnants of disease may be observed in the mediastinal and mesenteric lymph nodes as the speckled calcification on routine X-rays (fig. 189). Axillary lymph nodes may be involved by spread from the mediastinum.

FIG. 189.—Extensive calcification of cervical lymph nodes.

Tubercle bacilli most commonly reach a lymph node by lymphatics, when tubercles first form in the cortex. Blood-borne infection sometimes occurs, in which case the medulla of the lymph node is the first part to be affected. Microscopically, endothelial cells are in evidence, and giant cells are commonly seen with many nuclei arranged round the periphery like a horseshoe.

The stages of infection show most clearly in the neck. From the tonsillar portal of entry the infection spreads by the lymphatics to the nearest lymph

node. If resolution fails and the disease spreads, several lymph nodes are involved. They coalesce and break down to form caseous tuberculous pus, which may perforate the deep fascia and present as a fluctuant swelling on the surface (collar-stud abscess) (fig. 190). The skin is at first cold or white, but later becomes red (fig. 191), breaks down, and forms a sinus which if ignored will remain unhealed for years. From each of these stages resolution

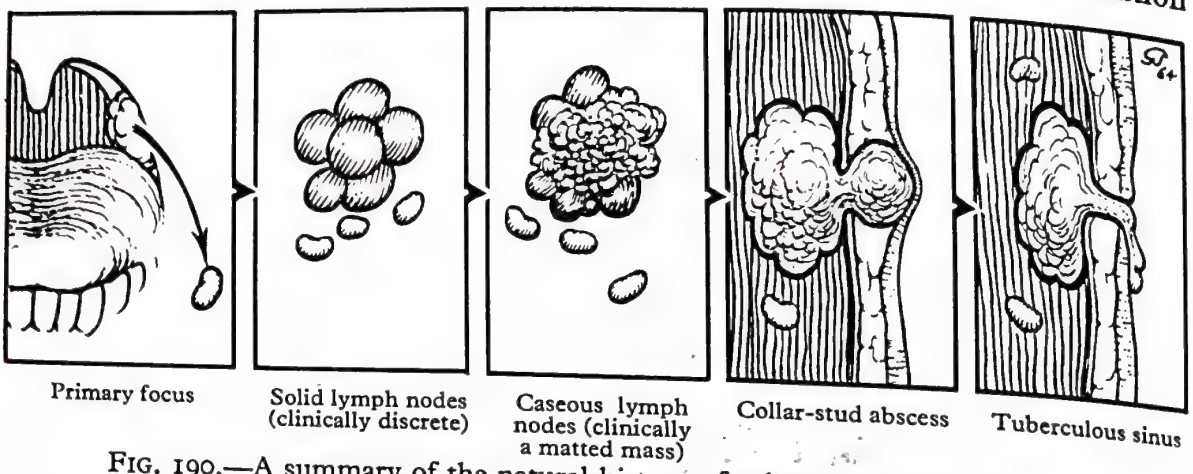

FIG. 190.—A summary of the natural history of tuberculous lymphadenitis.

may take place with calcification (if caseation has occurred), and with much scarring (if sinuses have formed).

Treatment.—(i) Attention to nutrition and general health.

(ii) Tuberculous material is aspirated for culture and drug sensitivity tests. A specimen must be obtained before the anti-tuberculous drugs are started.

FIG. 191.—A cold abscess of the neck.

(iii) Anti-tuberculous drugs are given immediately after the aspiration (page 32).

(iv) When the patient's condition begins to improve, breaking-down tuberculous lymph nodes must be removed, because the drugs will not reach the organisms in the avascular caseous material.

(*b*) **Syphilitic adenitis** can occur in any stage of the acquired infection. 'Shotty' lymph nodes in the groin associated with a genital chancre are characteristic. During the secondary stage a generalised enlargement of lymph nodes occurs. Especially noticeable are those above the internal epicondyles and along the posterior border of the sternomastoid.

3. *Other Infections*

Glandular Fever (*syn.* infective mononucleosis).—This is an acute virus infection, and variable in its manifestations. The incubation period is from five to fourteen days. The usual clinical manifestations are enlargement of lymph nodes, which are elastic and slightly tender, associated with an irregular fever. A sore throat, splenic enlargement and a rash are not uncommon. Examination of the blood reveals an absolute and relative lymphocytosis, and an unusual concentration of sheep-cell agglutins (the heterophile antibody of the Paul-Bunnell reaction). The condition may be mistaken for acute leukæmia or lymphadenoma, but blood examination is diagnostic. Treatment is symptomatic, and recovery is the rule, although it may be some months before the lymph nodes return to normal. The patient should be isolated while symptoms persist.

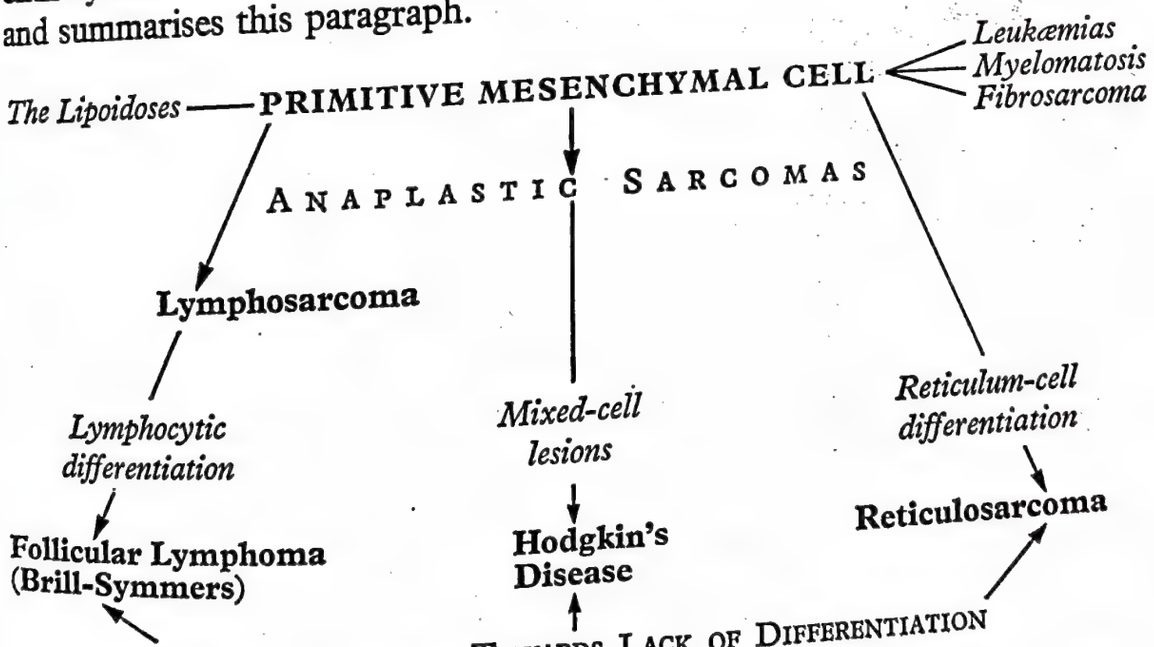
John Rodman Paul, Contemporary. Emeritus Professor of Preventive Medicine, Yale University School of Medicine New Haven, Connecticut, U.S.A.
Walls Willard Bunnell, 1902–1965. Physician, Hertford Hospital, Connecticut, U.S.A. Described this test in a joint paper with Bunnell in 1932.

Toxoplasmosis.—*T. Gondii*, a small intracellular protozoan is liable to be transmitted from mammals to humans who eat raw or underdone meat which has not been previously frozen. The most tragic manifestation is neonatal jaundice and encephalomyelitis followed by hydrocephalus or microcephaly, blindness and intracerebral calcification. Occasionally the disease manifests itself in children and adults with enlarged lymph nodes and fever causing difficulty in diagnosis (a complement fixation test being necessary).

Cat-Scratch Fever.—This is a distinct clinical entity with a world-wide distribution, and is probably due to a virus of the lymphogranuloma-psittacosis group. Localised inflammation occurs at the site of the lesion, associated with fever, malaise, and anorexia. This subsides in a few days, but from two to several weeks later the regional lymph nodes become enlarged. Suppuration often occurs, but the pus is sterile, and after evacuation the abscess subsides. Diagnosis is usually suggested by unilateral involvement of lymph nodes and the history of cat scratches. It is confirmed by a skin test with antigen prepared from human lymph-node pus. This distinguishes the condition from chronic pyogenic or tuberculous adenitis with which it is often confused. Broad-spectrum antibiotics have been tried; they do not influence the disease, though they may reduce the degree of fever.

THE RETICULOSES

Numerous progressive diseases arise from neoplastic change in the various elements of the reticulo-endothelial system. In general, the less they are histologically differentiated, the more rapidly do they grow. In addition, they may start as slowly growing well-differentiated lesions and then become rapidly growing and more primitive as time goes on (' drift-back '). There is a great deal of variation in the histological types and no rigid classification is entirely satisfactory. The following diagram gives a possible classification, and summarises this paragraph.



These diseases may either present as lymph node enlargement, or in the systemic form when virtually any structure can be affected. The lymph nodes are usually enlarged as one group, though other groups (e.g. Hodgkin's disease) may be affected. The nodes are discrete and elastic, being more rubbery in Hodgkin's disease and follicular lymphoma, but larger and softer in lymphosarcoma and reticulosarcoma. Tuberculous nodes classically

Nathan Edwin Brill, 1860–1925. Physician, Mount Sinai Hospital, New York, U.S.A. Described this disease in 1925.

Douglas Symmers, 1879–1952. Professor of Pathology, New York Hospital Medical School, New York, U.S.A. Published his description of this disease in 1927.

Thomas Hodgkin, 1798–1866. Curator of the museum and demonstrator of morbid anatomy, Guy's Hospital, London. In 1832, read a paper to the Medico-chirurgical Society of London entitled 'On Some Morbid Appearances of the Absorbent Glands and the Spleen,' in which he described a number of cases of lymphadenoma. In 1865, Sir Samuel Wilks (1824–1911), Physician, Guy's Hospital, London, suggested that the condition be called Hodgkin's disease.

are matted together by periadenitis, but may be discrete in early cases and in the senile form.

Diagnosis.—The clinical examination includes palpation of other groups of lymph nodes, and the abdomen for the presence of an enlarged spleen or liver. Investigations include X-ray of the chest (? mediastinal lymph nodes) and a full cytological examination of the blood (? leukæmia). A biopsy of an easily accessible lymph node should not be delayed. It is best to perform this under a general anæsthetic. The groin is avoided, if possible, as histology of the nodes is often complicated by inflammatory changes.

Hodgkin's disease is now described as an example:

HODGKIN'S DISEASE (LYMPHADENOMA)

Pathology.—Hodgkin's disease is a malignant neoplasm of the reticulum cells of lymphoid tissue and is the commonest of the malignant lymphomas. Wherever there is lymphoid tissue Hodgkin's disease may occur. On macroscopical section the involved nodes are pink-grey in colour and of rubbery consistency. Except in the more anaplastic forms the nodes are discrete with no periadenitis. The spleen, when involved, does not at first have the same homogeneous appearance as the lymph nodes, but as the disease advances the infiltration becomes more diffuse. Bone deposits occur in the vertebral column and pelvis. Rarely, Hodgkin's disease may be confined to a single organ such as the stomach.

The histological appearance may vary with the stage of the disease but a striking feature is the cellular pleomorphism. To a variable extent the normal nodal architecture is replaced by a cellular infiltration with lymphocytes, reticulum cells, eosinophils and fibrous tissue and the characteristic Reed-Sternberg cells will be seen—a giant cell containing two large pale mirror image nuclei which may overlap (like pennies on a plate).

The nature of Hodgkin's disease is still questioned. The Reed-Sternberg cell is an unusual cell in that it undergoes nuclear but not cytoplasmic division. Studies with tritiated thymidine suggest that the reticulum cell is really the basic malignant cell and that the binucleate giant cell is its product. Evidence against the malignant nature of Hodgkin's disease is based upon the fact that Reed-Sternberg cells have occasionally been found in the blood of patients with other diseases—e.g. glandular fever. In addition the similarity between the end stage of Hodgkin's disease and the graft-versus-host reaction suggests an immunological basis. The lymphocytic and acute inflammatory cellular response seen in involved nodes are thought to represent the host's immunological reaction.

HISTOLOGICAL TYPE: OLD	HISTOLOGICAL TYPE: NEW	CLINICAL SIGNIFICANCE
a. PARAGRANULOMA	LYMPHOCYTE PREDOMINANT	TENDS TO BE SEEN IN CLINICALLY STAGE I DISEASE. ASSOCIATED WITH A GOOD PROGNOSIS.
b. GRANULOMA	NODULAR SCLEROSIS	GOOD PROGNOSIS IF STAGE I.
b. GRANULOMA	MIXED CELLULARITY	TENDS TO INDICATE CHANGING DISEASE. SEEN IN ALL STAGES FROM I–III. PROGNOSIS TENDS TO VARY WITH STAGE.
c. SARCOMA	LYMPHOCYTE DEPLETED + DIFFUSE FIBROSIS	SEEN IN STAGES III & IV. PROGNOSIS TENDS TO BE POOR.

FIG. 192.—Histological classification of Hodgkin's disease.

Karl Sternberg, 1872–1935. Pathologist, Vienna. Described the giant cell of Hodgkin's disease in 1898.
Dorothy Reed, 1874–? Pathologist, Johns Hopkins Hospital, Baltimore, U.S.A. Described the giant cells in 1902.

Histological Classification.—The current histopathological classification of Hodgkin's disease is based predominantly on the lymphocytic infiltration, and the fibrous and reticular elements. The reason for the change in classification from the original of granuloma, paragranuloma and Hodgkin's sarcoma is that this classification

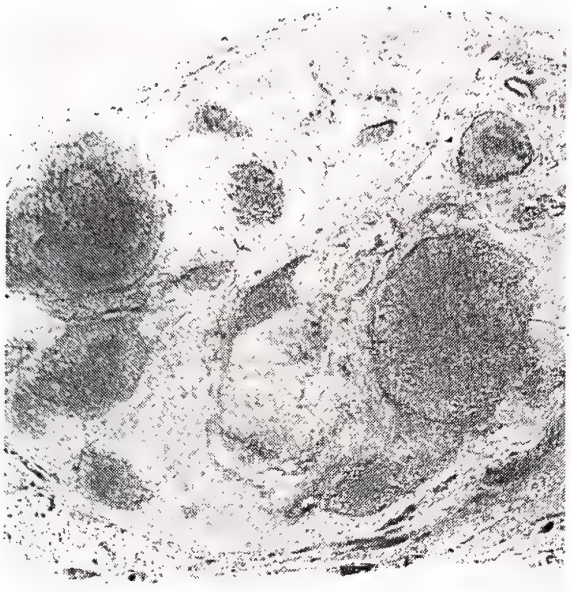


FIG. 193.—Section of whole lymph node (nodular-sclerotic).

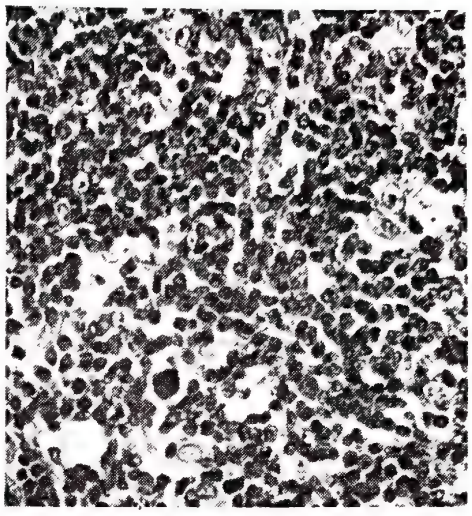

FIG. 194.—Lymphocytic predominance.

was found to be prognostically insignificant in a large proportion of cases, especially those showing the features of the so-called granuloma. Fig. 192 shows the comparison between the original and present classification and their prognostic significance and clinical correlations. The accompanying Figs 193, 194 and 195 illustrate the histological features seen in biopsy specimens of lymph nodes.

Clinical Features (figs. 196 and 197).—The disease is more common in males, and usually it affects young adults (25–40 age group), but both younger and older age groups may be affected.

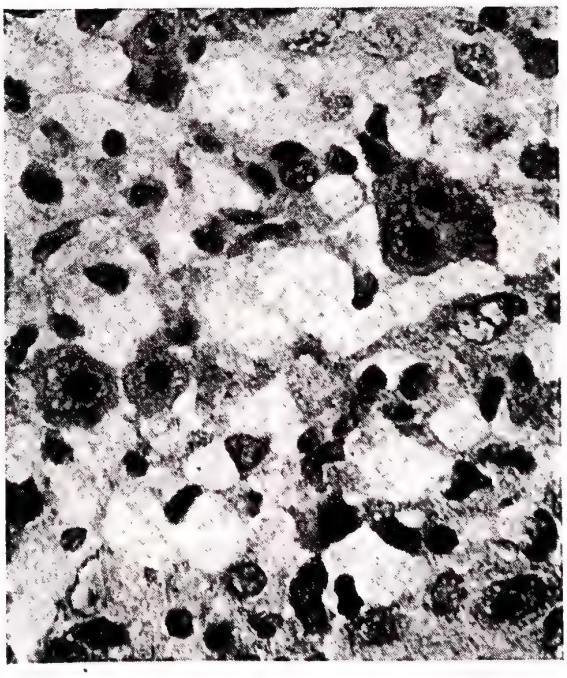

FIG. 195.—Mixed cellularity. Reed-Sternberg cells.

The most common presentation is painless progressive lymph node enlargement in the cervical or supraclavicular region; this may be associated with generalised symptoms such as malaise, fever, weight loss or pruritus, or it may be the only feature of the disease. Pressure effects such as superior vena-caval obstruction from enlarged mediastinal lymph nodes may follow or occasionally be the presenting feature. Bone pain, particularly spinal may indicate vertebral collapse secondary to bony metastases. A recognised but unexplained symptom is pain in the sites of disease induced by drinking alcohol.

On examination, the involved nodes tend to be discrete, non-tender and rubbery in consistency as opposed to tuberculosis where the nodes are matted together. In late or anaplastic cases however the nodes may become matted. Splenomegaly and hepatomegaly is a variable accompaniment (see below). As the disease advances irregular elevations of the temperature may occur.[1] With dissemination bony metastases, anæmia and pancytopænia may develop. There may also be skin deposits in advanced cases (Mycosis fungoides). Jaundice due to excessive hæmolysis of red cells or diffuse liver involvement is also seen.

FIG. 196.—Hodgkin's disease.

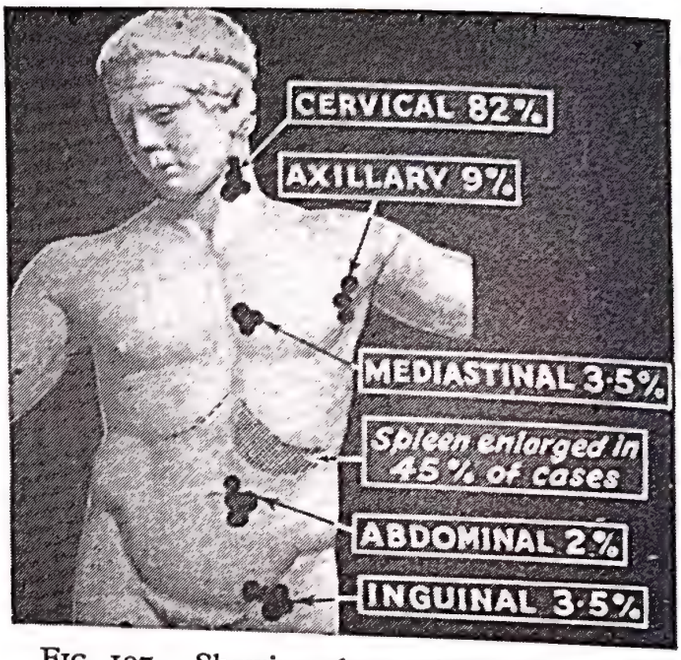

FIG. 197.—Showing the position of Hodgkin's disease when the patient was seen first. In 14% of cases more than one region was involved. (*Baker and Mann's statistics.*)

The course of the disease is very variable: death may follow in weeks but long term survivals are not uncommon and with modern methods of treatment the disease may be cured.

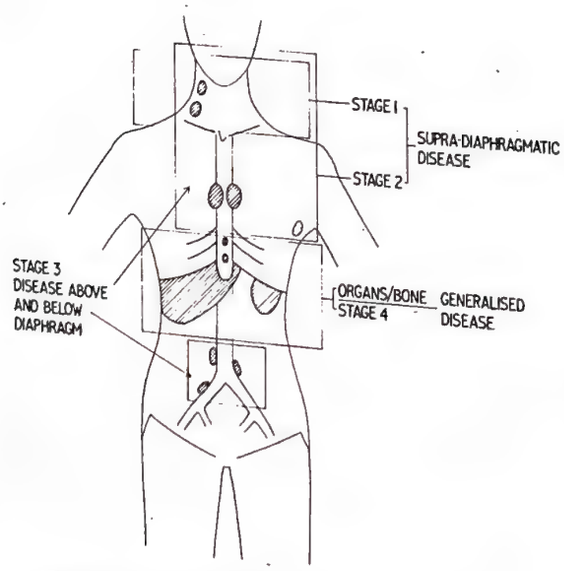

FIG. 198.—The clinical staging of Hodgkin's disease.

The Clinical Staging of Hodgkin's Disease (fig. 198).—The clinical staging of Hodgkin's disease, which includes localised, generalised and intermediate varieties, is necessary to determine accurately the extent of the disease, the subsequent treatment and the prognosis.

The disease is subdivided into four stages. Each stage is further subdivided into groups *a* or *b* according to the absence or presence

[1] The periodic Pel-Ebstein fever, originally described as a feature of Hodgkin's disease is a mistake. This Pel-Ebstein fever was due to Brucellosis.

Pieter Klazes Pel, 1852–1919. Professor of Medicine, Amsterdam, Holland. Described a relapsing fever in Hodgkin's disease in 1885.

Wilhelm Ebstein, 1836–1912. Professor of Medicine, Göttingen, Germany. Also described the relapsing fever of Hodgkin's disease in 1887.

of associated generalised symptoms such as weight loss, fever, pruritus, anæmia and bone pain.

Special Investigations Leading to Clinical Staging.—The following procedures are currently in use:—

A. *Node Excision Biopsy* to establish the diagnosis and accurate histological grading.

B. *Chest X-Ray* to demonstrate enlarged mediastinal nodes and tomography when indicated.

C. *Mediastinal Scanning* with Gallium 67 has been found to demonstrate involved mediastinal nodes.

D. *Intravenous Urography* may show distortion or compression of the renal calyces by retroperitoneal nodes.

E. *Lower Limb Lymphangiograms* will demonstrate both pelvic and retroperitoneal nodes. Unfortunately this investigation is associated with both false positive and false negative results.

F. *Laparotomy/Splenectomy/Liver and node biopsy* are being used more frequently to stage Hodgkin's disease. Clinical splenomegaly is unreliable in assessing splenic involvement. In one series 50% of patients with splenomegaly were found not to have splenic Hodgkin's at laparotomy. Moreover 25% of those cases without clinical splenomegaly were found to have deposits in the spleen at laparotomy. In addition this procedure may aid in decreasing the problem of hypersplenism and obviate splenic irradiation and its complications. Enlarged aortic, iliac and mesenteric nodes are sought and biopsied. While the value of this procedure must be weighed against its morbidity and mortality, its value is obvious in staging and treatment.

The Relationship between Histological Grade, Clinical Stage and Survival.—There are two clinical varieties of Hodgkin's disease; a localised predominantly non-aggressive form, and an aggressive, progressive and fatal variety. Between these two extremes there are intermediate or changing types of disease.

Histologically inactive disease is lymphocyte predominant, clinically stage I and potentially curable. Progressive disease is characterised histologically by diffuse fibrosis and lymphocyte depletion or anaplastic reticulum cells. Clinically it is seen in stage IIIb and IV and is associated with systemic symptoms. Changing disease is characterised by mixed cellularity or nodular sclerosis in stage II or III disease. Nodular sclerosis in stage I disease however may be associated with a good prognosis.

Treatment Policy for Hodgkin's Disease and Reticuloses.—There are two forms of treatment available according to the accurate staging of the disease, radiotherapy and combination chemotherapy. Both treatments are associated with bone marrow depression and toxic side-effects and must be carefully planned and controlled with regular blood counts. Radiotherapy is the treatment of choice in stage I, II and IIIa disease, whilst combination chemotherapy is used in stage IIIb and IV. Megavoltage radiotherapy allows wide areas to be treated. Supradiaphragmatic disease is treated by

radiotherapy to cervical, axillary and mediastinal nodes. Normal tissue is protected by lead shields. Radiotherapy is given in divided doses over several weeks and the dose is in the region of 3,500–4,000 rad. Infradiaphragmatic disease is treated by fields covering the para-aortic and iliac nodes (inverted Y fields). Combination chemotherapy involves repeated courses of cytotoxic drugs and steroids as it has been shown that the drugs produce better remission when used in combination. The combination commonly used is Nitrogen mustard, Vinblastine, Procarbazine and Prednisone.

FIG. 199.—Reticulosarcoma of the parotid 'lymph gland', which responded to radiotherapy.

Results and Prognosis of the Reticuloses.—Up to 50% five-year cures have been obtained in Hodgkin's Disease and reticulosarcoma (fig. 199). Lymphosarcoma is often dramatically radiosensitive, and the five-year cure rate for localised disease in the neck is 70%.

Malignant Lymphoma of Africa (Burkitt Tumour) (fig. 200).—*The ætiology* is of special interest. This rapidly growing tumour is the commonest malignant disease of children living in the equatorial regions of Africa. The age distribution is characteristic with over 80% of cases occurring between the ages of 3 and 12 years inclusive. Although this tumour is now known to occur occasionally anywhere in the world, it has only been reported in endemic proportions in tropical Africa and New Guinea. The observation that endemic distribution is limited to warm, moist climates strongly suggests the implication of some biological agent. A vectored virus was consequently considered the most likely ætiological factor. The realisation that many regions are apparently tumour-free, whereas the distribution coincides with that of hyperendemic and holoendemic malaria, suggests that variations in incidence may be dependent on malarial changes in the reticulo-endothelial system, with an added virus infection inducing malignant change. Evidence of E.B. virus infection which is now believed to be the cause of infectious mononucleosis has been almost invariably found in Burkitt's lymphoma and the two conditions may be associated.

Clinical and Pathological Features.—The tumour is multifocal, grows rapidly and is soft and relatively painless. In Africa, approximately 50% of patients present with jaw tumours which may affect one or more of the jaw quadrants. Maxillary lesions may present as oral or orbital tumours. The second commonest clinical presentation is an abdominal tumour. Renal involve-

FIG. 200.—Burkitt tumour. (*Dr. Denis Burkitt, London.*)

Denis Parsons Burkitt, F.R.S., Contemporary. Medical Research Council Scientific Staff. Described this type of sarcoma in 1958.

ment, usually bilateral, is present in 75% of all patients. In girls, ovarian involvement is particularly characteristic and paraplegia without vertebral collapse is also common. Peripheral or mediastinal lymphadenopathy or lung involvement is exceptional, but tumours are frequently observed in the thyroid, testicles, skeleton and breasts. Radiologically the tumours first appear as multiple, small osteolytic deposits which coalesce to form larger areas of bone destruction. On microscopic section dense masses of darkly staining primitive lymphoid cells interspersed with large clear histiocytes give an appearance under low power magnification of a 'starry night'.

FIG. 201.—Chloroma. (*A. A. McConnell, F.R.C.S.I., Dublin.*)

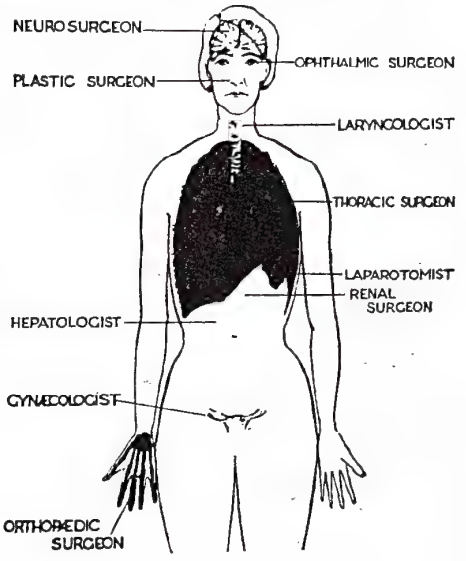

FIG. 202.—Presentations of sarcoid tissue to various surgical specialists.

Course and treatment.—Although most cases grow rapidly and relentlessly, a number of spontaneous remissions have been recorded. The tumour is unusually sensitive to both radiotherapy and a wide range of cytotoxic drugs such as cyclophosphamide, methotrexate and orthomelphalan. A much higher proportion of long-term survivors have been reported than in any other form of childhood cancer. Several of these have followed single doses of therapy suggesting a strong host defence mechanism, possibly immunological. Surgery is not indicated with the possible exception of removing large ovarian tumours.

CHLOROMA

(*syn.* myeloblastic reticulosarcoma) is a rare condition in which the bones of the face, and especially those of the orbits, are involved (fig. 201). It is a leukæmic condition, and at postmortem the tumours present a bright green colour.

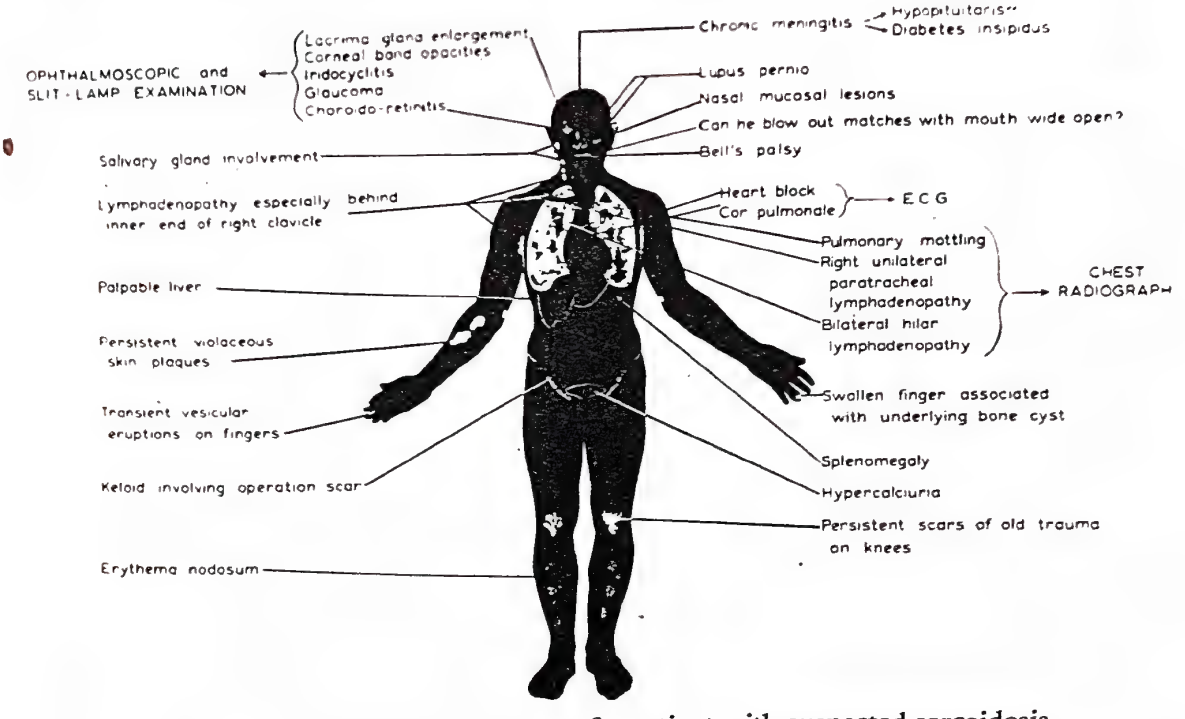

FIG. 203.—Clinical examination of a patient with suspected sarcoidosis.

DIFFERENCES BETWEEN SARCOIDOSIS, AND A NON-SPECIFIC LOCAL SARCOID-TISSUE REACTION

	Sarcoidosis	*Sarcoid-tissue Reaction*
No. of systems involved	Several	Usually one
Age group	20–50 years	Any
Chest radiograph	Abnormal in 84%	Normal
Slit lamp examination of eyes	Abnormal in 25%	Normal
Tuberculin test	Negative in 66%	Variable
Siltzbach-Kveim test	Positive in 84%	Always negative
Calcium metabolism	Abnormal in 20%	Normal
Response to corticosteroids	Good	Variable
Other treatments	Oxyphenbutazone Chloroquine p-Aminobenzoate	Depends on cause —Anti-Infective —Immunosuppressive —Cytotoxic

COMPARISON BETWEEN SARCOIDOSIS AND HODGKIN'S DISEASE

Feature	*Sarcoidosis*	*Hodgkin's disease*
Age	20–50	Any
Fever	Rare	Common
Weight loss	Infrequent	Frequent
Splenomegaly	In 12%	Very common
Submental lymph nodes	No	Yes
Erythema nodosum	Common	Very rare
Pruritus	Absent	Present
Bone lesions	'Punched out' phalangeal cysts	Sclerotic lesions of spine and pelvis
Leukocytosis; lymphopenia; eosinophilia	Absent	Present
Hilar lymphadenopathy	Bilateral	Bilateral or unilateral
Pulmonary infiltration	Common	Uncommon
Pulmonary infiltration followed by hilar adenopathy	Never	Frequent
Secondary infections	Rare	Common
Pleural effusion	No	Yes
Immediate-type hypersensitivity	Normal	Normal
Delayed-type hypersensitivity	Depressed	Depressed
Circulating antibodies	Normal	Normal
Serum immunoglobulins	Normal or nonspecific increase	Normal
Homograft rejection	?	Delayed
Histology	Distinctive	Distinctive
Radiotherapy	Unhelpful	Helpful
Corticosteroids	Therapy of choice	Helpful
Immunosuppressive regimes	Not indicated	Indicated
Prognosis	Good	Poor

BOECK'S SARCOIDOSIS

Description of Sarcoidosis.—Sarcoidosis is a multisystem granulomatous disorder of unknown ætiology most commonly affecting young adults and presenting most frequently with bilateral hilar lymphadenopathy, pulmonary infiltration, skin or eye lesions. The diagnosis is established most securely when clinicoradiographic findings are supported by histological evidence of widespread non-caseating epithelioid cell granulomas in more than one organ or a positive Kveim-Siltzbach skin test. Immunological features are depression of delayed-type hypersensitivity suggesting impaired cell-mediated immunity and raised or abnormal immunoglobulins. There may also be hypercalciuria with or without hypercalcæmia. The course and prognosis may correlate with the mode of onset: an acute onset with erythema nodosum heralds a self-limiting course and spontaneous resolution while an insidious onset may be followed by relentless progressive fibrosis. Corticosteroids relieve symptoms and suppress inflammation and granuloma formation.

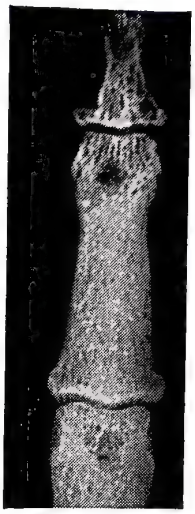

FIG. 204.—Bone cysts in sarcoidosis.

Clinical Manifestations.—It affects lungs, eyes, skin, spleen, lymph nodes, lacrimal and parotid glands, central nervous system so it presents to surgeons of different disciplines (fig. 202). Examination of a patient with suspected sarcoidosis comprises full physical examination (fig. 203), slit lamp examination of the eyes and chest radiography.

Diagnosis.—The diagnosis is based on the twin criteria of a compatible clinical picture and histological evidence of sarcoid tissue; the latter is obtained by biopsy of skin, lymph node or liver or by scalene node biopsy, mediastinoscopy or fibreoptic bronchoscopy. The Kveim-Siltzbach skin test is a simple specific outpatient technique which is positive in 80% of patients with sarcoidosis. It is an index of activity of the disease.

Differential Diagnosis.—Sarcoidosis must be distinguished from a non-specific sarcoid-tissue reaction and from Hodgkin's disease (see tables).

Treatment.—Corticosteroid therapy is indicated for uveitis, pulmonary infiltration, hypercalciuria and renal calculi, disfiguring skin lesions, neurosarcoidosis, myocardial sarcoidosis, and involvement of spleen, lymph nodes, parotid and lacrimal glands. Alternative treatments comprise oxyphenbutazone for acute exudative disease and chloroquine or potassium-p-amino-benzoate (Potaba) for chronic fibrotic sarcoidosis.

Cæsar Peter Moeller Boeck, 1845–1917. Professor of Dermatology, Oslo, Norway. Described sarcoidosis in 1899.
Louis Elliot Siltzbach, Contemporary. Clinical Professor of Medicine, Mount Sinai Hospital, New York, U.S.A.
Morten Ansgar Kveim, 1892–1967. Dermatologist, Oslo, Norway.

CHAPTER 11

THE HAND. HAND INJURIES. THE FOOT

INFECTIONS OF THE HAND

INFECTIONS of the hand are encountered most commonly in manual workers and housewives who frequently suffer small abrasions or pricks in the course of their work. The infective organism is the *Staph. aureus* in 80% of cases, *Strep. pyogenes* and gram-negative bacilli. Unless the infection can be aborted suppuration will follow. The early detection of pus and its accurate localisation are of cardinal importance. Œdema is a common feature in hand infections, being most evident on the dorsum of the hand (fig. 205) irrespective of the site of the lesion, and is a potent cause of subsequent stiffness of the digits.

FIG. 205.—Pitting œdema of the dorsum is usually due to infection on the palmar side of the hand.
(T. J. McNair, F.R.C.S., Edinburgh.)

Types of Infection

Acute Paronychia is the most common infection of the hand. The infection, which is subcuticular and under the eponychium, arises from a hangnail (fig. 206), careless nail paring, or an unsterile manicure instrument. Suppuration usually follows, and confined by the adherence of the eponychium to the base of the nail, the pus tends to track around[1] the cutaneous margin and, in 40% of cases, under the nail.

Treatment.—Cloxacillin or tetracycline given early may abort the infection. If pus has formed it must be let out (see principles of treatment p. 195).

FIG. 206.—Paronychia. Often organisms enter through a 'hang-nail', as in this case.

At operation only the eponychium is stripped gently and completely away from the base of the nail. All pus is wiped away; loose cuticle is cut away, and there should be a pocket under the corner of the nail fold, a wedge of overlying skin is removed to ensure healing from the bottom. The loose and ragged eponychium is then excised with delicate, sharp-pointed scissors. When pus has extended beneath the nail, the undermined portion must be excised with fine-pointed, but strong, scissors. 'Floating' nail is dead nail; consequently all unattached nail must be excised. Only when pus has extended beneath half or more of the width of the nail is excision of the proximal third of the nail required.

[1] The colloquial American term for paronychia is 'run around'.

Chronic Paronychia[1].—The history is measured by months, rather than days, and the onset is insidious[2]; seldom does it follow acute paronychia. Today the housewife who does not wear rubber gloves when 'washing-up' is the usual sufferer. Antibiotic therapy has little or no effect, but operative treatment following the lines detailed above is often successful if the infection is a bacterial one. In many cases, however, the infection is due to a monilia or yeast (p. 31). This can be settled by microscopical examination of scrapings and/or special cultures for fungi.

A useful method of treating these indolent infections is by 1:500 Bradosol (domiphen bromide) in spirit, or Penotrane tincture (hydraphen) dropped into the nail-fold twice daily. Nystatin ointment (Squibb) can also be tried. When the pockets become filled with granulations the treatment is discontinued, and the hands must be kept as dry as possible until epithelialisation occurs.

Subcutaneous infections and abscesses can occur at various levels (fig. 207). The volar surface of the hands of manual workers is often covered

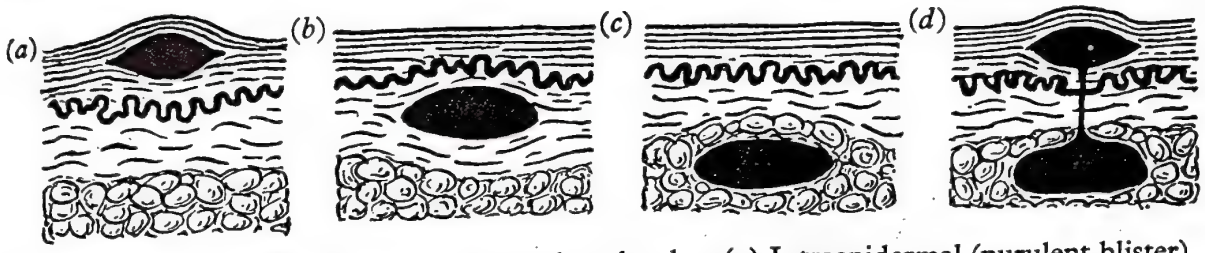

FIG. 207.—Superficial abscesses at various levels. (*a*) Intraepidermal (purulent blister), (*b*) Intradermal, (*c*) Subcutaneous, (*d*) The superficial loculus of a collar-stud abscess.
(After R. S. Pilcher, F.R.C.S., London.)

with greatly thickened epithelium. Especially in such individuals, a subcutaneous abscess may burst through the dermis and extend in the layers of the epidermis (fig. 207 (*d*)), in which event it is impossible to differentiate it from a purulent blister until the deeper loculus has been discovered at operation.

Treatment.—The abscess is opened by transfixion. The resulting undermined flaps are cut away with scissors. The unroofed cavity is swabbed free from pus which is examined by culture for the identification of the bacteria and for tests of their sensitivity to various antibiotics. Then it is explored for a sinus leading to a deeper loculus. If such is found, the communicating channel is stretched by inserting and opening the jaws of a small hæmostat.

Dorsal infection is usually a furuncle or boil of the overlying skin. Incision is only necessary if pus is present (see principles of treatment p. 195).

Infection of the terminal pulp space (*syn.* Felon[3]) is the second most frequent infection of the hand (about 25 per cent. of all cases). The index finger and the thumb are affected most often. The origin of the infection is usually a prick.

Surgical Anatomy.—The deep fascia, which is attached to the thin skin of the distal flexion crease, fuses with the periosteum just distal to the insertion of the deep

[1] Called by some dermatologists (quite descriptively) chronic *peri*onychia.
[2] A constant look out must be kept for the occasional case resulting from neuropathy, e.g. syringomyelia.
[3] Felon (Latin, *fel* = gall). An abscess near the nail; also, one who has committed a felony.

Robin Sturtevant Pilcher, Contemporary. Emeritus Professor of Surgery, University College Hospital, London.

flexor tendon, thereby closing the terminal pulp compartment at its proximal end. Through the space, which is filled with compact fat, feebly partitioned by fibrous septa, run the terminal branches of the digital artery. Thrombo-arteritis of these vessels accounts for the frequency with which osteomyelitis complicates infection of this closed space. The basal plate of the epiphysis is rarely involved.

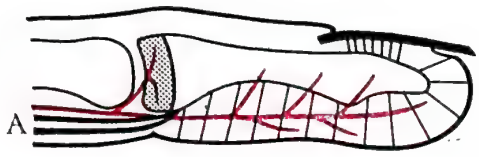

FIG. 208.—Distal pulp space to show how its proximal end is closed by attachment of the deep fascia and by the fibrous septa. The blood supply to the epiphysis does not traverse this area. A = tendon sheath and deep fascia.

Clinical Features.—Dull pain, worse when the hand is dependent, and swelling are the first symptoms. Forty-eight hours later there are severe nocturnal exacerbations of throbbing pain, interfering with sleep. Light pressure over the affected pulp increases the pain. Frequently the corresponding regional lymph node is enlarged and tender. If the pulp is indurated and has lost its normal resilience, pus is present (fig. 209). Untreated, the abscess tends to point towards the centre of the pulp beneath a patch of devitalised skin. A collar-stud abscess then occurs; if still untreated, the abscess bursts.

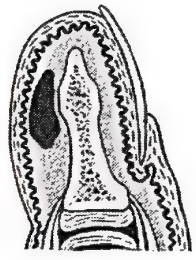

FIG. 209.—The location of pus in terminal pulp-space infection.

Treatment.—In the early stages when there is no localisation large doses of cloxacillin or tetracycline may bring about resolution. Once pus is present operation without delay is the rule (see General Principles, page 195).

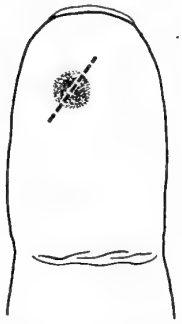

FIG. 210.—Incision for draining a pulp abscess. It is essential to drain the deep loculus of a collar-stud abscess, if such is present.

Operation.—A short incision as indicated in fig. 210 is made through the skin at the point of greatest tenderness. The beginner is warned not to be beguiled by entering only the superficial loculus of a collar-stud abscess. Removal of slough, which is frequently present, is most desirable, but great care must be taken not to traumatise the periosteum.

Osteomyelitis of the terminal phalanx may be a sequel of terminal pulp-space infection (fig. 208). That part of the bone bereft of its blood-supply will become a sequestrum and separates some weeks after the abscess has been opened, in which event the wound continues to discharge. Repeated radiographs and probing (revealing rough bone) will indicate when the sequestrum has separated. Only then must it be removed, after which healing will proceed apace. In case of a child, regeneration of the diaphysis is is possible, provided the periosteum is relatively undamaged. In the adult no regeneration occurs, and the patient is left with a shortened terminal phalanx covered by an ugly curved nail.

Apical subungual infection arises from a prick (including a splinter) beneath the nail, causing infection of the space between the subungual epithelium and the periosteum (fig. 211 (*a*)). The lesion (fig. 211 (*b*)), which is exquisitely painful, gives rise to comparatively little swelling. Tenderness is greatest just beneath the free edge of the nail, and pus comes to the surface here or beneath the nail.

Operation.—A small V is removed from the centre of the free edge of the nail, and a little wedge of the full thickness of the skin overlying the abscess is excised

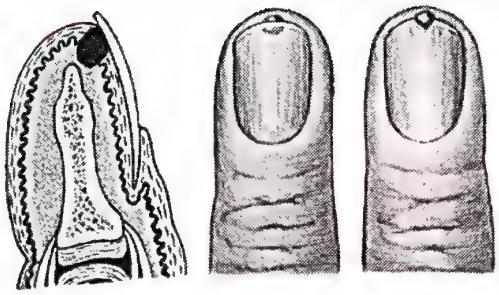

FIG. 211.—(*a*) Showing the anatomical relations of an apical abscess. (*b*) Apical abscess; clinical presentation. (*c*) V-exposure for evacuating the contents of the abscess.

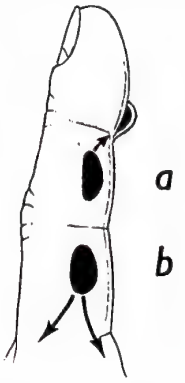

FIG. 212.—Abscess of (*a*) the middle and (*b*) the proximal volar spaces. Showing direction of spread.

FIG. 213.—An abscess of the proximal volar space (p. 193). (*After M. Iselin.*)

also (fig. 211 (*c*)). The amount of pus and debris evacuated is surprisingly small; commonly the abscess cavity extends down to the bone, but osteitis is unusual. Following the operation, relief of symptoms is immediate and the wound heals in about a week.

Infection of the Middle Volar Space of a Digit.—The fibro-fatty tissue occupying this space is more loosely packed than that of the terminal pulp space. The middle volar space is separated above and below by fibrous partitions while, like the proximal space, it is shut off from the dorsal cellular tissue by fibrous septa extending from the skin to the periosteum.

Clinical Features.—Infection of this space is much less common than that of the terminal pulp space. The finger is held in semi-flexion. In about one-third of cases attempts to straighten it are painful. There is tender induration over the space, while the soft tissues of the terminal and proximal segments, although swollen, are neither tender nor indurated.

Frequently a purulent blister appears in the distal flexion crease (fig. 212). In early cases it is difficult to distinguish infection of the middle volar space from infection of the underlying flexor tendon sheath; however, in the former, extreme tenderness over the proximal end of the tendon sheath is completely lacking.

Infection of the Proximal Volar Space.—This space is well partitioned from the middle volar space but it communicates freely with the corresponding web spaces. Once localisation has occurred (fig. 213) infection of the proximal volar space is comparatively easy to diagnose, and frequently the swelling is asymmetrical because of concomitant involvement of a web space (see below).

Operation.—After pus has become localised in either of the above spaces, it should be evacuated through a transverse incision made at the site of greatest tenderness. When the diagnosis is uncertain (localised tenosynovitis cannot be excluded) the space should be explored through a lateral longitudinal incision.

Infection of a Web Space

Surgical Anatomy.—The web spaces are the three triangular regions between the dorsal and volar skin filled with loose fat that bulges between the divisions of the palmar fascia (fig. 214). The spaces, when filled with pus, straddle the deep transverse ligament; consequently, although most of the pus is volar, the abscess points dorsally.

Ætiology.—The infection arises (1) from a skin crack, (2) from a purulent blister or from beneath a callosity on the forepart of the hand, or (3) via a lumbrical canal from an abscess in a proximal volar space.

Clinical Features.—As the constitutional symptoms are severe, patients with this condition are often seen before localisation of the infection has occurred. At this stage there is œdema of the back of the hand. Although the condition is strongly suspected from the location of the tenderness, a precise diagnosis cannot yet be made. The patient should be in bed with

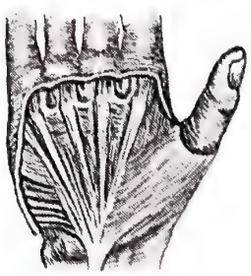

FIG. 214.—The three web spaces between the divisions of the palmar fascia are floored by the transverse ligaments.

the arm splinted and elevated by suspension. Cloxacillin or tetracycline are given. Once localisation has occurred, the signs of infection of a web space become manifest.

Localising Signs.—The base of one finger is swollen, and in severe cases the fingers immediately adjacent to the space are separated. Often there is a fan-shaped blush extending from the web on to the dorsum and a small area of purplish discoloration of the skin over the affected space (fig. 215). The maximum tenderness is found in the web and on the anterior surface of the base of one of the fingers extending a short way into the palm. Untreated, pus can track across the base of the finger into an adjacent web space, and also along the sides of the proximal segments of the digits related to the infected web.

Operation.—A transverse incision is made on the palmar surface over the affected web space (fig. 214). The incision must be deepened very cautiously until the subcutaneous fat is reached. Only a few strands of palmar fascia need to be divided, and if pus does not flow it is sought with a probe or director. If the diagnosis is correct, probing is soon rewarded by a gush of pus. The opening is enlarged to reveal an abscess cavity, often the size of a thimble. The edges of the wound are cut away, so as to leave a diamond-shaped opening (fig. 216). When the abscess communicates with a dorsal pocket, a counter-incision is advisable. If, as sometimes happens, there is a twin web abscess (one on each side of the digit), each space must be opened, but there is no need to slit the communicating channel.

FIG. 215.—Web-space abscess. Note the separation of the related digits.

Deep Palmar Abscess

An abscess beneath the palmar fascia is a serious, but rare (about 1 per cent.), infection of the hand.

Ætiology.—The infection can arise as (1) a penetrating wound; (2) infection via the blood-stream of a hæmatoma in this situation; (3) as a complication of suppurative tenosynovitis (p. 193).

Clinical Features.—As a rule the patient is a manual worker. At an early stage there is intense throbbing pain in, and deep tenderness of, the palm of the hand. Almost from the commencement this is accompanied by obvious œdematous swelling of the dorsum of the hand, which increases rapidly to become greater than that seen in any other infected lesion of the hand—so great as to give rise to what is known as 'the frog hand'. The fingers are held in a flexed position because the palmar fascia is more relaxed in this posture. Extension of the metacarpophalangeal joints is very painful, but extension of the interphalangeal joints is both painless and free. This is a most valuable observation in distinguishing the condition from suppurative tenosynovitis. The temperature is raised, and regional lymphadenitis is commonly present.

FIG. 216.—Incision for draining a web-space abscess.

As tension mounts, the normal concavity of the palm becomes flattened; a time is reached when the imprisoned pus erodes and bursts through the palmar fascia, then suddenly the intense pain passes off, but the palm becomes slightly convex. If the patient is seen for the first time after this happening, there is no means of

distinguishing a deep palmar abscess with a collar-stud extension from an abscess of a subaponeurotic space, except by operation.

Operation.—Under general anæsthesia (or regional block of the median and ulnar nerves at the wrist), a central transverse incision is made in the line of the flexion crease passing across the middle of the palm. Should pus be encountered beneath the aponeurosis, the floor of the abscess (the palmar fascia) must be probed systematically for a sinus leading to the deeper plane. In other circumstances the palmar fascia is divided *in a longitudinal direction* (to avoid digital nerves and blood-vessels). Pus is mopped up. Continued free drainage is ensured by trimming, with scissors, the skin edges as well as those of the incision in the palmar fascia. This obviates premature healing, which otherwise is prone to occur.

Lymphangitis.—Organisms, nearly always streptococci, gain entrance through an abrasion that may be microscopic. Within a few hours the adjacent portion of the hand becomes swollen and painful, and there is often considerable elevation of the temperature. Because superficial lymphatic vessels pursue the shortest course to the dorsum, œdema, which comes on early, is most in evidence on the back of the hand. Later, red streaks, so characteristic of lymphangitis (fig. 181), can be seen coursing up the arm. Especially in lesions of the ulnar half of the hand, the first lymph node to become enlarged and tender is the epitrochlear. In a few instances of infection entering the middle finger, the first lymph node to become swollen is *above* the clavicle (fig. 217), in which case infection is liable to enter the general circulation and give rise to severe constitutional symptoms. The lymphatics of the thumb and index finger pass straight to the axillary nodes. Lymphangitis can occur (*a*) without any other demonstrable manifestation of inflammation, or (*b*) as an accompaniment of the entities to be described, particularly terminal pulp-space infection and fulminating tenosynovitis. Lymphangitis responds well to the conservative measures detailed on p. 174.

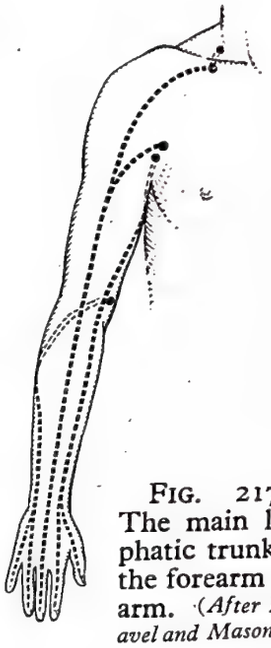

FIG. 217.—The main lymphatic trunks of the forearm and arm. (*After Kanavel and Mason.*)

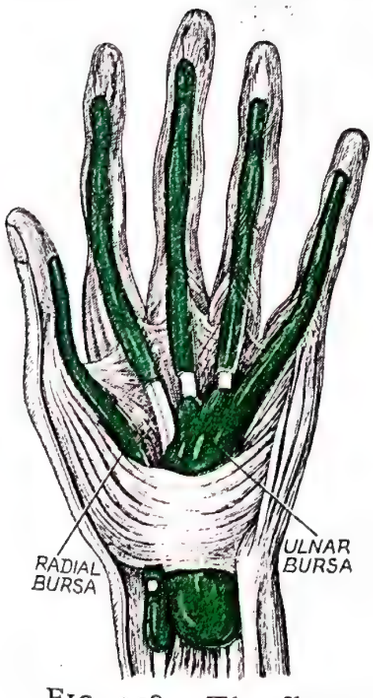

FIG. 218.—The flexor tendon sheaths. This typical arrangement is present in 75 per cent. of cases.

ACUTE SUPPURATIVE TENOSYNOVITIS

Usually infection of the sheath of a flexor tendon is due to bacteria introduced by the point of a needle or other sharp object penetrating the tendon sheath. Exceptionally the sheath is infected by extension from its terminal pulp space, in some cases from the scalpel transgressing the hallowed ground of the septum that closes the proximal end of the space (fig. 208).

Acute fulminating tenosynovitis involves the whole sheath rapidly, and nearly always the

infecting organism is the *staphylococcus aureus* or the *streptococcus hæmolyticus*. The classical local signs are:

1. Symmetrical swelling of the entire finger.
2. Flexion of the finger (the 'hook' sign) with exquisite pain on extension.
3. Tenderness over the infected sheath, especially over its proximal *cul-de-sac* (fig. 218).

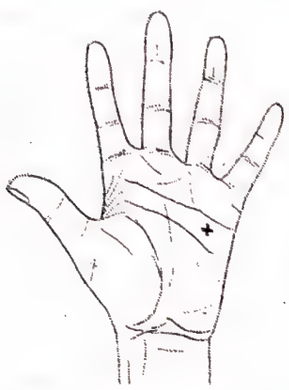

FIG. 219.—Kanavel's sign.

Localised suppurative tenosynovitis.—Swelling and tenderness are limited to one portion of the digit, rendering confident diagnosis prior to exploration difficult.

Infection of the ulnar bursa (fig. 218) is characterised by:

1. Œdema of the whole hand, especially the dorsum, due to lymphatic spread.
2. Moderate swelling of the palm.
3. Sometimes a fullness immediately above the flexor retinaculum.
4. The flexed fingers resist extension, the maximum difficulty being experienced in the little, and the least in the index finger.
5. Especially valuable is Kanavel's sign: the area of greatest tenderness is over that part of the ulnar bursa lying between the transverse palmar creases (fig. 219).

It should be noted that the ulnar and radial bursæ intercommunicate in 80 per cent. of cases, and often when an untreated infection of one has persisted for more than forty-eight hours, the other becomes involved also. In no less than 25 per cent. of cases the tendon sheath of the index, or the middle, or the ring finger communicates with the ulnar bursa, which is a fact of great surgical importance.

Infection of the radial bursa (fig. 218) is distinguished by:

1. The distal phalanx of the thumb is held in flexion, with rigidity and inextensibility of the interphalangeal joint. The other digits can be extended fully.
2. Tenderness over the sheath of the flexor pollicis longus.
3. Sometimes swelling just above the flexor retinaculum.

Treatment of Acute Infected Tenosynovitis.—Full doses of cloxacillin are given. The forearm and hand, the latter being placed in the position of rest (fig. 222), are splinted and elevated. Clinical re-examination is made every six hours. Non-operative treatment is continued only so long as there is a good local and general response. Delay in decompressing an unresponding infection may result in sloughing of the tendon.

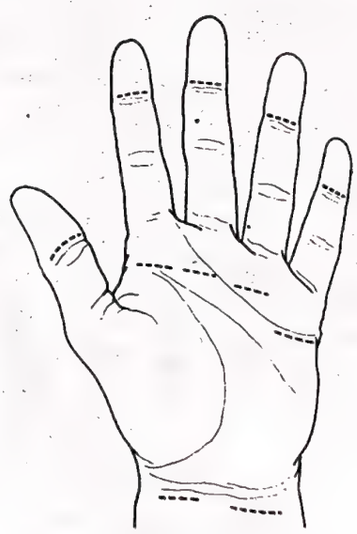

Fig. 220.—Sites of incision for treating acute suppurative tenosynovitis. The sheath is also exposed at the site of the initial trauma when such is discernible.

Operation.—When the site of puncture of the integument is visible, or has been indicated without hesitation by the patient, the first incision is made in a transverse direction directly over the tendon sheath. When there is no certain information as to where the sheath was punctured, the more distal of the two relevant incisions shown in fig. 220 is made and deepened until the fibrous portion of the sheath is displayed. This is divided and the thin, bulging theca comes into view. Some of the fluid within it is aspirated and sent for bacteriological examination; the theca is then incised in a transverse direction and its edges are pared so as to form a diamond-shaped opening. Pressure is now exerted over that portion of the sheath proximal to the incision, and if this results in a gush of hazy exudate, a second relevant incision (over

Allen Bucknell Kanavel, 1874–1938. Professor of Surgery, North Western University, Chicago, Illinois, U.S.A. The fascial spaces were described in his book 'Infections of the Hand' published in 1933.

the cul-de-sac) is made and similar steps to prevent premature closure of the wound are taken. Employing a fine catheter, the length of the sheath is irrigated with a solution of antibiotic.

Complications of Suppurative Tenosynovitis

Involvement of the Forearm from the Hand.—When a radial or ulnar bursa, distended with pus bursts, pus travels up the forearm between the flexor profundus ventrally and the pronator quadratus and interosseous membrane dorsally. It is here, in the space of Parona, that a quantity of pus can collect without giving rise to much swelling. There is, however, brawny induration above the wrist, unless the original lesion has been incised and continues to discharge pus. Therefore, in cases of infection of the radial or ulnar bursa, if pus can be expressed by pressure over the wrist at the time of operation or subsequently, it is essential that the forearm be drained by making the incisions shown in fig. 221 and deepening them until the periosteum is reached. A hæmostat is then thrust beneath the flexor tendons, and the jaws of the forceps are opened, as a result of which the proximal extremity of the infected bursa (or bursæ) is ruptured thoroughly into the space beneath the flexor tendons.

FIG. 221.—Incisions for draining the space of Parona.

Continuation of Suppuration.—Provided the principles set out above concerning early decompression of infected tendon sheaths have been followed, continued suppuration is rare. If it occurs, the first point to consider in most situations is the possibility of extension of the infection to a fascial space or another tendon sheath. Should suppuration continue for fourteen days, the hand should be radiographed for evidence of bone necrosis. In relevant cases, the possibility of a non-opaque retained foreign body should also be borne in mind. Sloughing tendon is a potent source of prolonged suppuration and much time will be saved by excising the diseased portion, care being taken to anchor its proximal end by sutures to prevent the cut end being carried into the forearm by muscular contraction, and thereby spreading infection.

Suppurative arthritis in a related joint occurs occasionally as a complication of suppurative tenosynovitis. In these circumstances timely amputation of any digit except the thumb will reduce the period of disability (S. Bunnell).

A Stiff Digit Results.—In the case of a finger, it should be remembered that in many walks of life total amputation of a digit is less of a handicap than a stiff finger, but amputation should seldom be undertaken until the infection has subsided completely. In the case of a thumb, the surgeon's watchword for infection as well as trauma is always ' Save all possible '.

Paralysis of the Median Nerve.—When signs of median nerve palsy develop in a case of infection of the hand, early decompression of the carpal tunnel by severing the flexor retinaculum is recommended (D. Bailey). In these circumstances, involvement of the median nerve is due to compression of the nerve by the distended radial or the ulnar bursa, or (more frequently) by both bursæ, which of course must be drained thoroughly at the same time.

GENERAL PRINCIPLES OF TREATMENT IN ALL CASES OF INFECTIONS OF THE HAND

The five principles in the treatment of infections of the hand can be summarised as follows :

(i) Antibiotic therapy.
(ii) Provision of rest and elevation to the affected limb.
(iii) Early recognition of the presence of pus and its accurate localisation.
(iv) Evacuation of pus and, in the case of fascial spaces, debridement of the walls of the abscess cavity.
(v) Adequate after-treatment.

To consider these principles in more detail:

Francesco Parona, 1861–1910. Surgeon, Ospedale Maggiore Novara and at Milan, Italy.
Sterling Bunnell, 1882–1957. Consultant in Hand Surgery to the Surgeon-General of the United States Army and to the United States Navy.
David Alan Bailey, Contemporary. Surgeon, University College Hospital, London.

Antibiotic Therapy.—Antibiotic therapy is given without delay. Because in over 90 per cent. of cases of infections of the hand the original infection is caused by staphylococci, streptococci and gram-negative organisms, cloxacillin or tetracycline are currently the antibiotics of choice. The final choice of antibiotic depends upon the sensitivity tests. It is futile, damaging, and often disastrous to rely on antibiotics when suppuration has occurred. *If there is pus in any part of the hand it must be evacuated.*

Rest and Elevation of the Hand.—If it is considered possible that resolution will occur, and also following operation, the hand must be placed in the position of rest (fig. 222). When it is anticipated that in all probability some portion of the hand will become stiff, as soon as the ultra-acute

FIG. 222.—The position of rest taken up by an acutely inflamed hand. The index finger is not flexed as much as the others.

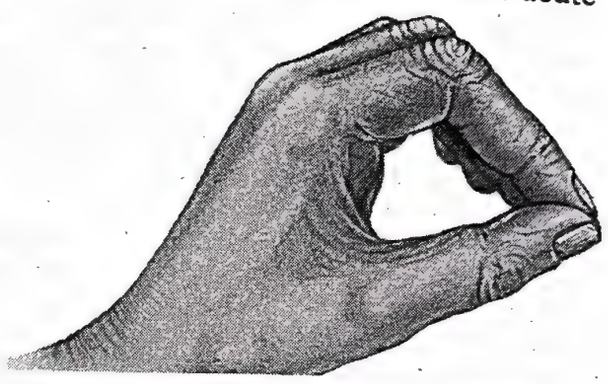

FIG. 223.—The position of function.

stage has passed the digits should be arranged in the position of function (fig. 223). For ambulatory patients a light plaster-of-Paris slab, moulded to fit the volar surface of the hand and forearm, cannot be bettered. In addition, the forearm is supported in a sling as high as possible towards the opposite shoulder, in order to lessen œdema. For in-patients a Cramer wire splint, which is readily suspended, is both efficient and comfortable. Full elevation in the manner shown (fig. 224) decreases œdema and lessens the throbbing pain.

FIG. 224. — Suppurative tenosynovitis being treated by immobilisation and elevation.

These remarks concerning elevation do not apply to cases of uncomplicated paronychia and minor superficial abscesses; for these an ordinary sling is all that is required.

In all cases rest for an inflamed hand should be insisted upon. When the acute phase has abated, gentle voluntary movements are encouraged.

Anæsthesia.—For the distal part of the finger regional anæsthesia is employed, using 2 per cent. procaine or xylocaine (*without adrenaline*, as vaso-constriction is harmful). After raising a weal, the hypodermic needle is introduced at the relevant dual points shown in fig. 225. While injecting the anæsthetic solution the needle is advanced distally and forward until it is judged that the digital nerve has been reached; 0·75 ml. of the anæsthetic solution is deposited here. The procedure is repeated on the contralateral aspect of the affected finger. In the case of an abscess of the hand itself, a general anæsthetic is administered, or a regional block of the median and ulnar nerves at the wrist is under-

Freidrich Cramer, 1847–1903. Surgeon, St. Joseph's Hospital, Würzburg, Germany.

taken. On no account should a short general anæsthetic, e.g. nitrous oxide gas, be employed. Complete muscular relaxation and ample time are most desirable when operating in this area.

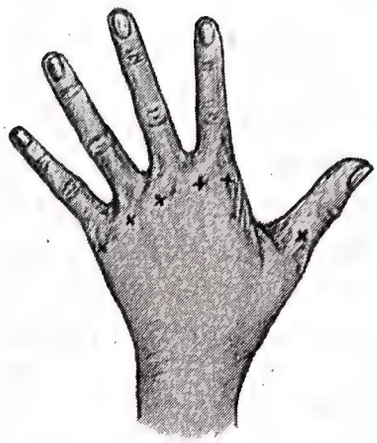

FIG. 225.—Points of puncture for anæsthetising a digit.

A bloodless field is essential. Only in the absence of bleeding can the exact site and extent of the lesion be determined and damage to tendon sheaths and nerves be avoided. The cuff of a sphygmomanometer is applied to the upper arm. The limb is then elevated for two minutes, after which the bag is inflated to a pressure of 40 mmHg (5·3 kPa) above the systolic blood-pressure.

Operation is undertaken at a time when there is a high antibiotic level in the blood. With the exception of tendon-sheath infection, it is insufficient merely to evacuate the pus. The operation must be meticulous. Slough is removed unless it is densely adherent and, what is extremely important, granulations are abraded by gauze or scooped away with a curette, avoiding the latter in situations where it might damage the periosteum or a tendon sheath. Only after granulation tissue has been removed, leaving the walls clean and oozing blood, will the injected antibiotic from the blood enter the cavity freely. Provided every nook and cranny has been attended to in this manner, no drainage material is employed, for no further pus is expected to form; merely a little serum, at first containing blood and dead bacteria is all that oozes from a cavity thus treated. This lessens in amount about the third day, when quick healing is to be expected.

After-treatment of Serious Infections of the Hand.—In all cases dry dressings are employed. The dressings are changed at the end of twenty-four hours after operation. Thereafter often an interval of two days can elapse between re-dressings. The patient must be instructed not to get the dressings wet. These instructions differ only in the case of paronychia; in this instance the patient is instructed to wash the hands frequently, dry them thoroughly on a towel kept for the purpose, and re-apply the dressing himself. Physiotherapy and exercises form an important part of the late after-treatment. In rare cases with persisting deformity, rehabilitation for a new job may be necessary.

OTHER INFECTIONS

Human Bites.—Because the wound becomes contaminated with so many types of bacteria (including Vincent's organisms from the mouth), a human bite can prove very dangerous to life or limb. Although not strictly a bite, a common type of injury of this kind is an incised wound over the knuckles resulting from a clenched fist of one combatant striking the front teeth of his opponent. The joint is usually penetrated, but the track closes when the fingers are extended. In such a case the wound must be excised and, if the capsule has been penetrated, a portion of the capsule must be included in the debridement. Because of heavy contamination, primary closure of the wound resulting from excision of a human bite is inadvisable (see Chapter 1).

Orf (Contagious Pustular Dermatitis of Sheep).—A virus disease of sheep transmitted to humans who handle infected animals and their skins or carcases. It forms granulomas on the hands.

FIG. 226.—Interdigital pilonidal sinus in a barber.

Barber's Pilonidal Sinus.—Hair clippings have a bevelled extremity like the point of a hypodermic needle. Barber's pilonidal sinus is due to the customers' clippings penetrating the skin, most frequently the web between digits 3 and 4 of the left hand. In the uninflamed state the lesion is marked by a small black dot with a collarette of epithelial scales around it; a cyst-like nodule can be palpated beneath the visible lesion. Recurrent attacks of subacute or acute inflammation (fig. 226) in the sinus cause the patient to seek relief. (For the common variety of pilonidal sinus see Chapter 50.)

HAND INJURIES

It is now appreciated that hand injuries require the combined skills of the plastic, orthopædic and general surgeon and are often best handled in specialised units. Basic understanding of the physiology of the hand and the appreciation of the complications of injuries and methods of overcoming them, has led to big advances in the management. Rank and Wakefield have laid the foundation of the modern approach, viz. primary reconstruction.

Classification (Based on Rank and Wakefield)

1. *Tidy Injuries.*—These are due to sharp agents, e.g. glass, knives, etc. The cuts are clean and incised. Tendons, nerves and blood-vessels (bone seldom) may be involved. Common in children, these injuries must receive the correct primary treatment.

2. *Untidy Injuries.*—These injuries are common in industry. The skin is often ragged and there may be multiple fractures. It is essential to get correct skin closure after excision of all the devitalised tissues, by whichever method is applicable—suture, grafting or flap (p. 119). Primary repair of nerves and tendons in these injuries is *not* advisable.

3. *Indeterminable Injuries*, for example the severe crush or burn (fig. 227). It is impossible to know early on the full extent of the injury. One must wait to see what remains viable. During the observation stage, elevation of the arm and antibiotic cover are vital. It may be necessary to wait up to 3 weeks before proceeding with excision of dead tissue and repair.

FIG. 227.—Indeterminable injury of the hand. (*E. Melmed, F.R.C.S., Dallas.*)

Evaluation of the Injury.—Careful examination of the injured hand is essential in order to ascertain the extent of injury of the following:—

1. *Nerves.*—The patient may be in too much pain and may be too apprehensive for accurate sensory testing. Motor testing may be impossible because of associated injuries to tendons or bones.

2. *Arteries.*—Arterial damage is suspected by profuse hæmorrhage. The state of the blood-supply to a finger distal to a laceration should always be carefully noted.

3. *Tendons and their Sheaths.*—Tendon sheaths may be lacerated without the tendon that they contain being involved. This injury can only be detected when the laceration is explored. Division of a tendon will result in lack of active movement whilst the appropriate passive movement remains possible although painful. The tendon may be visible in the wound. Isolated division of the superficial flexor tendons may be difficult to detect clinically, since flexion of the involved fingers will appear to be normal on casual examination.

Sir Benjamin Keith Rank, Contemporary. Plastic Surgeon, Royal Melbourne Hospital, Melbourne, Australia.
Allan Ross Wakefield, Contemporary. Plastic Surgeon, Royal Children's Hospital, Melbourne, Australia.

4. *Bones.*—The presence of a bony injury can usually be detected clinically and can always be detected radiologically.

5. *Joints.*—Injuries to joints may be clinically obvious, or may only be detected when the wound is explored.

Treatment, in order of importance at this time, is as follows:—

1. *Repair of Skin.*—Skin cover is *vital* as raw areas predispose to infection and fibrosis. Fibrosis is the big enemy of hand surgery.

2. *Treatment of bone and joint injuries.*

3. *Repair of nerves.*

4. *Repair of tendons.*

Principles of Technique

Tourniquet.—The use of a tourniquet in hand surgery is essential.[1] The maximum safe time for a tourniquet is 1·5 hours. Strict recording of the time of application, plus constant reminders to the surgeon of the progress of time (15 min. intervals) will avoid the risk of too long application. In finger surgery, rubber tubing can be tied around the base of the finger to give an adequate bloodless field.

Anæsthetic.—The type of anæsthesia varies with the type of injury and the general condition of the patient. If a tourniquet is used, it is often more comfortable for the patient to be under a general anæsthetic. Adequate sedation is usually necessary for a good brachial plexus or local block. Local blocks, or intravenous anæsthesia, with a tourniquet are very useful. Adrenaline in a local anæsthetic in finger surgery is strictly contraindicated.

Careful Wound Toilet.—The skin, the fingernails and the wound must be thoroughly cleansed. Any of the accepted antiseptics is adequate, e.g. Hibitane. It is very important to get rid of all the debris.

Excision (p. 5).—All devitalised tissue must be excised in untidy injuries.

Hæmostasis is essential. In an emergency, direct pressure applied over the bleeding area will stop hæmorrhage (p. 69). *Not* in any circumstances should the operator grab at bleeding points with artery forceps. After release of the tourniquet, all bleeding points are ligated.

Antibiotics and Antitetanus Toxoid.—These should be administered routinely (pp. 7 and 26).

REPARATIVE SURGERY

Skin Loss

Skin Loss without Involvement or Exposure of the Deeper Structures.—On the *dorsum* of the hand a split thickness (Thiersch) graft is the method of choice, due to the simplicity and speed. These grafts are unlikely to contract as the pull of the strong flexors of the fingers overcomes this tendency. On the *palm,* a split thickness graft will contract, and thus it is necessary to use a thicker skin, viz. a full thickness (Wolfe) graft (p. 119). This type of graft is more difficult in that its vascularity is more precarious and thus hæmostasis is essential, and adequate fixation and immobilisation vital to success.

Finger Tips—see p. 201.

Skin Loss with Exposure of Deeper Tissues.—Split thickness grafts will not take on the following—bare bone (devoid of periosteum), bare cartilage, or bare tendon (devoid of paratenon), and necessitates the choice between the following:—(*a*) *Local Flaps*: e.g. cross finger flaps. These are extremely valuable in covering bare flexor tendon in the finger. Flaps of the dorsum and the palm are very difficult as the blood supply can easily be misjudged and necrosis will follow.

(*b*) *Distant Pedicle Flaps:* These must be reserved for severe injuries. The donor site may be the abdomen, chest or arm. After raising the flap the donor site is grafted with split thickness skin taken from the thigh. There are several disadvantages, viz:— 1. Scarring; in a female, this may make it unacceptable as a method of

[1] Bunnell (p. 195) said, 'Can a jeweller repair a watch in a pool of ink?'

treatment and is reserved only when no other alternative exists. 2. Poor positioning of the limb may lead to œdema and consequent stiffness. In older people, this may remain permanently, despite physiotherapy. 3. The flaps tend to be thick and swollen.

Fractures (p. 337).

Nerve Injury (Chap. 26).—In tidy injuries primary suture is preferable. Digital nerves, easily identified at the initial operation, may be impossible to find at a secondary procedure.

Tendon Injuries

Timing of Tendon Surgery.—Tidy injuries may be dealt with immediately. In untidy and indeterminable injuries repair is delayed until the wound has healed.

Extensor Tendons.—Primary suture usually gives good results as these tendons are highly elastic and vascular and have a good paratenon. Moreover, the tendons act on the metacarpo-phalangeal joint and have a short movement. (The inter-phalangeal joints are extended by the interossei and lumbricals.)

Flexor Tendons. (*a*) *Palm and Wrist*: Simple suture of lacerated tendons give good results as there is abundant areolar tissue which prevents adhesions. When multiple tendons are severed, it is advisable to suture only the profundus tendons.

(*b*) *Divided profundus distal to the proximal interphalangeal joint*: Simple suture is the method of choice.

(*c*) *Tendon injury between the distal palmar crease and the proximal interphalangeal joint* (the ' danger area ' for tendon division): The correct procedure to be adopted is the subject of diverse surgical opinion and only an outline is given here.

(i) When both tendons are divided, most surgeons advocate excision of the sublimis tendon. Simple suture of the profundus is not favoured due to adhesion formation at the injury site with poor functional results. Most authorities advocate tendon grafting as a primary procedure.

(ii) When profundus only is divided, it may be advisable to do nothing (depending on the demand on the digit). Excision of the sublimis and primary grafting has been disappointing and it does not appear to warrant sacrifice of sublimis action. However, excision of half of the sublimis tunnel allowing primary grafting through the other half of the tunnel (Harrison) may prove to be the procedure of choice.

Thumb.—The tendon can either be sutured or grafted (if primary suture is not possible). Either way, the results are found to be adequate by most patients.

Post-operative Care

Elevation and Prevention of Stiffness.—Œdema occurs immediately following injury (and operation). Elevation is thus essential. During the phase of elevation, immobilisation is important as movement may lead to further hyperæmia, etc., with further œdema. This phase lasts 2–4 days. Immobilisation should continue until the wound is healed, i.e. up to 21 days with untidy or indeterminable injuries. *The aim is for early healing, not for early movement.* When bandages are removed some residual swelling is usually present which causes pain on movement. Active movement must be encouraged, however. After severe injuries the hand will need additional intensive physiotherapy, i.e. active exercises, combined with warmth and elevation.

Position of Splinting.—This is very important. The hand must be splinted with the metacarpo-phalangeal joints in 80° flexion, and the inter-phalangeal joints fully extended. This is the position in which the collateral ligaments are fully stretched and thus, should fibrosis and stiffness occur, it

Stewart Hamilton Harrison, Contemporary. Plastic Surgeon, Mount Vernon Hospital, Northwood, Middlesex, England.

will be maximum in that position and on restarting active movement, it should then be possible to regain a range of full movement.

Finger-tip Injuries.—On the thumb and index finger, a tender scar is a nuisance and good sensation is essential for fine movements. In judging what operation is best suited to his finger-tip loss, much will depend on the use to which a patient will put

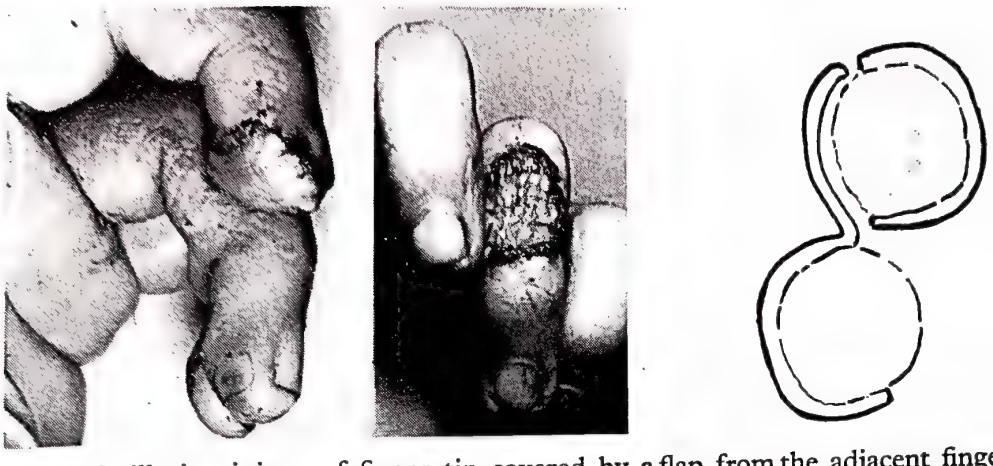

FIG. 228.—Guillotine injury of finger tip covered by a flap from the adjacent finger (see diagram), the bared extensor donor area being covered by a free split-thickness graft. *(E. Melmed, F.R.C.S., Dallas.)*

his hands, e.g. a miner whose bread winning depends on early return to work which does not require exquisite finger-tip sensation, will not appreciate the most successful delicate grafting which may take him off work for several weeks. If skin only is lost, then a free split-thickness graft is all that is needed. With time these may contract and hardly be noticeable.

When the pulp is lost, as well as the skin, then a Wolfe graft may be needed. The donor site is usually skin from the forearm (it is never justifiable to use skin from behind the ear for anything other than Wolfe grafts to the face, p. 119).

In 'Guillotine' injuries, one must take into account the type of work of the patient:

(*a*) Free grafting will preserve length. This is usually the most advisable procedure. However, the graft may adhere to bone and may remain tender. In children the graft may contract with time and not need any further treatment. If not suitable, a flap graft can always be applied at a later date.

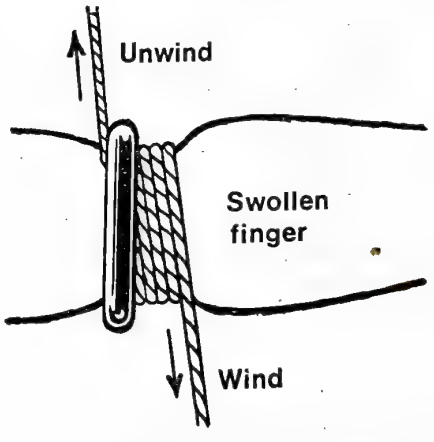

FIG. 229.—The string method for removing a ring. *(F. Exner and the 'Medical Tribune'.)*

(*b*) Repair by flap (fig. 228) gives a better result, but is time-consuming and may be very difficult. It gives the best results especially for thumb and index tip and pulp losses. It cannot be used in older people due to stiffness, and in children it may result in an unsightly donor area.

(*c*) The principle of sacrificing length for primary closure, by cutting back until the flaps will close, is only employed when it is imperative to get the patient back to work early.

Stuck Finger.—This emergency is common in children who poke fingers into small holes, but it is also encountered when wedding and other rings require to be removed (e.g. for operations). Soap or some fat may ease the ring. The string method (fig. 229) is nearly always successful and should be tried before resorting to saws (Exner).

Microsurgery in Hand, and Foot, Injuries.— The value of the operating microscope and microsurgical technique in the restoration of severed digits, hands and feet speaks for itself in fig. 230. Microsurgery is a rapidly expanding multidisciplinary area of modern surgery.

Frederick Blythe Exner, Contemporary. Radiologist, Seattle, Washington, U.S.A.

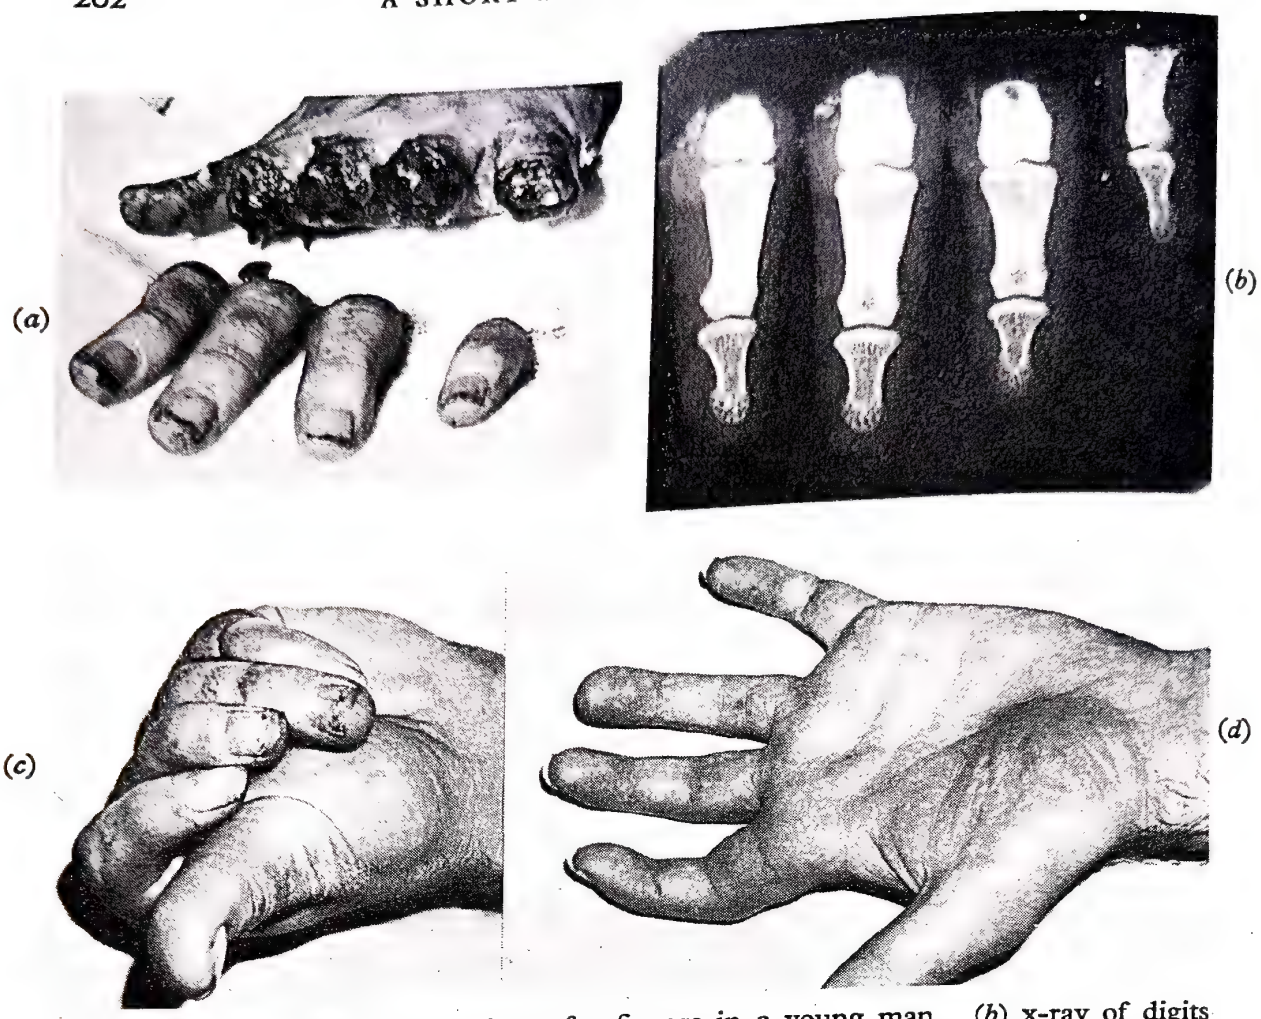

FIG. 230.—(*a*) Saw-cut amputations of 4 fingers in a young man. (*b*) x-ray of digits amputated through proximal phalanges. (*c*) Successful replantation of fingers with primary reconstruction after 1 year. (*d*) Flexion of replanted fingers of same patient at 3 years. The severed fingers require continued cooling—*not freezing*—until vascular continuity is restored. Two operating teams are employed. *(B. McC. O'Brien, F.R.C.S., Melbourne, Australia.)*

INFECTIONS OF THE FOOT

Especially in countries where some of the inhabitants go barefooted, infections of the foot are commonplace; they also occur in the shod. In each and all of the infections of the foot about to be described it will be assumed that the reader, remembering the lymphatic drainage of the foot, will examine the lymph nodes of the groin and, in relevant cases, those of the popliteal space. He should also examine the urine for sugar. Furthermore, he must remember that arterial disease may present as an infection of the foot.

The prelude to the treatment of any of these infections is thorough washing of the foot with soap and water or, preferably, a detergent, applied with sterile gauze or cottonwool. Except in trivial infections, bed-rest with elevation of the foot must be insisted upon until the inflammation has subsided.

Infected blister is one of the most common infections of the foot. When the patient's temperature is normal and the content of the blister appears doubtfully purulent, the blister can be aspirated. If the fluid is opalescent, the patient should be given tetracycline and the aspirated fluid sent for bacteriological examination. When a blister is frankly purulent it should be incised.

Paronychia of the great toe is also common. It often occurs as a complication of an ingrowing toe-nail. An abrasion of the eponychium with contaminated scissors is also a frequent cause. The clinical features and treatment do not differ from those of a paronychia in a finger or thumb, except that when an ingrowing toe-nail is present it is necessary to deal with it radically (p. 205). Washing, as described above, is carried out each time the wound is dressed.

Infected adventitious bursa beneath a corn is usually the result of improper chiropody. There are signs of inflammation around the corn, the slightest pressure on which evokes excruciating pain. Drainage is accomplished by paring the corn with a sterile scalpel until pus exudes.

Terminal pulp space infection is rare as compared with that of the hand. When it occurs in the foot, usually it is the great toe that is affected.

Infected Bursa over a Hallux Valgus (p. 312).

Infection of a Web Space.— The web spaces of the foot are four in number, the space between the great toe and the second toe being the largest. The clinical features of infection of this space are similar to those of the hand, but extension from the plantar to the dorsal aspect of the web occurs earlier, and with great regularity. The treatment also is similar. In a diabetic, orthodox drainage is so disappointing that disarticulation of the relative toe, leaving the flaps unsutured, is recommended (fig. 161).

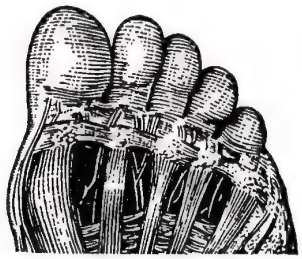

FIG. 231.—The four interdigital subcutaneous spaces, which are separated from the four corresponding web spaces by the transverse plantar ligament.

Infection of a Plantar Interdigital Subcutaneous Space.— There are four interdigital subcutaneous spaces that lie between the five digital slips of the central aponeurosis (fig. 231). Infection of one of these spaces is very common among coolies who work barefooted, especially in urban areas. As a rule the patient states that a sharp stone, a nail, or a thorn penetrated the sole. The patient complains of increasing pain between the shafts of the two metatarsals that bound the infected space. Soon he is unable to walk, and the constitutional symptoms are moderately severe. Exquisite tenderness located over the infected space proclaims the diagnosis. When pus decompresses itself between the two bones into the dorsal subcutaneous space, localisation is more difficult. Drainage must be placed well away from the weight-bearing area, and consequently an incision similar to that used for drainage of a web space is advised, after which a hæmostat is directed into the cavity filled with pus, and its jaws are opened. If the dorsal subcutaneous space is involved, a counter-incision should be made.

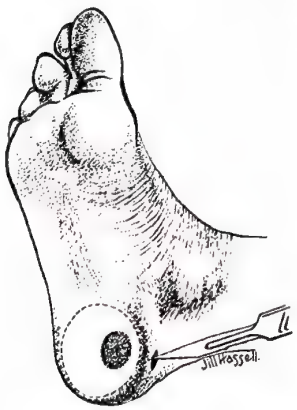

FIG. 232.—The fibrous septa of an abscess of the fat-pad of the heel are so tough as to require division with a scalpel.

Infection of the Heel Space.—The infection is intradermal in one-third of cases, a few of these being a collar-stud extension from a deeper plane. Two-thirds of cases are due to infection of the fat-pad of the heel, which is situated in the subcutaneous portion of the posterior third of the sole. The portal of entry usually is a crack in the overlying calloused skin, and seldom, as one would think, from treading on a thorn or similar object.

Steadily increasing throbbing pain, severe enough to interfere with sleep, is the leading symptom. The patient dare not put his heel to the ground. Swelling

of the soft tissues that cover one or both sides of the calcaneus is present, and in severe cases œdema of the ankle becomes manifest. Tenderness over the space leaves no doubt as to the diagnosis. As a rule, by the time the patient presents, the abscess is ready for incision, which is made through the medial or lateral side of the heel, so that the scar does not come to lie on a weight-bearing area. Fibrous septa within the abscess of the fat-pad need division with a scalpel (fig. 232). The lips of the cutaneous incision should be trimmed elliptically to prevent premature closing of the skin.

Deep Plantar Abscess.—The central plantar space situated deep to the plantar fascia is arranged like an apartment house of four stories, each of which is occupied by the muscles that constitute the flexors of the toes. Infection of the various floors becomes increasingly less common as one proceeds from the ground floor, upwards. For drainage of the central plantar space an incision parallel to, and just above, the medial border of the foot in the neighbourhood of the instep, is made (fig. 233).

FIG. 233.—Incision for draining the central deep plantar space.

Infections of the Dorsum of the Foot

The dorsal subcutaneous space usually is infected by extension from a subcutaneous interdigital space or a web space, while the *dorsal subaponeurotic space* is infected either from a direct puncture or from involvement by extension from the deep plantar space. To drain the former space the incision should be placed distal to the dorsal venous arch, but in the line of the digital vessels and nerves, in order to avoid them. To drain the latter space it is best to confirm the presence of pus by attempting aspiration, and if diagnostic aspiration is positive, to make a longitudinal incision alongside the needle.

Leprosy not infrequently attacks the toes, and the initial manifestation may simulate a chronically infected corn. Leprosy is discussed on p. 35.

Madura foot (*syn.* mycetoma pedis) is a chronic granulomatous disease encountered especially in tropical countries, notably in certain parts of India or Africa, but with increasing frequency in territories where hitherto it has been unrecognised, such as the Southern United States, South America, and Cuba. Most cases are caused by a filamentous organism (*Nocardia maduræ*) resembling actinomyces and abounding in road dust. In nine out of ten cases the organism gains entrance through a prick in those who go about barefooted. The first manifestation is a firm, painless, rather pale nodule. Soon other nodules appear. Later, the nodules become surmounted by vesicles which burst to form discharging sinuses. In the watery discharge granules can be discovered, sometimes only with perseverance. The granules may be yellow, red, or black. In 'black' madura foot, as it is called, spread is mainly in the subcutaneous plane; in the yellow and red varieties the infection burrows deeply, and bone necrosis ensues. As in actinomycosis, there is no lymphadenitis, but unlike actinomycosis, dissemination to other parts of the body does not occur. Gross swelling of the foot with flattening or convexity of the instep is characteristic. Sooner or later secondary infection supervenes, with rapid deterioration of the local condition.

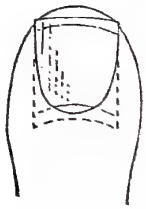

FIG. 234.—The relation of the nail to the nail fold and nail walls. Note the corners of the germinal envelope. (*Courtesy British Journal of Surgery.*)

Treatment.—A wide-spectrum antibiotic to deal with secondary infection, followed by a prolonged course of dapsone (100 mg. b.d.) improves many patients, and may obviate or postpone the necessity for amputation (Cockshott).

Guinea Worm.—This infestation is described on page 64, figure 70.

William Peter Cockshott, Contemporary. Professor of Radiology, McMaster University, Hamilton, Ontario, Canada.

INGROWING TOE-NAIL

Ingrowing toe-nail (*syn.* embedded toe-nail) of the big toe, usually results from encasing sweaty feet in tight shoes, and is encouraged by cutting the nail short and convexly. The side of the nail curls inwards and grows to form a lateral spike, which causes a painful infection of the overhanging nail fold (fig. 235)

FIG. 235.—Typical ingrowing toenail with infection.

Treatment.—Conservative measures can be successful, but much depends upon the patient's willingness to help himself. The overhanging nail fold is pushed away and reduced in size by daily packing of the lateral groove with a wisp of gauze soaked in a mild antiseptic. The centre plate of the nail is thinned slightly by filing; this encourages the nail to become flat. The end of the nail is cut straight across or concavely. The corners must not be cut back; it is necessary for them to extend over the pulp.

Operation.[1]—The nail is like a letter protruding from a shallow envelope. The envelope is the germinal matrix and this must be included in radical removal of the affected side or the whole of the nail. Failure to remove the

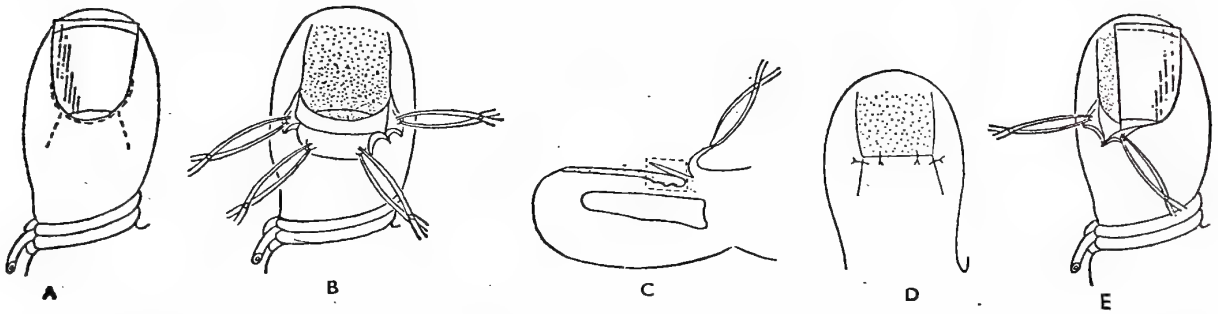

FIG. 236.—Technique of total excision of the germinal matrix. A, Skin incisions. B, Skin-flaps dissected and retracted. (Courtesy British Journal of Surgery.)

corners of the germinal envelope (fig. 234) will result in the recurrence of a nail spike. The technique (Fowler) is portrayed in fig. 236. A tourniquet is essential in order that the germinal envelope may be seen and dissected out in its entirety.

Onychogryphosis is a thickened and crooked overgrowth of a toe-nail, usually that of the big toe. Trauma and fungus infection are implicated as causes. It occurs in elderly people, especially if bed-ridden, and it may become so curled as to resemble a ram's horn. A Gigli saw will cut through the base and the remainder can be controlled by filing. If necessary the nail-bed and nail are removed as above.

CHAPTER 12

INFECTIONS OF BONES AND JOINTS

ACUTE OSTEOMYELITIS

ACUTE osteomyelitis used to be a common and serious, indeed often a fatal, disease in children. Over recent years there has been a fall in the incidence of the disease, probably due to an improvement in the general health of children. At the same time antibiotics have made the disease less serious: it need never now be fatal and should be curable.

Ætiology.—The bacteria reach the bone by the blood-stream. A primary focus may be obvious in the form of a boil or an infected graze, but not uncommonly no obvious source of infection is evident. Rarely the disease may be secondary to a frank septicæmia or pyæmia. More commonly the blood-borne infection takes the form of a bacteræmia.

It has been suggested that a lowered general resistance on the part of the patient, and local trauma, may predispose to this disease, but the evidence in support of these suggestions is unconvincing.

The usual causative organism is the *staphylococcus aureus*. Other organisms which may be responsible include the streptococcus, pneumococcus, staphylococcus albus and a number of other organisms, no one of which is present commonly.

Pathology.—The disease always, or nearly always, begins in the metaphysis. The infective process progresses through the thickness of the cortex via the Haversian canals and as it does so causes thrombosis of the vessels in the bone. As a consequence, by the time the infection reaches the sub-periosteal region of the bone a variable amount of the cortex may have been infarcted. In the first 24 or 48 hours after the onset of the infection, an inflammatory exudate forms deep to the periosteum, elevating the membrane from the bone. Periosteal elevation is painful and, since the periosteum is inelastic, the inflammatory exudate deep to it is under tension. As a consequence the patient rapidly develops marked toxic signs. Approximately 48 hours after the first symptom, frank pus develops sub-periosteally. Partly as a consequence of the resistance of cartilage to invasion by the septic process, and partly because of the very firm attachment of the periosteum (more accurately the perichondrium) to the epiphyseal plate, transgression of the plate itself and consequent interference with growth is rare. The inflammatory process progresses along the length of the medulla causing venous and arterial thrombosis as it does so. Sub-periosteally, pus tracks both longitudinally and circumferentially around the bone, stripping the periosteum and interrupting the periosteal vessels. Thus progressively larger areas of the cortex become infarcted and involved in the inflammatory process.

In the absence of treatment pus finally bursts through the periosteum, and tracks through the muscles to present subcutaneously. Eventually the skin breaks down and pus discharges from a sinus which connects the bone with the skin surface.

The bone infarct in acute osteomyelitis is known as a *Sequestrum*. Surrounding the sequestrum, the elevated periosteum lays down new bone which entombs the dead bone within. This ensheathing mass of new bone is known as the *Involucrum*. In the places where pus has broken through the periosteum to form a defect in it, sinuses develop which are represented in the involucrum by holes known as *Cloacæ* (fig. 237). The development of such advanced pathology is now rarely seen since modern treatment if adequate, aborts the disease before pus has formed, and certainly before a significant amount of bone has died. The presence of dead, infected bone is the factor responsible for the chronicity of this disease, for once bone has died and become infected, the body's normal defence mechanisms (leucocytes and antibodies) together with any antibiotics that may be given therapeutically are unable to reach bacteria in the sequestrum. Accordingly, the disease process may be sterilised in the living bone but recurrence is always likely as the bacteria in the sequestrum are never destroyed.

FIG. 237.— Sequestrum enveloped by an involucrum which is pierced by cloacæ.

Clinical Features—Pain is the presenting symptom.

It is essential that an accurate history is taken so that the onset of the first complaint if local pain can be timed exactly. The significance of this feature of the history is discussed further under *Treatment*. The pain gradually increases in severity, and the child becomes increasingly febrile and toxic, at a rate dependent upon the toxicity and virulence of the infective organism. It is usual for the mother to seek medical advice within 48 hours of the onset of the first symptom.

Physical Signs.—The essential physical sign is localised tenderness. When the docter first examines the child, the child is likely to be irritable and to resent examination. It is imperative that the physician should be patient, and gently palpate the child's limbs until the exact area of maximum tenderness has been identified. If this tenderness lies over the metaphysis of a long bone, the diagnosis of acute osteomyelitis should be presumed until it can be proved otherwise. The adjacent joint may contain an effusion, raising the differential diagnosis of suppurative arthritis. The joint itself however is not tender and although the child resists movement of the limb, with patience it is possible to demonstrate that some movement of the joint is allowed. This contrasts with acute suppurative arthritis in which absolutely no movement is permitted. The temperature is raised, often markedly so, and an associated increase in the pulse rate occurs. Some days after the onset of the first symptom noticeable swelling and heat may be detected in

addition to tenderness. Finally the area of the abscess (for such it is by this time) is fluctuant.

It is absolutely essential that blood cultures should be undertaken before antibiotic treatment is commenced. In order to provide the maximum possible chance of a positive culture, three separate venipunctures should be made and from each venipuncture three aliquots[1] should be cultured separately. The child's body surface should be searched minutely for possible primary foci of infection and if these are found they should be cultured.

Special Investigations.—Other investigations are of no diagnostic value early in the disease. The E.S.R. and white cell count are usually raised but this is entirely non-specific.

X-ray.—There are no abnormal radiological features in the first few days of the infection. As time goes by, new bone can be seen deposited by the elevated periosteum, but this sign does not appear until 2 or 3 weeks after the onset of the disease and will then be demonstrable whether or not the disease has been sterilised: it depends entirely upon the presence or absence of periosteal elevation. Some rarefaction in the bone due to local hyperæmia will also occur after 2 or 3 weeks but again does not distinguish continuing osteomyelitis from the sterilised disease. The radiological appearances of chronic osteomyelitis are dealt with elsewhere (p. 210).

Treatment.—The child is admitted to hospital and the limb is splinted, but in such a way that easy access to the tender area is retained. The outline of the tender area is marked on the skin.

If the patient is first seen within 48 hours of the appearance of the first symptoms, antibiotic treatment is begun immediately after appropriate samples have been taken for blood culture. Acute osteomyelitis is one of the few diseases in which it is justifiable to begin antibiotic treatment without waiting for bacterial sensitivity, a peculiarity which stems from the fact that if the disease can be sterilised within the first 48 hours, complete resolution can be guaranteed. If sterilisation fails or is not attempted in this time, the disease may become chronic, so generating life-long disability and a possible cause of death. Because at this stage the bacteriology is uncertain, a broad spectrum antibiotic should be administered. Currently the most effective is ampicillin in doses of 250 mg. four times daily. Unfortunately, an increasing number of staphylococci (the commonest causative organism in this disease) are insensitive to ampicillin and therefore cloxacillin should be administered as well as ampicillin in doses of 250 mg. four times daily. Other antibiotics are substituted if they are dictated by the sensitivity tests.

If the patient is first seen 48 hours or more after the onset of the first symptom, the possibility arises that pus is present. If pus is present, it may be sterilised by antibiotics, but the general surgical principle applies to bone as to other tissues that *an abscess requires surgical evacuation.* The presence of pus may be difficult or impossible to detect with certainty since fluctuation is late to develop. Fluctuation cannot be demonstrated in the early stage of abscess formation because the periosteal membrane is tense, the involved bone is often deep to muscle, and the area is too tender to palpate firmly. Therefore the surgeon has to rely upon his general impression as to the severity of

[1] Aliquot (L). Alius = Other. Quot = How many. In this case 3 other samples.

the disease and his knowledge of its duration in deciding either to treat the patient initially with antibiotics, or to combine this therapy with incision of the tender area.

If it is decided to rely on antibiotic therapy alone in the belief that no pus is present, antibiotics should be given and the effect of this treatment upon the toxic signs and upon local tenderness should be watched very closely. If the antibiotic is controlling the disease, and if no pus is present, the temperature will subside to become normal within 2 or 3 days and tenderness will progressively disappear. If, on the other hand, the antibiotics are inappropriate to the sensitivities of the organism or pus is present, the temperature is likely to settle but not to normality: spikes up to 38°C. will continue. If this occurs, the tender area must be explored surgically with a view to evacuating pus if any is present and to obtaining the organism for culture and sensitivity.

Operation.—Operation is carried out under general anæsthesia and is preceded by exsanguination of the limb by elevation and the use of an inflatable tourniquet. An incision is made over the tender area and carried down to the bone where pus is usually found deep to the periosteum. The abscess cavity is fully opened and the pus evacuated. A swab is taken for culture and sensitivity at this stage. There is controversy as to whether or not this procedure should be followed by drilling the cortex in order to enable any pus that may be present in the medullary cavity to drain to the surface. It is the author's opinion that a drill hole should always be made. If no pus is found, no harm is done in practice although in theory a previously sterile medulla might be contaminated. On the other hand if pus wells up from the drill hole, the hole should be enlarged until free drainage appears to have been obtained. The wound is then closed with interrupted sutures over a closed sterile suction drain. Antibiotics and local splintage are continued post-operatively.

Differential Diagnosis

Acute Suppurative Arthritis.—Here the sepsis is intra-articular, and therefore the patient allows no movement of the joint. In the 'sympathetic' effusion associated with acute osteomyelitis, a certain range of painless movement can usually be obtained if the patient is examined gently. The maximum tenderness is near the end of the bone in osteomyelitis rather than over the joint in suppurative arthritis.

Acute Rheumatic Arthritis is usually polyarticular and fleeting in any one joint. There is a history of a sore throat and cardiovascular signs are often present.

Hæmarthrosis may occur in hæmophilia. The patient is usually a known hæmophiliac and aspiration, if necessary, reveals blood.

Scurvy.—Sub-periosteal hæmatomata are sometimes very tender, and if near an epiphysis may be confused with acute osteomyelitis.

Acute Exanthemas and Typhoid Fever.—These conditions may be suspected on account of the profoundly toxic and even comatose condition of the patient. If careful palpation over a localised area of the end of a long bone induces resentful movements or moaning, the possibility of osteomyelitis should be considered.

Ewing's Tumour.—See p. 250.

Complications.—These may be divided into two types, general and local. The general complications are septicæmia and pyæmia which may give rise to metastatic abscesses. Either complication, if uncontrolled, may prove fatal. Amyloid disease may develop as a complication of chronic osteomyelitis (p. 210).

The local complications include: (1) secondary involvement of the joint if the epiphyseal line is intra-articular, (2) spontaneous fracture which is rare provided the limb is splintered and the disease adequately treated, (3) deformity which, surprisingly, is rare, and (4) chronic osteomyelitis.

Acute Traumatic Osteomyelitis

This condition arises as a result of infected wounds, for example compound fractures, and operations on bones. The constitutional disturbances are less severe than in acute (infective) osteomyelitis, as the causative wound provides some measure of drainage. Treatment consists of more extensive opening of the wound, removal of dead bone, and antibiotics. The prevention of this condition depends upon the adequate initial treatment of compound fractures (p. 325) and upon sterile operating conditions.

CHRONIC OSTEOMYELITIS

Pathology.—Acute hæmatogenous osteomyelitis may pass into chronic osteomyelitis if early treatment is not available, or is inadequate so that infected bone dies to form a sequestrum. The disease may take two forms. The pathology of the more common variety in which a large volume of bone is involved has been described under acute osteomyelitis (p. 206). The incidence of this condition has been greatly reduced by the modern treatment of the acute infection, but some cases remain as a legacy of the pre-antibiotic era, and more will probably occur in the future if the acute infection is inadequately treated. The second variety is known as Brodie's abscess. The infection in this form of the disease is closely contained so as to create a chronic bone abscess containing pus or jelly-like granulation tissue surrounded by sclerotic bone. The lesion may be the sequel to a pyogenic septicæmia from which the patient has recovered, leaving a bone abscess which may remain dormant for years. On the other hand, it may be found in a patient who is known to have had osteomyelitis (but not septicæmia) affecting a bone other than the one in which the Brodie's abscess is discovered.

FIG. 238. — Chronic osteomyelitis of the femur with a cavity containing a sequestrum.

FIG. 239.— Brodie's abscess of lower end of the tibia.

Clinical Features.—Chronic osteomyelitis may remain quiescent for months or years, but from time to time acute or sub-acute exacerbations occur. An exacerbation is ushered in with constitutional upset and local evidence of inflammation, which may culminate in a discharge of pus, often from a pre-existing sinus. An X-ray sometimes reveals a sequestrum which has separated from the surface of the bone or which lies in a cavity (fig. 238). Tomographs may help to demonstrate a sequestrum and a sinogram may delineate an abscess cavity in the bone.

A Brodie's abscess causes intermittent local pain and occasionally transitory effusions in the adjacent joint during an exacerbation. Examination may

Sir Benjamin Brodie, 1783–1862. Surgeon, St. George's Hospital, London.

reveal tenderness and thickening of the bone. A radiograph is diagnostic and reveals a band of sclerosis surrounding a central lucent area. The amount of sclerosis is variable, ranging from dense sclerosis extending a considerable distance round the cavity (fig. 239) to, more commonly, a faint line of sclerosis at the junction of the abscess with the cancellous bone.

The chronicity of a Brodie's abscess is the result of the physical characteristics of bone, because the abscess can never close by collapse of the walls as happens in soft tissues. Moreover, the infection kills the hard, bony walls of the abscess and provokes new bone deposition, thus preventing leucocytes, antibodies and antibiotics from reaching the contents of the cavity.

Treatment of exacerbations in chronic osteomyelitis consists of immobilisation of the limb and the administration of antibiotics. On this regime the exacerbation often subsides, but only to recur again later in life.

Surgical intervention in chronic osteomyelitis has as its objective the removal of dead bone and the elimination of dead space. Dead bone in the form of a sequestrum may be detected by probing a sinus or by X-ray. Seams of dead bone dispersed within living bone cannot be detected with certainty but may be suspected if an X-ray shows an area of sclerosis. An appropriate antibiotic (which is chosen in the light of the sensitivity of the causative organism) is administered for some days prior to operation. Access to the bone is usually gained through a previous scar. The soft tissues are stripped from the bone, and the involucrum is removed to reach the sequestrum. If a cavity is present, the over-hanging walls are removed with an osteotome, until it is ' saucerised '. Sclerotic bone is removed *en bloc* if this is practicable. The wound is drained and closed in such a way as to eliminate dead space as far as possible.

So difficult is it to guarantee that an operation will cure chronic osteomyelitis affecting a large volume of bone, that operative intervention is not to be considered lightly unless a sequestrum is known to be present. If, however, a sequestrum is present and is removed, sinuses will often close and the disease may be cured. If only a cavity or sclerosis is present in the bone without a sequestrum, the attempt to ' saucerise ' may fail and still leave a sinus. There are many patients for whom, if the discharge is slight and easily controlled by a dressing, it is preferable to retain the sinus and dressings permanently. Amyloid disease need be feared only when a copious discharge of pus has persisted for some years.

Amputation may be advisable if exacerbations are frequent or prolonged, in order to rid the patient of recurring periods of painful disability, and to forestall the onset of amyloid disease.

A Brodie's abscess should be treated by surgical evacuation and curettage of the cavity under antibiotic cover followed, if the cavity is large, by packing with cancellous bone chips.

ACUTE SUPPURATIVE ARTHRITIS

Like acute osteomyelitis, this used to be a common disease especially in children, but is now rare. Acute infection of a joint occurs as a result of:

1. Direct infection, as by a penetrating wound or a compound fracture which involves the joint.

2. Local extension, from some neighbouring focus, such as acute arthritis of the hip joint from osteomyelitis of the femoral neck.

3. Blood-borne infection, the usual organisms being the streptococcus, staphylococcus, and pneumococcus, and less commonly the gonococcus and *B. typhosus*.

The knee joint, owing to its large size and exposed position, is the commonest joint to be involved by penetrating wounds, while suppurative arthritis from blood-borne infections is the more common cause in other joints.

Clinical Features.—The patient complains of steadily increasing pain, inability to move the joint and malaise. On examination the patient is often severely toxic with a raised temperature and pulse rate. The joint is held in the position of its greatest capacity (the 'position of ease') and, if subcutaneous, it can be seen to be swollen (see Table below). Palpation reveals increased heat, tenderness and an effusion. Movements are prevented absolutely by muscular spasm, and attempts at either active or passive movement cause severe pain.

Joint	Position of ease	Site of maximum swelling	Position for ankylosis
Shoulder	Adducted	Under the deltoid along the tendon of the biceps and in the axilla	40° to 50° of abduction, with elbow joint just anterior to the coronal plane and hand in front of the mouth.
Elbow	Flexed at a right angle and pronated	On either side of the triceps tendon	90° of extension semi-pronated. If both sides, one elbow at 75° of extension, the other at 135°. These positions enable the patient to reach the external orifices.
Wrist	Slight flexion	Under extensor and flexor tendons	Slightly dorsi-flexed to allow a firm grasp.
Hip	Flexed (fig. 252), adducted, and externally rotated	Upper part of Scarpa's triangle	20° to 30° of flexion to allow sitting, and in neutral position as regards abduction and rotation.
Knee	Flexed	Suprapatellar bursa, and either side of patellar tendon	5° to 10° of flexion to allow foot to clear ground in walking.
Ankle	Slightly plantar-flexed (and inverted at the subtalar joint)	Anteriorly and on either side of the Achilles tendon	At a right angle.

Treatment.—*The position of ease may differ widely from the position which is most useful should ankylosis occur.* As any case of suppurative arthritis may be followed by ankylosis, the first duty of the surgeon is to anticipate this possibility by immobilising the joint in the best position for ankylosis (i.e. the position of optimum function), as indicated in the table on p. 212. The limb is supported and fixed by a suitable splint or appliance in the correct position, an anæsthetic being administered if necessary. Traction, which was commonly used in the past with the idea of holding the joint surfaces apart and preventing damage to the cartilage, is no longer used.

Antibiotics are administered systemically as in acute osteomyelitis (p. 208).

The following lines of treatment are then to be considered.

1. *Aspiration*, which is useful for both diagnostic and therapeutic reasons. The nature of the fluid can be ascertained, and the organism cultured to obtain its antibiotic sensitivity. Aspiration reduces the tension within the joint, thereby relieving pain, and limiting the stretching of ligaments and capsule. It has the disadvantage that a previously uninfected ' sympathetic ' effusion may be infected if the needle traverses a septic focus on its way into the joint. On balance, the advantages outweigh this disadvantage. If frank pus is aspirated, the joint is opened (see below).

2. *Aspiration and Injection.*—After fluid has been aspirated, antibiotics may be injected into the joint. Repeated injections of antibiotic into a joint are unnecessary, since systemic administration is adequate.

3. *Arthrotomy and Drainage.*—In neglected cases with radiological destruction of bone the joint is opened, washed out, and closed suction drains are placed down to the synovial cavity. This is only done if the joint contains frank pus, or if bone destruction has involved the articular surfaces so that some degree of ankylosis is all that can be expected when healing has occurred. Though commonly used 30 years ago, this technique is now less often needed, because the disease, if diagnosed early, can be treated by antibiotics and aspiration. In all cases adequate immobilisation is essential.

Extra-articular abscesses sometimes require to be opened and drained. In the case of the knee joint, pus is particularly liable to track upwards beneath the quadriceps, where its presence may be overlooked.

4. *Excision.*—In modern medicine this is rarely if ever required but if the condition of the patient deteriorates in spite of treatment, or if suppuration is prolonged, drastic surgical ablation of the diseased bone is necessary.

TUBERCULOUS ARTHRITIS AND OSTEOMYELITIS

Historical and Social Background.—At the end of the 19th century, tuberculosis was widespread—especially in towns—because patients with open human pulmonary tubercle remained in the dense urban populations, because milk was infected with bovine tubercle, and because the general health of the population suffered from overcrowding, poor food and air pollution. Since no specific treatment was available until the advent of anti-

biotics, the disease usually ran a slowly progressive course to death or crippledom. The social consequences surrounded the disease with an aura of dread and even shame which still persists. All medicine could offer was improvement of the general health of the patient by reversing his social circumstances —substituting rural sunlight for urban smoke, rest for work, and good food for poor—in the hope that his own body mechanisms would arrest the disease. 'Arrest' in this context rarely amounted to cure, but rather to an unsteady equilibrium between the patient and his quiescent disease. Against this backgound, sanatoria were constructed and a variety of physical signs and stages in the disease were described. With the advent of antibiotics and early surgery where necessary, the nature of the disease and of its social consequences changed entirely: sanatoria and sunlight became irrelevant; cure became the usual outcome and persistent disability uncommon.

Pathology.—Bone and joint tuberculosis is hæmatogenous in origin. The primary focus is related either to the gastro-intestinal tract if the disease has been acquired by the ingestion of bovine tubercle, or to the lungs if the disease has been acquired by the inhalation of the human strain. Fifty years ago, when cow's milk was often infected, bone and joint tuberculosis in the United Kingdom was usually bovine. With the eradication of bovine tuberculosis in dairy herds and of human pulmonary tuberculosis, bone and joint tuberculosis has become a rarity in the United Kingdom. However, in underdeveloped countries, where bone and joint tuberculosis is still common, it is usually due to the human strain of the organism since little milk is drunk.

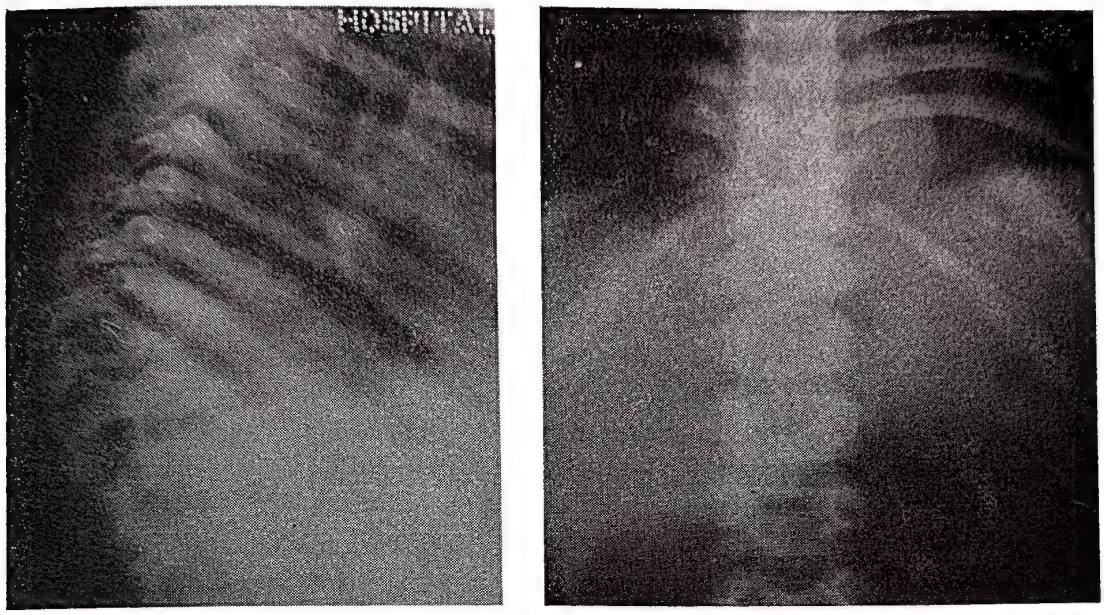
FIG. 240.—Tuberculosis of the left hip.

The disease starts either in the *synovial membrane* or in *intra-articular bone*. The disease may develop in any synovial joint (especially those with extensive synovial membranes such as the hip and knee), in tendon synovial sheaths (especially those of the finger flexors), or in bursæ (such as that over-lying the greater trochanter). The spine is also commonly involved and tuberculosis here carries the eponymous description of 'Pott's Disease'. The vertebral bodies—almost always those of two neighbouring vertebræ—are involved first.

Typical tubercles develop in the synovial membrane which becomes bulky and inflamed, and an infected effusion collects in the synovial cavity. If the infection can be diagnosed and cured at this stage, full function may be restored to the joint. If, on the other hand, the pathological process progresses, articular cartilage is destroyed and the adjacent bone is involved. At this stage some loss of function is certain since healing leaves a fibrous ankylosis, not two healthy surfaces of articular cartilage separated by the synovial cavity. If the disease starts in intra-articular bone, the synovial membrane rapidly becomes involved. For practical purposes involvement of both the synovial membrane and of the bone must be assumed when a diagnosis is made of tuberculous arthritis.

Percival Pott, 1714–1788. Surgeon, St. Bartholomew's Hospital, London.

In the spine, the diagnosis is rarely made until the bodies of two neighbouring vertebræ are significantly involved so that the end result, at best, is the replacement of an intervertebral disc and of the diseased bone by fibrous tissue. Should treatment for spinal disease be delayed, abscess formation occurs and the vertebral bodies collapse (fig. 241). The pus tracks along tissue planes to present superficially in places often distant from the involved



(*a*) (*b*)

FIG. 241.—Tuberculosis of the 11th and 12th dorsal vertebræ. (*a*) Collapse of two vertebral bodies into a wedge. (*b*) Perispinal abscess shadow.

vertebræ; for example, pus arising from D12/L1 may track along the psoas muscle to present in the groin (fig. 245). Vertebral collapse produces forward angulation of the spine (a 'Kyphus': fig. 242) and the combination of pus formation and spinal angulation compresses and may damage the spinal cord. The cord may also be prejudiced by interference with its blood supply from the anterior spinal arteries. As a consequence paraplegia (Pott's paraplegia) may develop.

Tuberculosis of the shaft of a long bone occurs in miliary tuberculosis, but is rare.

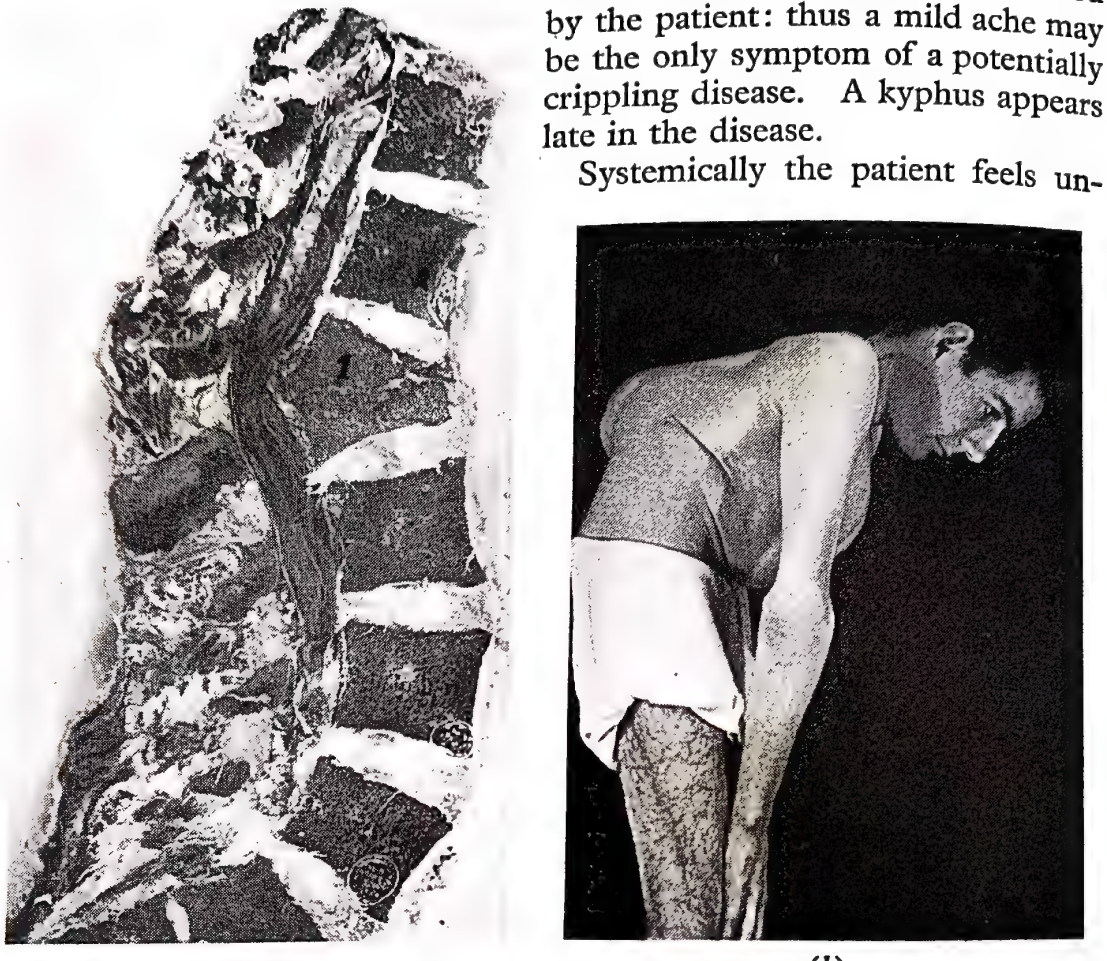
Clinical Features

Symptoms.—These may arise from the diseased joint, from the primary focus, and from the systemic effects of the disease.

Locally the patient complains of an ache in the joint, at first mild in nature, which is worse on exertion or at night. If the joint is subcutaneous, it may be noticed to be swollen, a feature made more obvious by the wasting of the associated muscles. As the disease progresses the joint becomes increasingly stiff, partly because movement is painful and partly because movement is limited by adhesion formation, muscle spasm and bone destruc-

tion. As the bone is destroyed, the joint may dislocate until local deformity is obvious. In the spine swelling is not visible until a considerable quantity of tuberculous pus has collected and stiffness may be too slight to be noticed by the patient: thus a mild ache may be the only symptom of a potentially crippling disease. A kyphus appears late in the disease.

Systemically the patient feels un-



(*a*) (*b*)

FIG. 242.—(*a*) Tuberculosis of the spine. L1 and L2 (1) have collapsed to produce wedging (and hence kyphus). A further tuberculous lesion is present in D12 (2). (*b*) The clinical appearance of a kyphosis due to tuberculosis of the spine.
(*from London Hospital Museum*)

well in himself, listless and febrile—the latter especially at night when he may have ' night sweats '.

Physical Signs.—If the joint is superficial, the synovial thickening and effusion may be visible. The muscles acting on the joint are markedly wasted. The joint is held in its position of ease (figs. 243 and 244 and Table, p. 212).

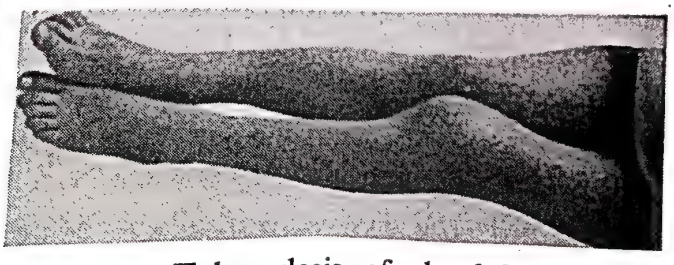


FIG. 243.—Tuberculosis of the left knee joint showing flexion, swelling, and muscle wasting.

On palpation, the synovial thickening and effusion can again be made out and the joint will be found to be moderately tender. The skin overlying the joint, even if abscess formation has occurred, is not red and is only

slightly warm: a feature which is characteristic of tuberculous inflammation and abscess formation, so that such abscesses are known as 'cold abscesses'. Active and passive movement of the joint will be limited and painful.

In the spine the only physical signs of the disease in its early stages are tenderness on percussion of the spinous processes of the involved vertebræ and minimal limitation of movement. Later, a kyphus may be seen (fig. 242 (*b*)) and abscesses may be visible in the groins (fig. 245) or posteriorly in the triangles of Petit. A kyphus in the lumbar spine may be masked by the normal lumbar lordosis.

FIG. 244.—Tuberculosis of the left hip. The arrow indicates a periarticular abscess.

FIG. 245.—A psoas abscess pointing in the right groin.

FIG. 246.—Tuberculosis of the wrist joint. Note the loss of density in the carpus (especially in the capitate) compared with the radius and metacarpals.

Special Investigations.—*Hæmatology and Immunology.*—The ESR and white cell count are raised, the latter with a lymphocytosis. The Mantoux test is positive—sometimes violently so. The hæmoglobin concentration should be measured since anæmia is common and requires correction.

FIG. 247.—X-ray appearances in active tuberculosis of the hip joint in a child.

Radiology.—The early radiological signs are not dramatic: the bone adjacent to the joint is a little less dense than normal (fig. 246) and it may be possible to make out a soft tissue swelling. As the disease advances, the joint space or disc space narrows and bone destruction becomes visible as an area of osteolysis. Thus in the spine a characteristic appearance now develops: narrowing of the disc space, and lytic lesions, typically anterior, in the bone of the adjacent vertebral bodies. Further bony destruction is accompanied by abscess formation so that diseased bone is seen to lie in and around a soft

Jean Louis Petit, 1674–1750. French Surgeon.
Charles Petit Mantoux, 1877–1947. Physician, Le Cannet, France.

tissue shadow containing loose fragments of bone and calcified soft tissue (figs. 241 (*b*) and 247). At this stage deformity may be radiologically obvious (fig. 241 (*a*)).

A chest X-ray should always be taken and may reveal active tuberculosis.

Histology.—Early accurate diagnosis is imperative, since tuberculous arthritis can be cured (to leave the patient with no loss of function) provided it is adequately treated before bone and cartilage are destroyed. Since early in the disease the clinical, hæmatological, immune and radiological features are not diagnostic, histological examination of biopsy material (revealing acid-fast bacilli and typical tubercles) is essential.

Methods of Surgical Biopsy

1. *Removal of Lymph Nodes.*—An involved node draining the diseased joint may be removed. The disadvantage of this method is that a negative result does not exclude the presence of the disease.
2. *Arthrotomy and Biopsy of the Synovial Membrane.*—This method allows the appearance of the joint to be noted and provides certain histological diagnosis. The disadvantage is the risk of sinus formation through the operative wound. Provided the operation is carried out under antibiotic cover (see p. 219) this risk is negligible. This is therefore the method of choice.
3. *Needle biopsy* of radiologically involved tissue. This is the method of choice in the spine because direct surgical access may be difficult.

Bacteriology.—Joint aspirate, biopsy material, sputum and urine should be cultured for tubercle bacilli and inoculated into the guinea-pig. A positive culture may take some weeks to obtain. A diagnosis should have been made by this time on the basis of the histology, and treatment started. Bacteriology is therefore confirmatory only.

Differential Diagnosis.—Tuberculous arthritis may be confused with rheumatoid arthritis in a single joint, infective arthritis, and hæmarthroses occurring in hæmophilia. In the spine the differential diagnosis is from osteomyelitis due to other organisms (especially staphylococcus, typhoid bacillus), ankylosing spondylitis, back pain due to disc prolapse and degeneration, and neoplasm.

Treatment.—With the advent of antibiotics, the treatment of bone and joint tuberculosis has become similar in principle to the treatment of pyogenic infections. Early in the disease the pathological process can be arrested and cured by the use of antibiotics. Should treatment be deferred until pus has formed, surgery will be required to evacuate the tuberculous abscess in exactly the same way as surgery is required for the evacuation of abscesses in pyogenic arthritis and osteomyelitis.

If abscesses form and require evacuation, the joint never regains its normal function: it is stiff, movement is painful, and weight-bearing in the spine and the legs is painful or impossible. Accordingly further surgical treatment is required in order to make the joint permanently comfortable. Such treatment always takes the form of arthrodesis, so that the final result is a permanently stiff, but painless and stable joint. Occasionally the disease leaves a joint which is replaced by short firm fibrous tissue (a 'sound fibrous ankylosis'). Tissue of this kind may be sufficiently stable to allow the joint to function as

if it were arthrodesed, especially in the upper limb, so that no further surgery may be necessary.

Antibiotics.—A minimum of two antibiotics are used for the treatment of tuberculosis: streptomycin, para-amino-salicylic acid (PAS), isoniazid (INAH), ethambutol and rifampicin are all effective. Treatment with two antibiotics is begun immediately the diagnosis is made. If the diagnosis depends upon synovial biopsy, antibiotics are started immediately postoperatively, without awaiting the histological result. The drugs are given in the following (adult) doses: streptomycin 1 g daily, PAS 12–15 g daily, INAH 300 mg. daily, ethambutol 15 mg/kg body-weight, rifampicin 600 mg daily for 3 months and thereafter 450 mg daily (p. 32). Treatment is continued for a minimum of 18 months (but streptomycin should not be used for more than 3 months in patients under 50, and not at all in patients over 50).

Immobilisation.—The diseased joint is immobilised in the position of function (see Table, p. 212) until local symptoms have settled and the ESR has returned to normal. In the case of the spine, immobilisation requires the use of a plaster bed. Recently, especially in Africa where hospitalisation may be difficult, tuberculosis of the lumbar spine has been treated by antibiotics alone, the patient remaining ambulant throughout the period of treatment.

General Management.—There is no need for special diet nor for special atmospheric conditions such as sunlight. Sanatoria are unnecessary. The general health of the patient should of course be improved as far as possible by providing an adequate normal diet and by giving an iron supplement or even blood transfusion if there is significant anæmia. Should there be coincidental pulmonary tuberculosis with tubercle bacilli in the sputum, it will of course be necessary to isolate the patient until this aspect of the disease is brought under control.

Surgery.—Surgery is not required at the synovial stage of the disease since the disease can then be arrested by antibiotics alone. If, however, the synovial membrane is very markedly inflamed and thickened, synovectomy and joint toilet may be helpful.

If abscess formation has occurred, the abscess is incised and evacuated 3 or 4 weeks after the commencement of antibiotic treatment. When the abscess has been evacuated, the originally articulating bones terminate in the abscess cavity. Some form of arthrodesis will then be required in order to provide the patient with a stable limb. Before antibiotics became available, arthrodesis of a tuberculous joint was carried out avoiding, if possible, the infected tissue (fig. 248). Such

FIG. 248.—Brittain's ischio-femoral, extra-articular arthrodesis of the hip (see text).

H. A. Brittain, 1904–1954. Orthopædic Surgeon, Norfolk and Norwich Hospital, England.

operations ('extra-articular arthrodeses') were technically difficult. Since the advent of antibiotics, the bone ends can be brought into apposition across the evacuated abscess cavity and sound bony fusion can commonly be obtained in this way.

In the spine, exactly the same surgical principles apply. The disease, however, is rarely diagnosed before bone involvement has taken place so that some form of arthrodesis is nearly always required. If no significant pus formation has occurred when antibiotics are given, it is usually possible to sterilise the lesion in the vertebral bodies with little or no vertebral collapse. The lesion itself can then be ignored surgically and the spine stabilised by a posterior fusion. Should pus formation have occurred, the abscess requires evacuation through an antero-lateral approach. At the same time as the abscess is evacuated bone grafts are packed between the involved vertebral bodies so that healing results in an anterior body-to-body fusion.

Prognosis.—The prognosis for this disease is now excellent. Death either from the tuberculous process itself or from secondary amyloidosis is now rare. Disability of any kind can often be prevented by early, adequate antibiotic treatment combined with appropriate immobilisation. At the worst the patient may spend 3 to 6 months in hospital and although finally cured of the tuberculous process, have a permanently stiffened joint.

Tuberculous Tenosynovitis.—This may take two forms:

(*a*) The endothelial lining of the sheath is replaced by œdematous granulation tissue containing miliary tubercles. Very little free fluid is present. A soft elastic swelling appears and if the disease progresses, pus may form and track into neighbouring sheaths or joints.

(*b*) An effusion occurs in the tendon sheaths and 'melon-seed' bodies are usually present in large numbers, so that a soft, coarse crepitus is detected on pressing fluid from one part of the sheath to another. Melon-seed bodies resemble grains of boiled sago. They are composed of collections of fibrin, cellular debris and occasional tubercle bacilli (fig. 249). The term 'compound palmar ganglion' is applied to this condition when it occurs in connection with the flexor tendons of the fingers.

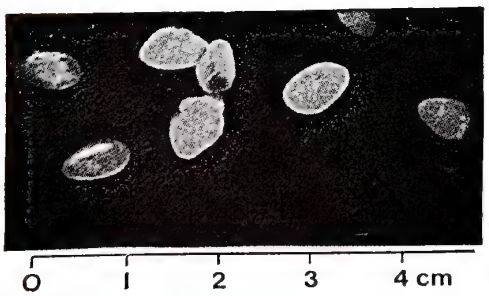

FIG. 249.—'Melon-seed' bodies from tuberculosis synovitis at the wrist.

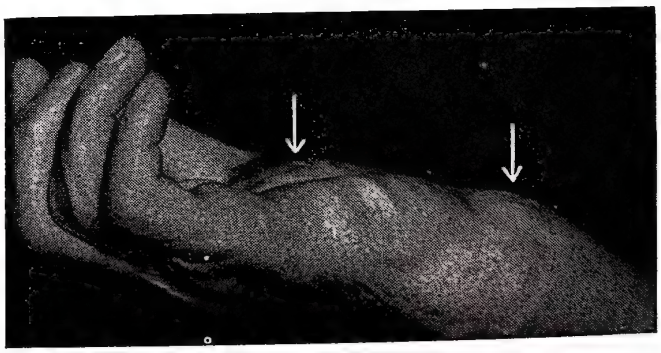

FIG. 250.—A compound palmar ganglion (tuberculous flexor synovitis at the wrist). The swelling in the palm communicates with the swelling above the wrist.

A soft, painless swelling appears (fig. 250), and fluctuation may be transmitted above and below the anterior carpal ligament. As with all forms of tuberculous disease of bone, joint or tendon, obvious wasting of adjacent muscles is present. Treatment consists of general measures, the use of antibiotics and the application of an appropriate plaster cast to immobilise the involved tendon sheath. If the condition progresses, careful dissection and removal of the tendon sheath is indicated.

CHAPTER 13

THE RHEUMATIC DISEASES

OSTEOARTHROSIS (OA)[1]

Ætiology.—Normal synovial joints may be regarded as being in a state of equilibrium between the mechanical properties of the articular cartilage and the mechanical stresses imposed upon this tissue. If the loads applied to the joint rise or the same loads are applied through unusually small areas (i.e. the joint becomes abnormally incongruous), this equilibrium will be disturbed because the applied stresses rise. The equilibrium will also be disturbed if disease damages the cartilage so as to prejudice its mechanical properties. OA can perhaps be viewed as the outcome of any such dis-equilibrium and, as such, as the final common path travelled by any joint whose mechanics have been disturbed. Thus OA is perhaps best thought of, not as a specific disease entity, but rather as a constellation of clinical and anatomical features, analogous to heart failure: indeed it might with advantage be renamed ' joint failure '.

There is some evidence that OA is not initiated by abrasive wear caused by a breakdown in lubrication. Thus, if OA be loosely regarded as ' wear ' in a joint, it is probably wear in the sense that linoleum ' wears ' when walked over by stiletto heels, not wear in the sense in which it occurs in a poorly lubricated bearing.

OA developing after some recognised predisposing event is known as Secondary OA. All such predisposing causes either damage cartilage or reduce the contact area in a joint. Thus injuries to articular cartilage, especially if they interrupt the normal contour of the subchondral bone to produce ' high points ' in the articular surface, render the joint liable to develop osteoarthrosic changes over the ensuing years. Diseases which make the joint surface irregular (such as Perthes' Disease (p. 278) or Slipped Femoral Epiphysis (p. 276)) predispose to OA by reducing the contact area in the joint and hence raising the contact pressure on the cartilage so as to damage the tissue mechanically. Articular cartilage may also be damaged enzymatically, for example, in septic arthritis, tuberculous arthritis, or rheumatoid arthritis and all these conditions may cause Secondary OA. (Since the rheumatoid process (see Rheumatoid Arthritis) can ' burn itself out ' after it has irrevocably damaged the articular surfaces, the late disability

[1] The Rome Conference of the International League Against Rheumatism in 1961 proposed that this condition should be named alternatively *osteoarthritis* or *osteoarthrosis*. These alternatives were accepted by the American Rheumatology Association in 1963. The term *osteoarthrosis* is now in almost universal use amongst British rheumatologists and is to be preferred to *osteoarthritis* since the latter implies, misleadingly, that the condition is an inflammatory disease of joints.

in this disease is not always strictly attributable to the rheumatoid process but rather to secondary osteoarthrosic changes superimposed upon a burnt-out rheumatoid joint.) Recurrent hæmarthroses (as in hæmophilia) and chemical infiltration of cartilage, for example with pigment (in ochronosis) or calcium pyrophosphate (in chondrocalcinosis), also damage articular cartilage and may result in OA.

Most cases of OA—at least at the hip where the disorder is most common in Caucasians—are idiopathic and are (misleadingly) called 'Primary'. Although the ætiology is unknown, there is mounting evidence that (1) a number of anatomical variants, not easily detectable in life, may exist at the hip and produce high local contact pressures on the cartilage and (2) that the repeated application of these pressures may cause fatigue failure in the collagen network in cartilage thus initiating the destruction of the tissue.

Pathology.—The first visible abnormality in primary OA affects articular cartilage, the surface of which becomes roughened (a change known as 'fibrillation'). This surface roughening signifies fragmentation of the collagen network in the tissue and is accompanied by a loss of matrix proteoglycan and by softening. Fibrillation extends progressively deeper into the tissue until bone is exposed, a condition described pathologically as ulceration.

Fragments of cartilage become detached from the subchondral bone as ulceration occurs. They may form loose bodies in the joint, but most eventually become attached to the synovial membrane. Here they set up a low-grade inflammatory response which spreads to involve the capsule. The resulting gradual fibrosis of the synovial membrane and capsule shortens the capsule and thus limits joint movement. Endochondral new bone formation occurs around the periphery of the joint surface (where the articular cartilage is usually preserved because it is not exposed to significant load carriage) and leads to typical excrescencies around the joint known as 'osteophytes'. In the bone adjacent to the joint there is an increase in vascularity very early in the disease, indeed it is suggested by some authorities that the alteration in bone hæmodynamics represents the initial change in the disease process. Later, as the cartilage becomes destroyed, the subchondral bone and trabeculæ become thickened, a change known as 'sclerosis', and areas of soft tissue, ('cysts') often liquefied in the centre, form in the cancellous bone adjacent to the joint. The bone separating such cysts from the synovial cavity may collapse into the cyst leading to progressive deformation of the bony articular surfaces and the separation of loose fragments of bone.

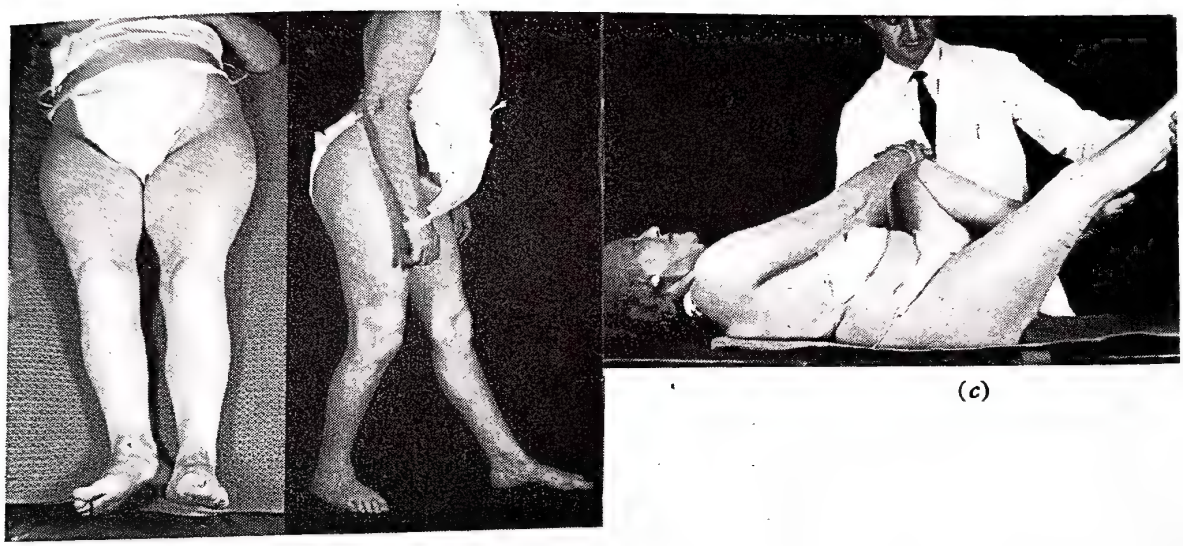
Clinical Features

The sequence of events by which the pathological process in OA causes the clinical features is discussed in relation to surgical treatment on p. 228.

Symptoms.—The initial complaint is always of pain felt on exercise and/or at night. The pain on exercise gets gradually more severe as the joint is used, a symptom particularly noticeable in the weight-bearing joints such as the hip and knee. Pain is also felt when the joint is first moved after a period of immobility. Pain at night may be so troublesome as to be a predominant

symptom: it is not uncommon for a patient with OA of the hip to be woken several times every night by pain. As the pain increases, the joint gradually loses movement because of muscle spasm, reluctance to move the joint, fibrosis of the capsule, and the bony changes described above. In the joints of the lower limb pain and stiffness combine to produce a limp. As the disease progresses the stiffness becomes increasingly severe until all movement at the joint is lost. By this time the joint usually lies in the position of 'ease' (Table p. 212) which may well be a position which is functionally useless, for example the hip typically becomes fixed in flexion, adduction and external rotation (fig. 251). This development of complete stiffness in a functionally inappropriate position constitutes deformity. Thus the patient, especially if more than one joint is involved, may be completely crippled and either bed-ridden or forced to use a wheelchair.

Physical Signs.—On inspection the abnormal position of the joint may be evident and a swelling attributable to a small synovial effusion may be



(*a*) (*b*) (*c*)

FIG. 251.—OA right hip. (*a*) Note external rotation, adduction and shortening. (*b*) Fixed flexion causing lumbar lordosis and protruding buttocks when the patient tries to stand erect. (*c*) Thomas's test to reveal fixed flexion (here 45°) at the right hip. The patient flexes her left hip fully and in so doing straightens her lumbar spine until it touches the couch. The right leg rises from the couch to reveal fixed flexion at the hip. The surgeon places his right hand under the spine to ensure that the lumbar lordosis is fully flattened and with his left hand supports the right leg to prevent pain but does not attempt to flex the hip.

visible in subcutaneous joints such as the knee. On palpation the joint may be mildly tender and fluctuation produced by an effusion may be detectable. When the patient is asked to move his joint, the loss of movement in certain directions will be evident and in the subcutaneous joints a sensation of grating can be appreciated if the hand is placed over the joint as it moves. This sensation is known as 'crepitus'. At the hip the tendency for the joint to become stiff in adduction and flexion leads to apparent shortening of the leg (fig. 251). True shortening may also occur as the femoral head and acetabular roof collapse.

Hugh Owen Thomas, 1834–1891. Surgeon, Liverpool, England. *See footnote p. 385.*

Radiological Appearances.—These are characteristic (figs. 252 and 253). In the first instance they consist merely of narrowing of the joint space: a space which is of course occupied by radio-lucent articular cartilage. As this cartilage thins and ulcerates the radiologically apparent joint space diminishes. Shortly thereafter bone changes become evident: sclerosis in the subchondral bone is the first abnormal feature to appear followed by cyst and osteophyte

FIG. 252.—Osteoarthrosis of the hip.

FIG. 253.—Osteoarthrosis of the lateral compartment of the knee superimposed upon knock knee.

formation. Finally the bone collapses. The very marked new bone formation (manifest as sclerosis and the presence of osteophytes) distinguishes this disease radiologically from rheumatoid arthritis, in which the predominant radiological feature is one of bone loss.

Treatment.—There is no specific conservative nor pharmacological treatment for OA. In the early stages of the disease, the patient can usually be made comfortable by advice as to how to keep his joints mobile whilst loading them as little as possible, and by simple analgesics. The advice concerning the use of the joint may be supplemented by physiotherapy, by which the muscles acting across the involved joint are built up in strength and in which an attempt is made to regain a full range of active movement. In OA affecting the joints of the leg, weight loss, when possible, is desirable and the use of a walking stick and of a raise to the heel of the shoe (if the leg is short) may well make the patient more comfortable. Should these measures fail operative treatment has to be considered (p. 228).

RHEUMATOID ARTHRITIS (RA)

In this text-book, the pathology, clinical features and conservative treatment of rheumatoid arthritis can only be touched on in outline. For a more detailed treatment of these aspects of the disease the reader is referred to a textbook of rheumatology.

Ætiology.—The ætiology of RA is unknown, but a number of theories have been advanced of which probably the most widely credited today rests upon the belief that the disease is immune in nature.

Pathology.—The tissue first affected in rheumatoid arthritis is the synovial membrane, which becomes inflamed and bulky. A striking histological feature in the synovial membrane is the presence of numerous lymphocytes and plasma cells which can be shown to be actively synthesizing antibodies. In addition an effusion accumulates so that the volume of material (synovial fluid and membrane) within the capsule of the joint becomes very considerably increased. Thus the capsule becomes progressively stretched and the joint increasingly unstable. As the synovial tissue enlarges, it gradually encroaches upon the articular cartilage where it is known as *pannus*[1]. Beneath the synovial pannus, the articular cartilage is destroyed and never subsequently regenerates. Intra-articular structures, such as the cruciate ligaments in the knee, may also be destroyed. The bone adjacent to the joint is eroded by the intrusion of exuberant synovial membrane. It also becomes osteoporotic, partly as a consequence of the hyperæmia associated with the disease, but sometimes partly as a consequence of its treatment with steroids. The combination of a loss of cartilage and osteoporosis may lead to rapidly progressive, severe bone collapse and hence to instability and deformity at the involved joint.

Clinical Features

Symptoms.—The disease may commence in childhood, when it is known as Still's disease, or at any time in adult life. RA developing in the elderly seems to run a more benign course than the disease developing in the young adult. Women are more commonly affected than men. The disease is typically poly-articular and often starts in the small joints of the hands or feet. Thereafter all the synovial joints of the body may become involved simultaneously or consecutively. Each joint as it is involved is painful, stiff and swollen. The activity of the disease tends to wax and wane both in the patient as a whole and locally in the involved joint, so that a joint may be painful, stiff and swollen for a period of 2 to 3 months and then gradually settle to be followed after an interval by a similar episode in another joint. The patient often feels unwell in himself and is mildly febrile.

FIG. 254.—The hand in rheumatoid arthritis.

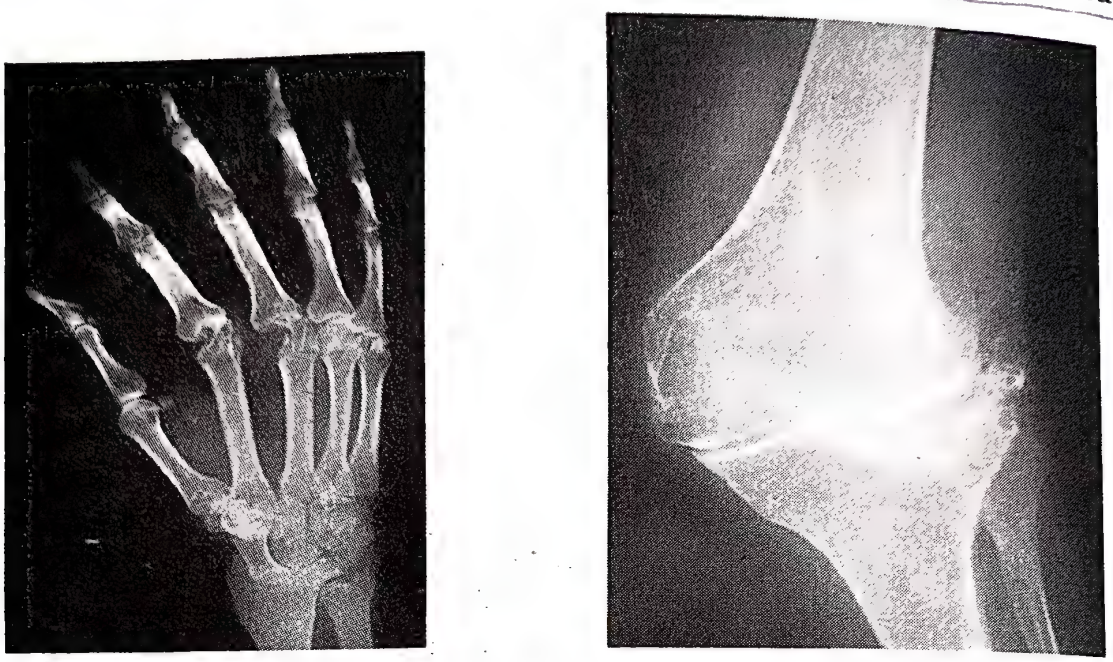
Physical Signs.—The involved joints, especially those of the hand, show marked synovial thickening and as the disease advances typical deformities develop (fig. 254). On palpation the synovial thickening, together

[1] Pannus (Latin) = cloth.

Sir George Frederic Still, 1868–1941. Professor of Diseases of Children, King's College Hospital, London.

with the presence of a synovial effusion, may be obvious. The joint can often be felt to be mechanically unstable and movement is painful and limited. As the disease progresses, limitation of movement, muscle wasting and deformity gradually develop at involved joints so as to cripple the patient.

Radiological Features.—The joint space is initially narrowed as in OA (fig. 255 (*a*)) but the intrusion of affected synovium into the bone produces



(*a*) (*b*)

FIG. 255.—(*a*) The hand in rheumatoid arthritis: note loss of joint space, erosion of the metacarpal heads and disorganisation of the wrist. (*b*) The knee in rheumatoid arthritis. Gross collapse of the lateral tibial and femoral condyles.

typical lytic lesions in the latter. In contrast to OA, osteophytes are small or absent and the bone adjacent to the joint becomes increasingly porotic so that it collapses under the compressive loads to which it is subject (fig. 255 (*b*)). As the disease advances, a combination of bone destruction and capsular stretching allows the joint to subluxate and finally to dislocate.

The active rheumatoid process may remit in a particular joint, leaving its articular cartilage destroyed. Thereafter the joint may progressively develop osteoarthrosic changes so that the final X-ray appearances are to some extent those of OA.

The sequence of events by which the pathological process in RA causes the clinical features is discussed in relation to surgical treatment on pp. 228 and 236.

Special Investigations.—The ESR is raised and an abnormal immune globulin known as the *rheumatoid factor* may be demonstrated in the blood by use of the Latex or Rose Waaler tests. The demonstration of rheumatoid factor is not, however, diagnostic of RA since it is found in healthy individuals and in those suffering from various chronic infections, neither is rheumatoid factor always present in RA. These abnormal hæmatological findings are in sharp contrast to OA in which the blood picture is entirely normal and in which there is no systemic disturbance of any kind.

Harry M. Rose, Contemporary. Professor of Medical and Surgical Research Chemistry, Department of Microbiology, Columbia-Presbyterian Medical Centre, New York.
Erik Waaler, Pathologist, Ullevaal Hospital, Oslo, Norway.

Treatment.—The conservative treatment of RA consists of exercises and splintage to maintain joint function and to prevent deformity, combined with drug therapy. Surgery (p. 228) may be used to remove involved synovial tissue, to relieve the disability of a destroyed joint, or to treat isolated soft tissue lesions such as compression of the median nerve in the carpal tunnel (p. 232).

ANKYLOSING SPONDYLITIS

Pathology.—This is a crippling disease which, although it has some features in common with RA, forms a distinct clinical entity and is regarded as such in the U.K. On the other hand the initial histological appearances of this disease are so similar to those of RA that in the U.S.A. ankylosing spondylitis is regarded as a variant of RA.

FIG. 256.—Ankylosing spondylitis.

FIG. 257.—Ossification of the lumbar spine ('bamboo' spine).

The disease is essentially a process of calcification and then ossification of the ligaments and capsules of joints, which results in complete bony ankylosis of the central articulations of the body. (This contrasts with rheumatoid arthritis which is not predominantly an ankylosing disease and which affects the small, distal joints of the extremities first). Whereas RA affects mainly females, ankylosing spondylitis is more common in men, starting in early adult life.

It has recently been shown that the tissue antigen HLA-B27 occurs in 96% of patients with ankylosing spondylitis, while present in only about 6% of general Caucasian populations. Tissue typing may thus help in diagnosing

the condition, but the mechanism by which this genetic factor operates in predisposing to the disease is not yet established.

The joints most affected, in order of frequency, are the sacro-iliac joints, the joints of the spine (ascending from the lumbar level), the hips, the costal joints, and the shoulders. In addition to developing bony ankylosis, the spine becomes flexed so that eventually the patient is bent double and can no longer see in front of herself (fig. 256).

Special Investigations.—The diagnosis is confirmed by the finding of a raised ESR (an investigation which should never be omitted in the examination of young adults complaining of low back pain), by the radiological demonstration of bony obliteration of the sacro-iliac joints, and finally by the presence of ossification in the spinal ligaments ('bamboo spine') and ankylosis of other involved joints (figs. 257 and 258).

Treatment.—There is no specific treatment for this condition. Fortunately the disease sometimes arrests spontaneously before the full picture of spinal ankylosis in gross deformity is reached. Patients in whom the thoracic cage

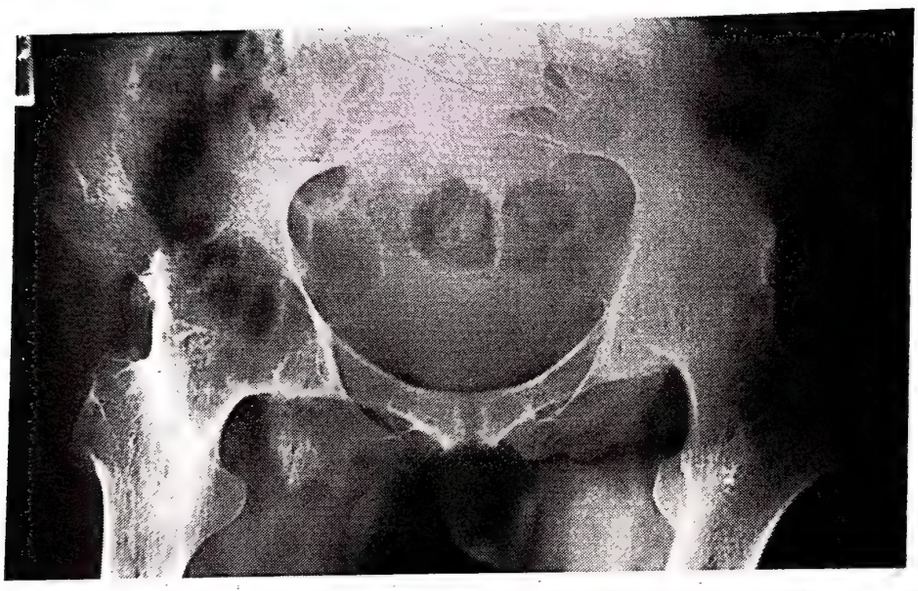


FIG. 258.—Ankylosing spondylitis: ankylosis of the hips.

is ankylosed and the spine is flexed, may die of pulmonary infection because of the reduction in their vital capacity. Simple analgesics help to relieve pain and postural exercises may help prevent increasing deformity. Osteotomy of the spine (p. 239) is occasionally indicated to correct severe deformity. Pain and stiffness in the hips may be relieved by arthroplasty (p. 238).

OPERATIVE SURGERY IN THE RHEUMATIC DISEASES

In this section, the general principles of the surgery of the rheumatic diseases are outlined in relation to the probable causation of the disability. The application of these principles will then be discussed in relation to the joints involved in RA, ankylosing spondylitis, and OA.

Operative surgical treatment in the rheumatic diseases is never curative: rarely, the pathological process may be arrested or even reversed, more commonly its existence and progression have to be accepted and surgery

offered to provide palliation of the patient's disability—pain, stiffness and deformity. The exact causation of this disability is sometimes obscure, but an attempt must be made to explain it in the rationale if operative surgery is to be understood.

The Ætiology of Pain, Stiffness and Deformity

Pain in the rheumatic diseases appears to arise mainly in three tissues: the capsule of the involved joint, the bones of the joint, and the muscles acting on it. Cartilage is not innervated and accordingly is insensitive to pain. Synovial membrane is poorly innervated and experiments with human volunteers have shown that it is almost insensitive to pain arising from mechanical stimulation. No doubt active inflammation of the synovial membrane, as of the capsule, is painful, but active inflammation of these tissues in the rheumatic diseases is not treated surgically.

The fibrous capsule and ligaments of all joints are well innervated both with mechanoreceptor afferents subserving perceptual and reflex proprioception and with pain afferents. The effective mechanical stimulus for the provocation of capsular pain appears to be excessive tension in the capsule. In the context of the rheumatic diseases excessive capsular tension may be brought about by two pathological events: firstly, an increase in the volume of material within the capsule, that is to say by an increase in the bulk of the synovial membrane or by an accumulation of intra-articular fluid, and secondly, by capsular fibrosis leading to shortening and tethering of the capsule. Joint movement and position affect the severity of this pain in two ways. In all joints some position within the normal range draws the capsule most tightly against the synovial contents and it is this position which provokes pain when the bulk of the intracapsular tissues is increased. Secondly, the pain arising from capsular fibrosis is provoked only or chiefly when the capsule has shortened to such an extent that it limits movement: when this limited movement is attempted by the patient with sufficient force to apply tension to the capsule pain is provoked. Thus capsular pain interferes with movement and in an attempt to avoid it the patient tends to hold the joint immobile in a position of capsular relaxation.

Although histologically nerve fibres which might be pain afferents have been described in bone, the effective stimulus for the provocation of pain in bone is unknown. Experimentally, pain may be induced when the intraosseous venous pressure is raised and venous engorgement of juxta-articular bone has been demonstrated in OA. (Traction on the periosteum is painful but this is not relevant to pain induction in intra-articular bone where the true periosteum is replaced by cartilage or synovium.) Whatever may be the precise nature of the effective stimulus for bone pain, it may be regularly observed in clinical practice that if the arthritic bony surfaces are replaced with appropriate prostheses securely fixed to the skeleton, the patient's arthritic pain both at rest and on weight-bearing is abolished at once. This observation proves that the major component of the pain of arthritis originates in bone and it may be speculated that this is due to the generation of

abnormally high stresses in the bone, possibly leading to trabecular micro-fractures and hence to vascular engorgement.

Muscular pain is probably provoked by local anoxia or by the accumulation of metabolic end-products, arising from abnormally sustained muscular contractions. Such contractions—known clinically as muscle spasm—have not been convincingly demonstrated electromyographically but their existence may be inferred from the fact that the passive range of movement in a diseased joint is often increased under a general anæsthetic producing muscle relaxation. Muscle spasm of this type appears to be a reflex consequence of joint disease and imposes immobility on the affected joint.

Joint stiffness is a loose term covering two disturbances of function—a sense of added resistance encountered by the patient when he attempts to move the affected joint, and a total inability to move the joint through some part of its normal range. The first factor is perhaps in part due to a rise in intra-articular friction caused by disruption of the normal cartilaginous bearing surface, but seems mainly attributable to articular and extra-articular soft tissue thickening, adhesions and œdema, and probably to over-contraction (' spasm ') of the antagonist muscles.

A reduction in the passive range of movement may be due to pain and muscle spasm—in which case the range will return under anæsthesia—or to such mechanical factors as capsular and peri-capsular fibrosis, osteophyte formation and collapse of the articulating bony surfaces.

Deformity.—In its early stages deformity may be regarded simply as a loss of part of the normal range of movement: thus, for example, a patient who is unable fully to extend his knee may be said to have a flexion deformity or contracture of that joint. Deformity may progress to a point at which the two articulating bones start to take up a position in relation to each other which does not occur anywhere in the normal range of movement: in other words the joint becomes subluxated and finally dislocated.

Dislocation implies a mechanical derangement of the tissues of the joint and the presence of a deforming force. The factor chiefly responsible for dislocation in the rheumatic diseases is the collapse of the bony articular surfaces. In the leg the ligaments stretch little, if at all, but at the hand they are said to do so sufficiently to permit dislocation. The deforming forces at work consist of the body weight and the play across the joint of muscles of normally unequal power (such for example as the finger flexors and extensors), muscles in ' spasm ', or muscles suffering progressive fibrosis. In the leg, the position of a joint may be normal until weight-bearing is attempted. The deforming force of the body weight may then be sufficient to subluxate the diseased joint. Subluxation or dislocation of this kind affects particularly the knee and is referred to as *instability*.

The Role of Surgery

Surgical intervention has as its objective the relief of pain, stiffness and deformity, and have been directed towards six tissues: synovial membrane, articular cartilage, capsule, bone, nerves, and muscles and their tendons.

1. **The Synovial Membrane.**—Removal of the synovial membrane—synovectomy—is employed in RA in those joints in which the synovial membrane is extensive and accessible. The joints which fall into this category and which are most commonly treated by synovectomy are the knee and the metacarpo-phalangeal joints of the fingers. Since the synovial membrane is the tissue primarily involved in RA, it would seem theoretically possible to arrest the disease in an involved joint, or even in the patient as a whole, by synovectomy. There is controversy as to whether or not this theoretical objective can be realised in practice, but in the author's opinion this outcome occurs rarely if ever and the benefits of synovectomy are entirely symptomatic. The operation relieves *pain* by removing inflamed synovium and by reducing the bulk of the intracapsular contents and hence the tension on the capsule. It also retards the capsular stretching which precedes *deformity*. It might be expected that by reducing intracapsular bulk the operation would also reduce *stiffness*, but in practice any such possible increase in the range of movement is usually more than offset by a decrease due to post-operative adhesion formation.

2. **The Articular Cartilage.**—Healing by regeneration does not occur in articular cartilage and hence surgical intervention cannot produce a new cartilage surface once the original has been destroyed by disease. Drilling and shaving of fibrillated cartilage on the patella has however been employed for OA of the patello-femoral joint and may lead to the formation of some fibro-cartilage on the articular surface. Osteotomy may have the same result. Cartilage grafting is being studied experimentally.

3. **The Capsule.**—Removal of a fibrotic capsule would theoretically be an attractive procedure to relieve *pain* and *stiffness*. In practice capsulectomy alone is rarely employed but the procedure represents an important step in various forms of arthroplasty. Capsular reefing may be undertaken as part of the reconstruction of joints in RA to reduce *instability*.

4. **The Bone.**—Three types of operation may be undertaken on bone: arthrodesis, arthroplasty or osteotomy.

In *arthrodesis* the joint is excised and the originally articulating bones are brought into apposition so that they unite with each other. *Pain* is relieved since the diseased joint is obliterated. The bones may be fixed in a better functional position than that taken up by the diseased joint so as to reduce deformity, and *instability* is eliminated. These advantages are achieved, however, at the cost of a total loss of movement.

The operation of *arthroplasty* aims ideally to reconstruct a joint so that pain, stiffness and deformity are relieved. At its simplest this may be achieved by excision of one or both of the articulating bone surfaces without a subsequent attempt to obtain fusion. This procedure, excision arthroplasty, relieves *pain* by reducing capsular tension and, probably, by the removal of painful bone. It may also reduce *deformity* by allowing—for example—realignment of the dislocated toes or fingers in RA. Movement may be retained at the new false joint but the range is never full, it is not always painless and the joint, if loaded, is likely to be unstable.

In an attempt to reduce stiffness and increase stability following excision arthroplasty, various materials have been placed between the freshly resected bone ends in the hope of reducing the degree of adhesion formation between the excised joint surfaces. Since separation of the joint surfaces now depends upon the interposed implant rather than upon the creation of a broad gap between the bone ends, the bone resection can be more limited. As a consequence the normal architecture is more nearly retained and hence the final joint is more stable. Unfortunately the anatomy of only a few joints lends itself to interposition arthroplasty and for practical purposes the only example of the procedure in current use is cup arthroplasty at the hip.

As an alternative method of improving the stability of joints such as the hip after excision arthroplasty, the excised component may be replaced with a prosthesis fashioned of one of the implantable metals. Although improving the stability of the joint, such procedures often lead to relatively poor pain-relief—perhaps because the other diseased bony articulating surface is still loaded by the prosthesis and the tension in the capsule remains unchanged.

Theoretically the most effective arthroplasty would be the replacement of both components of the joint with a prosthetic implant. Appropriate implants are now available for the hip—where the results are good—and on a smaller scale for the knee, ankle, shoulder, elbow and fingers. Ideally total replacement arthroplasty should bring pain relief since both bone surfaces would be removed whilst the capsule could be relaxed or excised; stiffness post-operatively would be due only to muscle shortening and scar formation; and stability would be conferred by an appropriately designed device. In practice a final evaluation of this procedure at the hip must await the results over the next 10 years since only in this period of time (i.e. a total experience of 20 years) can the function of the prosthesis and of the bone-prosthesis bond be adequately assessed. At the other joints the surgical and biomechanical problems posed by the procedure are in an earlier stage of a solution.

The final type of bony procedure available in the rheumatic diseases is *osteotomy*. In this operation the bone adjacent to the joint is divided surgically and then allowed to unite. Mere division of the bone appears to relieve *pain* but why this is so is not understood: possibly the blood flow to the bone between the osteotomy site and the joint is altered, or conceivably the articular bone is partially denervated. Following division, the bone may be angulated so as to compensate for fixed *deformity* at the joint and it was with this objective in mind that the operation was originally introduced. Such displacement, besides correcting the overall deformity, may relieve pain by bringing cartilage-covered bone into the weight-bearing area, by redistributing load (for example in an osteoarthrosic knock-knee), or by transposing the range of movement so that the everyday range does not apply traction to the capsule. It is suggested that osteotomy may sometimes reverse the pathological process in OA.

5. **The Nerves.**—Articular neurectomy has been attempted to relieve joint *pain*. The procedure is not useful in practice since joints are supplied by numerous irregular small nerves which cannot be displayed surgically. Theoretically a neurectomy sufficiently complete to relieve joint pain effectively would expose the patient to the risk of neuropathic changes.

Tunnel Syndromes (see also p. 295).—In certain places in the body, peripheral nerves traverse tunnels whose walls are inelastic: for example the carpal tunnel contains the median nerve and is bounded by the transverse carpal ligament and the

carpal bones with their intervening articulations. If such a tunnel also contains synovial tissue, the nerve may become compressed in the tunnel if the bulk of synovial membrane increases. For example in RA, the synovial sheaths of the flexor muscles of the digits and to a lesser extent the synovial membrane of the carpal joints may proliferate and compress the median nerve in the carpal tunnel. Such compression can be relieved surgically by dividing the transverse carpal ligament, an operation which may be combined with the removal of involved synovium.

6. **The Muscles and Tendons.**—Muscles may become permanently shortened in a position of *deformity* which cannot be corrected unless the affected muscles are divided. Such divisions are usually carried out by tenotomy: besides helping to relieve deformity tenotomy may temporarily bring pain-relief, perhaps by reducing muscle spasm. In RA, tendons may rupture and require repair (p. 237). Proliferation of their synovial sheaths may necessitate synovectomy or the incision of the retinacula retaining the tendons.

A Summary of the Present Position

This is a rapidly changing field so that it is difficult to summarize: in general, however, there is a trend towards the use of total replacement arthroplasty since, when successful, procedures of this kind give incomparably better function than do the alternatives. The extent to which replacement arthroplasty has supplanted the alternatives varies from joint to joint (it is for example virtually the only procedure used at the hip) and from hospital to hospital (in centres specializing in this work for example replacement has supplanted the alternatives at the knee whereas elsewhere alternatives are still widely employed). Synovectomy, surface drilling and capsular procedures are being abandoned. Arthrodesis, osteotomy and other forms of arthroplasty are still in use but on a diminishing scale. Tenotomies are never carried out by themselves but form a component of some arthroplasties.

THE SURGERY OF OSTEOARTHROSIS

Primary OA affects certain joints, such as the hip, knee and carpo-metacarpal joint of the thumb, much more commonly than it affects others such as the shoulder and wrist. Secondary OA following injury or another primary disease process may affect any joint.

Bone and capsular changes are marked in OA but changes in the synovial membrane are insignificant. Hence operations designed to affect the bone and capsule play a large part in the surgery of OA: operations on the synovial membrane (*synovectomy*) play none.

The Upper Limb

The Hand.—The only joint in the hand commonly requiring surgical treatment for primary OA is the carpo-metacarpal joint of the thumb. Here the disease may be treated by *arthrodesis* of the diseased joint or by *excision arthroplasty* of the trapezium. At their best these operations give indistinguishable results with an excellent return of painless function.

The Radio-Ulnar Joints.—The distal radio-ulnar joint may be affected by secondary OA following fractures adjacent to the joint, such as Colles' fracture. The proximal radio-ulnar joint is similarly affected following fractures of the head of the radius. In both cases the treatment of choice is *excision arthroplasty:* in the distal joint by excision of 2·5–5 cm. of the distal ulna, in the proximal joint by excision of the head of the radius.

The Elbow Joint.—Primary OA may affect all components of the joint. Should the joint be so painful as to require surgery, which is rare, the most commonly

Abraham Colles, 1773–1843. (*See footnote, p. 343.*)

employed procedure is *arthrodesis* of the humero-ulnar joint in sufficient flexion to allow the patient to feed himself and wash, together with excision of the head of radius.

The Shoulder.—The shoulder is rarely affected by OA, primary or secondary, but if so, it may be treated by *arthrodesis*. Although fusion is not easy to secure, it is easier than in RA because the bone is hypertrophic rather than porotic. The functional results of a sound arthrodesis in the position of function (i.e., approximately the position taken up by the shoulder when the hand is brought to the mouth) are good.

The Lower Limb

The Toes.—OA and other degenerative changes affecting the toes are considered in Chapter 20.

The Foot and Ankle.—OA, primary or secondary, occasionally affects any of the tarsal (especially the subtalar) joints or the ankle. If surgical treatment is necessary, arthrodesis is the only procedure available at joints other than the ankle. The latter however can now be replaced.

The Knee

Chondromalacia Patellæ.—A condition which has been thought to be analogous to primary OA affects the patello-femoral joint of young adults (especially women). In this disease the articular cartilage covering the patella and subsequently that covering the patella articular surface of the femur becomes softened, fibrillated and finally ulcerated: a sequence of events identical with that seen in primary OA elsewhere but which in this joint occurs in early adult life as a normal event so that its pathological significance is hard to ascertain. It has alternatively been suggested that the pain in this disease is due to patchy osteoporosis in the patella causing isolated trabecular fatigue fracture or to minor degrees of mis-alignment of the patella (see Dislocation of the Patella, p. 381). The condition has been treated by various surgical procedures aimed directly at the cartilage: the cartilage and subchondral bone have been *drilled* and the fibrillated cartilage *shaved*. It is doubtful if these procedures are beneficial, although the regeneration of fibrocartilage following drilling of the patella in advanced OA of the knee has been described. Recently the view has gained ground that the condition is due to an increase in the contact pressure between the patella and the lateral femoral condyle caused by a tendency for the patella to be drawn laterally in involved knees. Treatment based on this view takes the form of division of the lateral patellar retinaculum and occasionally of transposition of the tibial tubercle. Useful pain relief has been reported after these operations. As a last resort the patella may be excised.

Chondromalacia Patellæ apart, the knee, after the hip, is the joint most commonly affected by OA.

Arthrodesis should not now be carried out as a primary procedure since it is irreversible. It is used as a last resort if one of the modern forms of total joint replacements fail and cannot be revised. Several methods of arthrodesis have been described but the Charnley arthrodesis is perhaps the most reliable and widely used (fig. 259).

Excision arthroplasty of the patella has a small part to play in OA of the knee.

Total replacement arthroplasty is now giving very encouraging results. At the time of writing its place in OA cannot be defined but it is being used on a steadily increasing scale and may well displace all other surgical procedures in the next 5 years. A variety of prostheses is available (p. 238).

If pain demands surgical relief whilst the range of movement is too good to make total replacement arthroplasty necessary, *osteotomy* is the only available procedure. The operation is particularly indicated if there is significant bow-leg since the opportunity can then be taken to re-align the knee and thus improve weight-transmission through it. The varieties of osteotomy used in RA are also applicable to OA (p. 232).

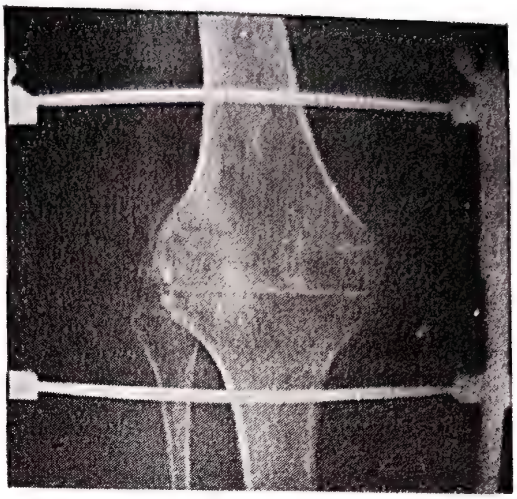

FIG. 259.—Charnley compression arthrodesis of the knee

The Hip

OA of the hip requires surgical treatment more commonly than does any other rheumatic disease in any other joint.

Arthrodesis, excision arthroplasty, interposition arthroplasty and partial replacement arthroplasty have all been used in the past but have been abandoned in favour of total replacement arthroplasty.

Total replacement arthroplasty using a prosthesis replacing the acetabulum as well as the head of the femur was introduced in Great Britain by Charnley in the late 1950s. The device now most widely used in the UK is the Charnley prosthesis in which the acetabulum is constructed of high density polyethylene, and the head of the femur of stainless steel. Both devices are attached to the bone with a cold-curing acrylic cement. It is still too early to give a definitive assessment of this operation since it has been progressively introduced over the past 15 years and has only in the last few years been universally available. The results to date, however, have been extremely encouraging: pain is relieved, a useful range of motion is regained, and the hip is stable. Post-operatively, the convalescence is short, weight-bearing may be allowed within days of operation, and the prolonged, tedious and sometimes painful physiotherapy which some other procedures require is unnecessary. If these results are maintained over the next 10 years the operation will be indicated for most cases of OA of the hip: at the present time, because of uncertainty surrounding the long-term results, the operation is avoided if possible in patients under 60 years of age unless the prognosis for life is shortened by intercurrent disease.

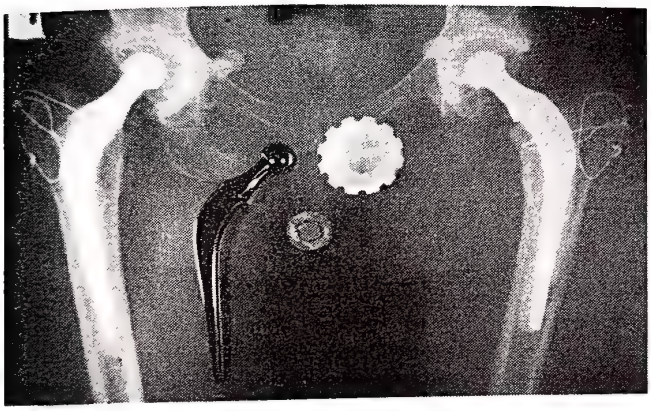

FIG. 260.—Total replacement of the hips using the Charnley prosthesis.

Capsulotomy and tenotomy, especially of the adductor muscles and occasionally of the ilio-psoas muscle, may be included in all forms of arthroplasty.

Osteotomy is employed—at the intertrochanteric level using internal fixation of the osteotomy site (fig. 261)—when pain, especially night pain, demands surgical relief but the range of movement is still good: the presence of 70° of active flexion being taken as a rough dividing line between a hip suitable for osteotomy and one suitable for arthroplasty. Since total replacement arthroplasty is avoided in patients under 60 years of age, osteotomy is employed particularly in this age group: over the age of 60 it has been generally replaced by total replacement arthroplasty. In some centres the operation has been abandoned in favour of replacement in younger age groups as well.

Correction of deformity now forms a secondary objective of osteotomy although the procedure was originally introduced for this purpose. There is some clinical evidence to suggest that osteotomy performed early in the disease may reverse the pathological

Sir John Charnley, Contemporary. Formerly Professor of Orthopædic Surgery, University of Manchester, England.

process. If this is so, osteotomy represents the only operation capable of producing this result. It has additionally been argued that osteotomy can be used to improve the stability of a subluxing hip and to bring relatively healthy cartilage into the line of maximum weight-transmission.

Whatever may be the reason, osteotomy brings significant relief of pain, especially of night pain, to about 60% of patients who have the operation. Stiffness is often not relieved, however, so that in terms of the return of function osteotomy is by no means an entirely satisfactory procedure.

FIG. 261.—Intertrochanteric osteotomy at the hip with internal fixation using a Müller-Harris spline.

THE SURGERY OF THE INFLAMMATORY ARTHROPATHIES

Of the inflammatory arthropathies by far the commonest requiring surgical relief is RA and it is with this disease that this section is largely concerned. During the active phase of RA the joint surfaces may become partially or totally destroyed. Even if the active phase of the disease then remits, symptomatic progression in the involved joint is common as a consequence of secondary degenerative changes. Thus the surgery of chronic, 'burned-out', RA merges into that of OA.

Of the other inflammatory arthropathies, ankylosing spondylitis affecting the spine and hips and Reiter's disease (Chap. 57) affecting the feet may require surgical relief.

RA in childhood (Still's disease (p. 225)) does not readily lend itself to the surgical procedures available in the adult: operations on bones are avoided if possible because they may interfere with growth and soft tissue procedures are rarely indicated.

The Upper Limb

The Hand and Wrist.—*Synovectomy* is widely employed at the metacarpo-phalangeal joints of the fingers, the radio-carpal and inferior radio-ulnar joints, and for the extensor (and, less commonly, flexor) tendon sheaths.

At the metacarpo-phalangeal joints of the fingers increasing synovial bulk progressively distends the capsule, and erodes the cartilage and bone. As a consequence the joints subluxate and finally dislocate. Since the finger flexors are stronger than the extensors, dislocation takes the form of palmar and then proximal displacement of the phalanx on the metacarpal. A similar mechanism produces anterior dislocation of the wrist, and disruption of the inferior radio-ulnar joint. The extensor tendons may rupture as a consequence of a nutritional disturbance, combined with abrasion over the prominent dorsum of the distal radius and ulna. As the fingers deviate ulnar-wards the extensor tendons come to lie to the medial side of the metacarpal head so that their line of pull tends to exacerbate this deviation.

By removing bulky synovium before subluxation has taken place this evolving deformity may be arrested. At this stage, however, marked pain from capsular distension is not a feature so that the surgical decision is a difficult one: probable slowing of the progression of deformity and some pain-relief have to be set against the loss of movement which often follows this procedure.

Maurice E. Miller, Contemporary. *Professor of Orthopædic Surgery, Berne, Switzerland.*
Nigel Henry Harris, Contemporary. *Orthopædic Surgeon, St. Mary's Hospital, Harrow Road, London.*

At the time of synovectomy the capsule may be incised and reefed so as to stabilise the joints and re-align the extensor tendons. The tendons themselves may be repaired if they have ruptured and their synovial sheath may be excised if their bulk interferes with the function of the hand (p. 233).

Once deformity has occurred, and especially when the metacarpo-phalangeal and wrist joints have subluxated, operations on the bones of the hand are indicated.

Arthrodesis of the radio-carpal joint is an excellent procedure and is one of the mainstays in the surgical treatment of the rheumatoid hand. The wrist can be rendered stable and pain-free so that the power of the grip is much improved. The loss of movement compared with that occurring in the normal wrist impairs function very little: compared with the pre-operative state of the wrist any loss is insignificant.

Excision arthroplasty of the metacarpal heads and of the bases of the phalanges from dislocated metacarpo-phalangeal joints makes it possible to realign the fingers with the metacarpus. The consequent improvement of function is limited by stiffness at the false joint due to adhesion formation. In an attempt to improve motion *total replacement arthroplasty* may be employed. Excision of the dorsally dislocated distal ulna from the inferior radio-ulnar joint (a second example of *excision arthroplasty*) usually combined with fusion of the radio-carpal joint, produces a useful increase in the range of painless supination and pronation.

The Elbow.—*Synovectomy* is occasionally useful when the joint is painful, the synovial membrane thickened, but the bone intact.

Arthrodesis is occasionally indicated to confer painless stability, but the objections to this procedure in RA—that fusion is difficult to obtain and that the presence of other involved joints makes loss of movement functionally objectionable—usually outweigh the advantages.

Excision arthroplasty of the radial head may increase the range of painless motion—especially of pronation and supination. Excision of the entire joint may provide a good range of painless movement but the associated instability is such that little increased function is obtained. *Total replacement arthroplasty* of the humero-ulnar joint has been carried out but the results to date have not been satisfactory.

The Shoulder.—*Synovectomy* is not undertaken at this joint since the membrane is relatively inaccessible surgically and its bulk is hard to assess clinically.

Arthrodesis is hard to secure in RA, but is occasionally indicated in a severely painful joint. The loss of total shoulder movement is not as severe as might be expected since scapulo-thoracic motion is unaffected and by itself provides a useful range of shoulder movement.

Excision arthroplasty of the humeral head may be undertaken as an alternative to arthrodesis: the operation and the after-care are less arduous than for arthrodesis and the pain relief is comparable. However the false joint is too unstable to allow effective abduction so that the functional result is worse than that following arthrodesis. *Partial replacement arthroplasty* using a prosthetic replacement for the humeral head (the Neer prosthesis) has not proved useful in RA. *Total replacement arthroplasty* is now available.

The Lower Limb

The Toes.—The commonest consequence of RA requiring surgical relief in the feet is a claw toe deformity. As a result of this deformity—which consists of dorsal dislocation of the phalanges on the metacarpal heads and flexion contractures of the proximal inter-phalangeal joints—the dorsum of the involved toes rubs on the upper of the shoe whilst the head of the metatarsal is driven painfully downwards through the sole on weight-bearing.

Synovectomy has not been used extensively in an attempt to prevent this deformity in the foot in the way in which it has been used in the hand. However *excision arthroplasty* of the metatarsal heads, together occasionally with excision of the base of the proximal phalanx, is used commonly (fig. 262). At the time of excision arthroplasty, the extensor tendons may be divided. This procedure allows the toes to be brought into line with the forefoot and very successfully relieves pain under the metatarsal heads. Post-operatively the gait lacks the 'toe-off' spring of normal gait, but such a spring has already disappeared by the time the operation becomes indicated. At the metatarso-phalangeal joint of the great toe the deformity is that of a hallux valgus rather than a claw toe, but again the operative treatment is *excision arthroplasty*.

Charles Sumner Neer II, Contemporary. Orthopædic Surgeon, Columbia-Presbyterian Medical Center, New York.

As an alternative to excision arthroplasty, grossly deformed toes may be amputated through the metatarso-phalangeal joints.

The Midtarsal and Ankle Joints.—Pain arising from the midtarsal and ankle joints is best treated by well-fitting shoes or boots with appropriate insoles. Isolated involvement of one of these joints may merit arthrodesis, or, at the ankle, total replacement.

FIG. 262.—Excision of the metatarsal heads (Fowler's operation).

The Knee.—As in the hand, *synovectomy* is a useful procedure in the knee. The operation is indicated for a joint in which there has not been gross destruction of bone but in which extensive chronic synovial thickening is causing pain. The systemic state of the patient's disease is not affected by the operation and neither does it affect the decision to operate. Although useful, synovectomy is being abandoned at the knee since conservative treatment has improved whilst the long-term effects of synovectomy are not encouraging.

As the disease advances increasing pain, stiffness and deformity may necessitate *arthrodesis, arthroplasty* or *osteotomy.*

Arthrodesis offers the patient a stable painless knee but at the price of absolute stiffness (fig. 259). This disadvantage is particularly serious in a poly-arthritic disease such as RA, for with a stiff knee patients need good hand, hip and spine function in order to reach their feet and dress themselves. With two stiff knees it is only possible to rise from an ordinary chair by using the arms—which may be impossible if the arms are involved with the disease—whilst if the patient falls she cannot get up from the floor unaided. These disadvantages make bilateral arthrodesis of the knee a disaster in RA and the operation should never now be carried out, even on one knee, as a primary procedure: its only place is as a salvage operation if replacement fails.

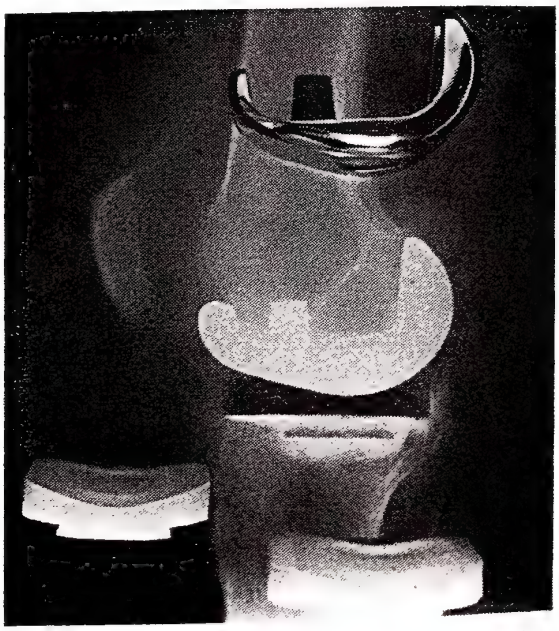

FIG. 263.—Replacement of the knee with the ICLH (Imperial College London Hospital) prosthesis.

Excision of the patella and replacement of the tibial or femoral condyles in isolation have been abandoned. Osteotomy is used on a limited scale in some centres.

The best available treatment for the severely damaged knee in RA is total replacement of the tibiofemoral joint and this procedure is now becoming generally available. A number of prostheses are in use, one of which is shown in fig. 263.

The Hip.—*Synovectomy* is not undertaken at the hip for the same reasons as those which apply to the shoulder.

Arthrodesis is never indicated since it suffers from the same objectionsas those which apply to arthrodesis of the elbow and knee. Furthermore joints in addition to the involved hip have to be immobilised in plaster-of-Paris to obtain fusion, and in RA this risks disastrous stiffness affecting several joints.

Excision arthroplasty is only used as a salvage procedure after failure of total replacement arthroplasty and takes the form of removal of the femoral head and proximal

Alan William Fowler. *(See p. 205.)*
Gathorne Robert Girdlestone, 1881–1950. Nuffield Professor of Orthopædic Surgery, Oxford.

femoral neck (the Girdlestone operation). This operation relieves pain and permits a sufficient range of movement to enable the patient to lie and sit comfortably. The hip, however, is unstable so that walking is difficult and usually requires the aid of two sticks.

Interposition arthroplasy and partial replacement has now been abandoned in favour of total replacement.

Total replacement arthroplasty using the implants already described (p. 235) is now the standard, indeed the only, surgical treatment for the hip in RA: at its best the operation results in almost normal hip function.

The Spine.—RA may affect all the facet joints of the spine but surgery is indicated only in the cervical spine, especially at the atlanto-axial joint, where the disease may lead to instability of the atlas on the axis with consequent danger to the spinal cord. This complication of RA is treated by *arthrodesis* (called 'fusion' when applied to the spine) of the unstable level.

Ankylosing spondylitis produces progressive, rigid, flexion contractures particularly at the cervical and lumbar levels. Arthrodesis has not been attempted to arrest the progress of the deformity but lumbar and, more hazardously, cervical spinal *osteotomy* is used to correct the deformity followed by a fusion at the osteotomy site.

CHAPTER 14

TUMOURS OF BONES AND JOINTS

ALL primary bone tumours are rare: the incidence of osteosarcoma, the commonest primary malignant bone neoplasm, is only 1 per 230,000 of population. From the collective standpoint of the community therefore they are unimportant, almost insignificant. From the individual standpoint of the patient and his family, however, they may represent a tragedy, for many of the malignant tumours occur in the young (at which age they constitute one of the commonest malignant tumours), they are usually fatal, and the attempt to cure them involves mutilating surgery.

Nomenclature and Classification

These tumours are named after the predominant type of tissue matrix formed by the tumour. The benign tumours take the suffix—'oma' and the malignant tumours the suffix—'sarcoma'. Thus a benign tumour forming bone and/or osteoid is named an osteoma and the corresponding malignant tumour an osteosarcoma. Tumours forming a cartilaginous matrix are named chondroma and chondrosarcoma, the fibrous series fibroma and fibrosarcoma. Tumours differentiating to a synovial pattern are named synovioma and synovial sarcoma. A number of primary bone tumours arise from the cells contained in the bone marrow and these are also named, so far as possible, after the type of tissue differentiation. The matrix of some tumours is too poorly differentiated to allow specific classification.

Based upon the appearance of the cells and matrix of the tumour, Price has classified bone tumours into 11 groups, most of which may be subdivided into benign and malignant (Table 1). In this chapter only the clinically more important tumours will be considered, excluding those of dental and bone marrow origin.

BENIGN TUMOURS

Pathology

Most of the benign tumours of bone occur in children and young adults and often stop growing with the cessation of skeletal growth. Such lesions might more properly be regarded as localised dysplasias rather than neoplasias, and indeed those which are multiple, for example multiple osteochondromas and chondromas, may well be viewed in this light.

The exceptions to the general rule that the tumour ceases to grow at skeletal maturity are giant cell tumours, which are probably better regarded as locally malignant, and osteoid osteomas, the precise pathological nature of which is unknown. Aneurysmal bone cysts are almost certainly not neoplastic but can conveniently be considered under the heading of benign tumours.

Charles Hedley Godfrey Price, Contemporary. Formerly Research Fellow in Pathology, University of Bristol, England.

TABLE I. TUMOURS OF BONES AND JOINTS

The Bristol Bone Tumour Registry Classification (Revised—1969)

Section A. Angioid tumours	
Benign	Angioma
	Aneurysmal Bone Cyst (? neoplasm)
	Glomus Tumour
Malignant	Haemangioendothelioma (Angiosarcoma)
Section B. Bone forming Tissue	
Benign	OSTEOMA
	Osteoblastoma
	Osteoid Osteoma (? neoplasm)
Malignant	OSTEOSARCOMA
	Juxtacortical osteosarcoma
Section C. Cartilage forming tumours	
Benign	OSTEOCHONDROMA
	CHONDROMA
	Chondroblastoma
Malignant	CHONDROSARCOMA
Section D. Dental and allied structures	
	Odontogenic cyst
	Cyst—not clearly odontogenic
	Ameloblastoma
	Composite odontome
	Malignant odontome
	Cementoblastoma
Section E. Embryonic Vestigial Tissue	
Benign	—
Malignant	Chordoma
Section F. Fibroblastic Tissue	
Benign	Fibroma. (Non-osteogenic: chondromyxoid: desmoplastic: alveolar)
	Myxoma
Malignant	FIBROSARCOMA (Inc. spindle cell sarcoma)
Section H. Heterotopic Tissue	
Benign	Dermoid
Malignant	Adamantinoma (of long bones)
	Central maxillary carcinoma
Section N. Non-osseous connective tissue	
Benign	Lipoma
	Neurofibroma
	Neurilemmoma
Malignant	Liposarcoma
	Reticulosarcoma
	Myeloma
	Leukaemia
	Ewing's tumour
	Leiomyosarcoma
Section S. Synovium	
Benign	SYNOVIOMA
	Chondroma
Malignant	SYNOVIAL SARCOMA (Malignant synovioma)
Section U. Undifferentiated connective Tissue	
Benign	GIANT CELL TUMOUR (osteoclastoma)
Malignant	Malignant forms of giant cell tumour
Section X. Undiagnosable primary tumours	

Osteochondroma.—This lesion is almost certainly the result of a localised disturbance of bone growth at an epiphysis. A portion of epiphyseal cartilage remains in the periosteum of the metaphyseal segment of the bone and endochondral ossification takes place in it, usually in continuity with the metaphyseal cortex. The cartilage cap proliferates, endochondral ossification continues, and thus the osteochondroma grows. With continued bone growth the osteochondroma moves away from the epiphysis and tends to become 'hooked', its tip pointing away from the epiphysis (fig. 265). Growth of an osteochondroma usually ceases with the completion of skeletal growth. The lesion may be solitary or multiple (p. 267).

Compact Osteoma (syn. Ivory Exostosis).—This lesion consists of a small knob of extremely hard, dense, but otherwise normal bone usually arising on the inner or outer table of the skull.

Osteoid Osteoma.—This 'tumour' consists of a small area of arborescent trabeculæ of osteoid and bone with a vascular connective tissue ground work. The tumour itself is usually less than 1 cm. in size and provokes dense new bone formation around it. Its neoplastic nature is unsure, and

James Ewing, 1866–1943. Professor of Oncology (Tumours), Cornell University Medical College, U.S.A

the lesion may possibly be a low grade osteitis. The tumour is most commonly seen in patients between 10 and 25 years old, is slightly more common in males, and usually occurs in the long bones. Any bone may be involved, the most commonly involved bones being the femur and the tibia. Lesions over 1 cm. in size are sometimes designated 'Osteoblastoma', but are histologically indistinguishable from Osteoid Osteomas.

Chondroma.—This tumour consists of a lobulated mass of cartilage. The tumour may arise in any bone, but is most frequent in the metacarpals, phalanges or metatarsals (fig. 264). Occasionally the tumours arise in synovial membrane. If situated in the medulla (*enchondroma*), the bone is thinned or expanded by the tumour so that pathological fracture is common. Tumours on the surface of the bone are known as *ecchondromas*. The matrix of the tumour may calcify and sometimes ossify. Like osteochondromas, chondromas may be solitary or multiple (p. 267). Malignant change is rare in solitary tumours, but may occur when the tumours are multiple.

FIG. 264.—Multiple chondromas in the phalanges resulting in milder (and more typical) deformities than those shown in fig. 266.

Fibroma.—These occur in bone as islands of fibrous tissue of characteristic radiographic appearance. They range from a small oval cortical defect to quite large lesions. Areas of fibrous dysplasia are distinguished from fibromas by the presence within them of new bone.

Aneurysmal Bone Cysts.—These occur mainly in the ends of growing long bones. They form expanding osteolytic lesions containing bloody fluid through which pathological fractures may occur. Callus formation following such a fracture may obliterate the cyst. Care must be taken to distinguish them from osseous hæmangiomas.

Clinical and Radiological Features

Tumours growing on the surface of a bone, such as osteochondromas, may form an appreciable mass or they may interfere with the action of an adjacent soft tissue such as a tendon. The complaint of severe or persistent pain in such a tumour should raise the suspicion of malignant change.

Lesions which replace bone, such as chondromas or bone cysts, may present with pain, a pathological fracture, or deformity.

Radiologically, benign lesions have certain features in common which suggest their benign nature. These are:

1. Growth of the lesion is slow, and when situated within a bone it leads to cortical erosion and expansion.
2. The line of separation between the tumour and adjacent normal tissue

is usually sharply defined. This applies equally if the tumour is bony and lies in soft tissue, or if the tumour is radiolucent and lies in bone.

The radiological features of the common benign tumours are illustrated in figs. 265 and 266.

Biopsy.—A diagnosis can usually be made on the basis of the clinical and radiological appearances but, as a general rule, the lesion should always be biopsied, or when possible excised, since histological examination is advisable.

FIG. 265.—Multiple osteochondromas (exostoses) each of a typical hooked shape growing away from the epiphysis, of all the bones round the knee.

Osteoid Osteoma, alone amongst the benign neoplasms of bone, presents with pain which is severe, unrelieved by rest, but often specifically relieved by salicylate. The only abnormal physical sign is bone tenderness, and even this is often absent so that patients with osteoid osteomas may sometimes be regarded as hysterical. Radiologically, the bone in the area of the tumour is densely sclerotic. Towards the centre of the sclerotic area and often obscured by it, there is a radio-opaque ' nidus ' in a radiolucent zone which represents the tumour itself (fig. 267). If the tumour lies in cortical bone, there may be overlying subperiosteal new bone formation. Tomography may be required to demonstrate the nidus.

(*a*) (*b*)

FIG. 266.—(*a*) Multiple ecchondromas in the hand (Ollier's disease). (*b*) Appearance of the hands shown in (*a*).

Treatment

Osteomas can be ignored unless they give rise to symptoms which demand treatment. They should then be removed.

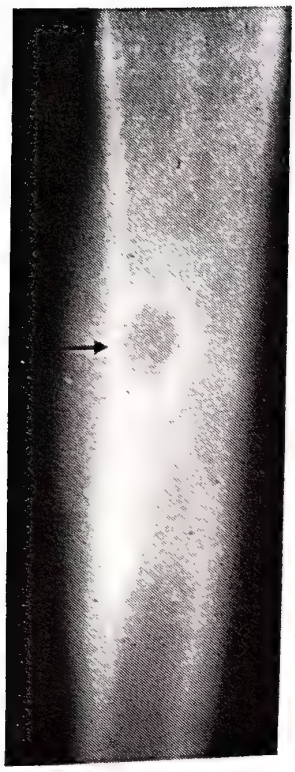

FIG. 267. — Osteoid osteoma in the tibia.

Lesions which significantly weaken bone such as chondromas or aneurysmal bone cysts should be treated, even if symptomless, to prevent pathological fracture. The lesion is excised by curettage and the resulting cavity in the bone is packed with autogenous bone chips. (In multiple chondromatosis (Ollier's disease), it may, of course, be impractical to treat all the tumours in this way.)

MALIGNANT TUMOURS

Pathology

Osteosarcoma. — This is a highly malignant tumour: reported 5 year survival rates vary, but few exceed 15%. Osteosarcomas arising in hitherto normal bone, occur mainly in the second and third decades of life and tend to occur in the metaphyseal region of the long bones, especially those of the leg. Paget's disease predisposes bone to develop a sarcoma, about 60% being osteosarcomas. Such tumours develop late in life (because Paget's disease is a disease of the elderly), arise in any bone involved by Paget's disease, and are almost invariably fatal. Excessive irradiation also predisposes bone to sarcomatous change.

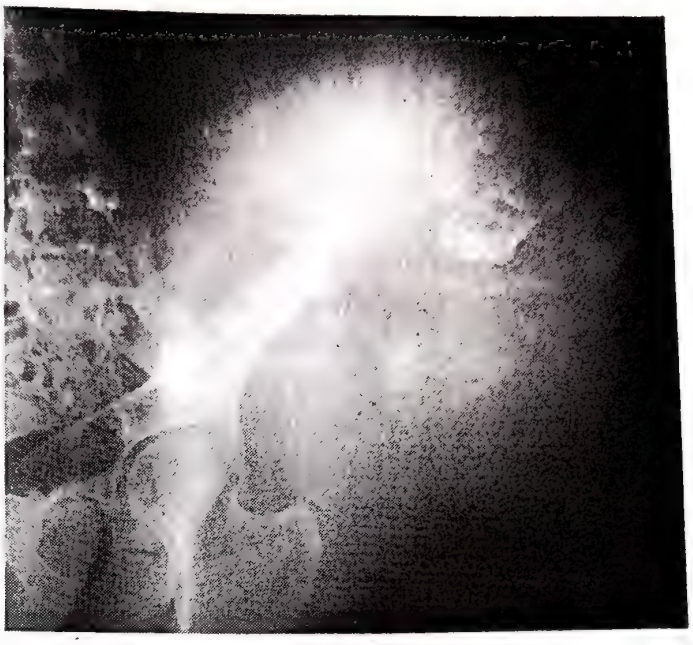
The tumour is composed of pleomorphic cells which invade and destroy the bone producing a radiologically osteolytic lesion with ill-defined edges. Although they destroy normal bone, the tumour cells may themselves produce abnormal bone of irregular structure. If the tumour has invaded the soft tissue (fig. 268), neoplastic bone can be seen radiologically outside the confines of the normal bone, where it tends to be deposited as irregular spicules of bone radiating away from the shaft to give a 'sunray' appearance. As the tumour grows in size, the periosteum is elevated so that above and below the tumour reactive new bone may be deposited subperiosteally. Radiologically, this bone appears as a triangle of new bone (*Codman's triangle*, fig. 271).

Metastasis occurs via the blood-stream to produce pulmonary secondary deposits. Locally, pathological fracture may take place. Finally, if the tumour is untreated, it fungates to produce an infected malignant ulcer sometimes overlying a painful pathological fracture.

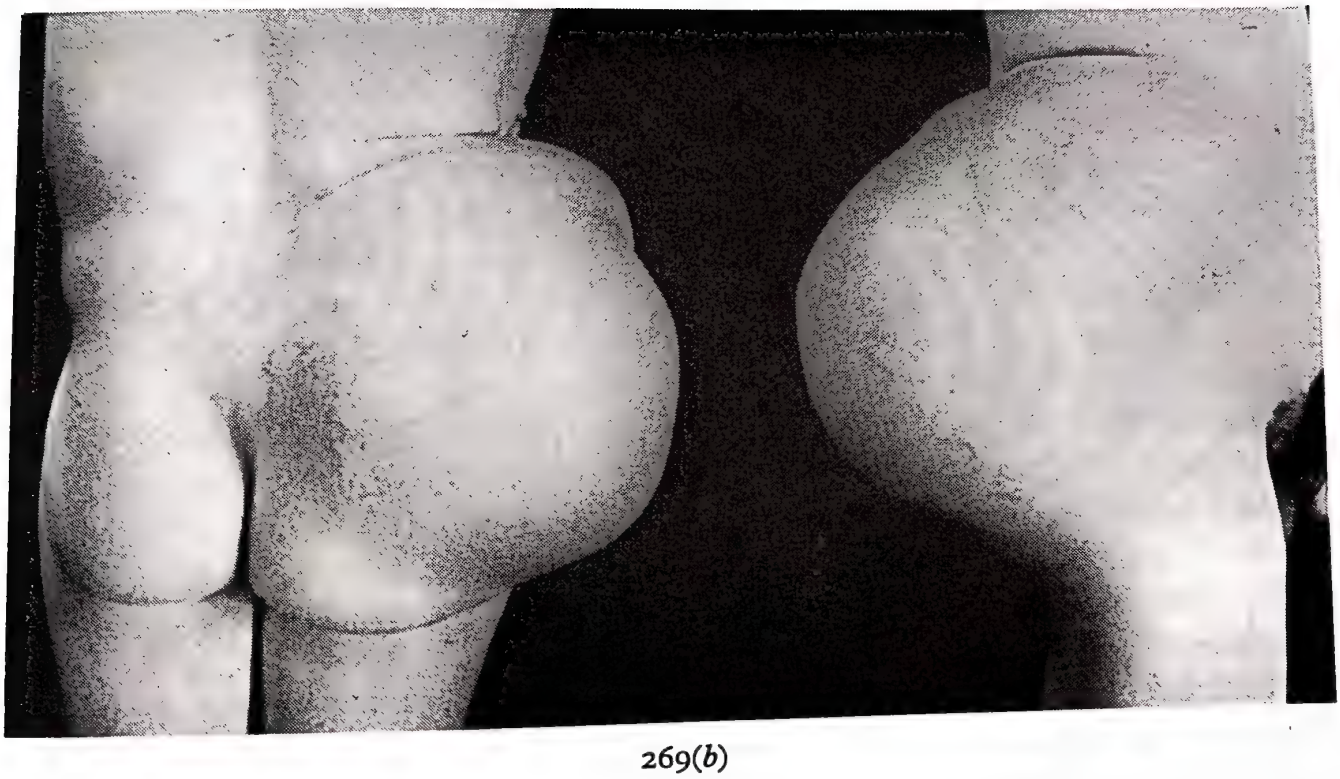
FIG. 268. — Osteosarcoma of the humerus. Note that the tumour is metaphyseal and eccentric and that the underlying cortex is eroded. The extraosseous mass seen here is much larger than that which might be expected from the mere trace of new bone which was present in the radiograph.

Louis Ollier, 1830–1900. Professor of Surgery, Lyon, France.
Sir James Paget, 1814–1899. Surgeon, St. Bartholomew's Hospital, London.
Ernest Amory Codman, 1869–1940. Surgeon, Massachusetts General Hospital, Boston, Massachusetts, U.S.A.

Chondrosarcoma.—This tumour arises usually in hitherto normal bone. It may however appear as a complication of any pre-existing cartilagenous tumour. It may arise in any bone, with a predilection for the flat bones and



269(*a*)



269(*b*)

FIG. 269.—(*a*) Chondrosarcoma of the ilium. (*b*) The clinical appearance of the buttock shown in (*a*).

ribs. Unlike osteosarcoma, it occurs mainly in middle aged persons, is very rare in children, and uncommon in teenagers.

Although malignant, the tumour may be slow-growing and mitoses so infrequent that malignancy may be impossible to decide on biopsy material. The tumour is locally invasive and, although often slow to metastasise, it may give rise to blood-borne pulmonary secondaries which are eventually fatal.

The matrix of the tumour is more or less cartilagenous. It may ossify in patches but more commonly calcifies.

The tumour invades and destroys bone, transgresses the periosteum and invades the adjacent soft tissues. In the spine, where it is rare, the tumour usually manifests itself whilst it is still small by causing collapse of a vertebra or by invading or compressing the cord or a nerve root. In the pelvis, on the other hand, the tumour may reach a considerable size before the patient notices a mass (fig. 269).

Fibrosarcoma.—These tumours are usually composed of spindle-shaped fibroblasts which produce a collagenous matrix but they may be pleomorphic. In bone, the tumour arises centrally or periosteally. (The tumour may, of course, also arise in any soft tissue.) They are of varying malignancy, produce blood-borne pulmonary secondaries, and are associated with a 5 year survival rate of about 30%.

Synovial Sarcoma.—This is histologically a bi-phasic tumour composed of elements simulating synovium mingled with malignant fibroblasts. It is extremely malignant, and may appear at any age.

The tumour usually arises close to a major joint (most often the knee, ankle or wrist), but it may arise, apparently primarily, in connective tissue, in muscle or subcutaneously. Metastasis appears to occur via the blood stream, the lymphatics and by the migration of cells through the tissue planes of the limb. Secondary involvement of regional lymph nodes is not unusual.

Giant Cell Tumour.—It is uncertain from what cell this tumour arises. It is composed of undifferentiated spindle cells and multinucleate giant cells in a vascular stroma. Microscopically it is indistinguishable from the so-called 'brown tumour' of hyperparathyroidism and this condition must be excluded by biochemical and radiological investigations (p. 289).

The tumour occurs most often in the third and fourth decades of life and tends to be more common in women. The epiphyseal regions of the long bones, especially around the knee, are the most common sites of origin but tumours of the humerus, radius and ulna occasionally occur.

The tumour is osteolytic and expands the bone with thinning, often perforation, of the cortex to cause a pathological fracture in some cases. The bone is destroyed irregularly so that the tumour is traversed by remnants of the original bone and comes to lie in a cavity with heavily trabeculated walls. As a consequence, it has a typical 'soap-bubble' radiological appearance (fig. 270). It rarely invades soft tissues but may do so when fracture occurs. Thus locally the tumour is only of low-grade malignancy. Metastasis is rare, but occurs via the blood stream to the lungs. Recurrence following local removal is common, and such recurrences are more likely to be frankly malignant than the original tumour.

Secondary Tumours in Bone.—Two thirds of all secondary malignant tumours in bone arise from carcinomas of the breast or prostate. One sixth arise from a variety of other primary neoplasms (especially those of the bronchus, kidney, and thyroid). In the remaining one sixth, no primary tumour is found at the time when the secondary presents. The majority of

tumours are osteolytic but a few, mostly arising from the prostate, stimulate new bone formation and are then called ' osteosclerotic '

Clinical and Radiological Features

Regardless of the pathology, these tumours present by causing pain, a noticeable lump or tender area, or a pathological fracture.

The diagnosis depends upon the clinical features of the tumour, its radiological appearance and its histology: the clinical features suggest a neoplasm; the radiological appearances indicate its size and whether it is benign or malignant; the diagnosis usually depends upon histological study of an adequate sample of tissue. Hæmatological investigations are unhelpful. An exact diagnosis can usually be made only by considering the clinical, radiological and histological features of the tumour in conjunction with each other, but even then, an exact diagnosis cannot be made in approximately 10% of tumours.

Clinically the important features are the mode of presentation (the more malignant the tumour the more likely is it to present with severe pain or pathological fracture rather than as a mass), the age of the patient, the fact that on physical examination the tumour is attached to bone, the location of the tumour, and the presence of any evidence of a primary neoplasm elsewhere. The clinical features of the more common bone tumours are set out in Table 2 (p. 248).

Radiologically two features suggest malignancy irrespective of the exact nature of the tumour. These are:

1. The presence of an ill-defined osteolytic lesion in the bone. Although the lesion is osteolytic, tumour new bone or calcification may occur within it or reactive new bone may occur around it.
2. Evidence that the tumour has breached the periosteum and invaded soft tissues.

The distinguishing radiological features of the commoner tumours are summarised in Table 2 and illustrated in Figs. 269–272.

Biopsy.—Histological material should always be obtained by biopsy before treatment is undertaken. If possible, open biopsy is undertaken: the naked-eye appearance of the tumour is noted and material is taken from the edge of the tumour together with adjoining normal tissue. The cell morphology of the tumour, the type of matrix formed, the presence of abnormal mitoses, and the invasion of adjacent tissues permit a diagnosis of malignancy and usually serve to identify the tumour. Needle biopsy may be employed for tumours of the spine but since this technique yields only a restricted sample of tissue it is not as reliable as open biopsy.

Treatment

Osteosarcoma.—There is no general agreement as to how this tumour should be treated but the most widely followed practice is that first advocated by Sir Stanford Cade. The tumour is irradiated with 9000 rads over 3 months, a dose which locally controls most tumours. Over the following 6 months pulmonary secondaries become manifest in most patients and from these they die without having had (what would have been) an unnecessary

Sir Stanford Cade, 1895–1973. Surgeon, Westminster Hospital, London.

TABLE 2. *Malignant Tumours of Bones and Joints: The principal clinical and radiological features of diagnostic significance*

	Osteosarcoma	*Chondrosarcoma*	*Fibrosarcoma*	*Synovial Sarcoma*	*Giant Cell Tumour*	*Secondary Neoplasm*
Common Mode of Presentation	Pain, swelling and/or pathological fracture	Mass	Mass or pathological fracture	Soft tissue mass	Pain, swelling ± fracture or joint symptoms	Pain and/or pathological fracture
Age of the Patient	2nd and 3rd decades, or the elderly in Paget's disease	3rd and 4th decades	Any age—mainly 25–60	Any age	3rd and 4th decades	Middle-aged and elderly
Location of the tumour	Ends of shafts of long bones especially femur, tibia, humerus. Any bone with Paget's disease	Ribs, ilium, scapula. Proximal ends of femur and humerus	Any bone. (May occur in Paget's Disease.)	Usually a joint	Epiphyseal region of long bones especially distal femur, proximal tibia and fibula	Any bone
Radiological Appearance	Area of bone destruction with ill-defined edges. Tumour transgresses the bone to produce a shadow in the soft tissues. Codman's Triangle. Sunray spicules. Pathological fracture. Secondaries in the lungs	Area of bone destruction with ill-defined edges. Tumour transgresses the bone to produce a shadow in the soft tissues. Large tumour (in the flat bones) with ossifying or calcifying matrix	Area of bone destruction	Soft tissue swelling ± spotty calcification.	Expands the bone. Sharp edge—unless frankly malignant. Soap-bubble appearance	Area of bone destruction with ill-defined edges. Occasionally marked sclerosis in adjacent bone.

and mutilating amputation. Those without secondaries at 6 months are then treated by amputation since in this group amputation offers a real chance of cure. Patients whose tumours are not locally controlled by radiotherapy

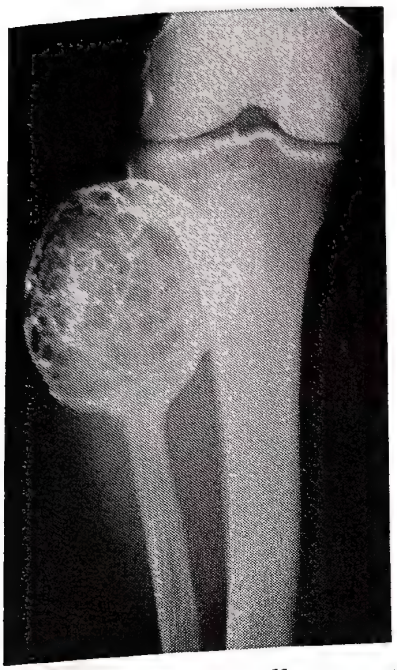


FIG. 270.—Giant cell tumour of fibula.

FIG. 271.—Osteosarcoma of the femur. Note Codman's triangle well seen in the proximal part of the tumour and 'sunray spicules'.

should be treated by earlier amputation to avert the suffering of death with a painful fungating malignant ulcer and a pathological fracture.

Amputation should be carried out at the site of election through the bone or joint immediately proximal to that involved in the tumour. Thus for example, osteosarcoma of the tibia should be treated by amputation through the femur, and at the proximal end of the femur disarticulation of the hip or hind-quarter amputation is required. Solitary pulmonary secondaries have been successfully treated by lobectomy.

FIG. 272.—Multiple osteolytic secondaries in the pelvis.

Chondrosarcoma.—In spite of the difficulty that this tumour nearly always arises in the proximal limb skeleton, treatment is by amputation. The tumour is nearly always large when first diagnosed, and when large is radioresistant. Hence radiotherapy has no part to play in its treatment.

Fibrosarcoma.—This tumour is treated by early amputation or, in the trunk, by wide block resection.

Synovial Sarcoma.—This tumour carries an extremely poor prognosis regardless of treatment: few or no survivors have been reported after 5 years. The tumour should be treated by a proximal amputation together with irradiation of the stump of the limb.

Giant Cell Tumours are treated where possible (for example in the proximal fibula or distal radius) by block resection of the tumour and adjacent bone. Unfortunately such a resection is often disabling since the tumour may be located, for example, in a tibial condyle, block resection of which would render the knee useless. An attempt should then be made to eradicate the tumour by curettage followed by packing the cavity with bone chips. Unfortunately, the incidence of recurrence following curettage is high. Recurrent tumours may be frankly malignant and require amputation.

Ewing's Tumour.—There is uncertainty about the pathology of this lesion. Some hold that it is a malignant endothelioma arising from the endothelial cells in the bone marrow, others that it represents a secondary deposit from a neuroblastoma. The tumour usually occurs in the middle of a long bone in childhood or early adolescence. Radiography shows a number of layers of sub-periosteal new bone formation expanding the shaft and giving the characteristical appearance of a cut onion. Clinically a painful hot swelling is noticed and the patient may show intermittent elevations of temperature. In this way the condition may be difficult to distinguish from acute haematogenous osteomyelitis. Treatment is by radiotherapy although the long-term prognosis is guarded and widespread dissemination usually occurs. Amputation may be considered after irradiation.

CHAPTER 15

CONGENITAL DISEASES OF BONES AND JOINTS

THE congenital diseases of bones and joints are of two kinds: developmental anomalies and dysplasias.

The developmental anomalies are characterised by the fact that the fundamental abnormality of growth occurs *in utero* and is static at birth: the evolution of the disease thereafter is due to secondary changes.

The dysplasias are characterised by abnormal growth both *in utero* and throughout the period of post-natal skeletal development. Many dysplasias are clinically detectable at birth and hence are certainly congenital; others remain undetected until later in life. It is assumed, almost certainly correctly, that in the latter a tendency to abnormal growth was present at birth and hence that they are also congenital.

Some congenital diseases are genetic in origin, some are thought to be due to disturbances in the intra-uterine environment. For the majority, the aetiology is unknown.

DEVELOPMENTAL ANOMALIES

Certain of these disorders are of the greatest orthopædic significance and will be dealt with at length. Others are of minor significance and will only be mentioned.

THE LOWER LIMB

Congenital Dislocation of the Hip (CDH)

Overall Incidence.—Before it was realised that instability of the hip could be diagnosed at birth (p. 252) CDH was diagnosed in 1 child in 1,000. The reported incidence of unstable hips (see below) is much higher, varying from 8 to 20 per 1,000 live births.

Pathology.—The hip may be either dislocated or dislocatable at birth. The precise details of the morbid anatomy at birth are not certain, but the essential practical fact is that the bones of the pelvis and femur are broadly within normal limits, but the ligaments of the hip are unduly lax so that the femoral head can be dislocated from the acetabulum. The infant may lie with the hip in the dislocated position, or the hip may be in the reduced position but be easily dislocatable. Over the first few months of life the ligaments of the hip shorten so that if the femur is maintained in the acetabulum during this period, the hip becomes stable and normal development results. On the other hand, if the femoral head is allowed to remain out of the acetabulum during this period, shortening of the ligaments makes reduction of the dislocation increasingly difficult. If the hip is allowed to remain

dislocated until the child crawls and then walks, the acetabulum and femur fail to develop normally. It is then difficult to return the hip to normal whatever treatment is instituted, and osteoarthrosis in the involved hip may develop early in adult life.

Ætiology.—The condition may be unilateral or bilateral, and is familial. Three factors appear to be important in its ætiology:

1. An hereditary predisposition to joint laxity: the patient's relatives may either have dislocated hips themselves or may have hypermobile joints so that they can perform 'party tricks' such as extending their wrists and fingers until the fingers lie parallel with their forearm or extending their thumb until the thumb touches the radius;

2. Female sex on the part of the infant: the condition is 3 to 5 times more common in girls. This may be due to the fact that maternal *relaxin* crosses the placental barrier to enter the fœtus. If the hormonal environment of the fœtus is also female, relaxin acts on the fœtus' joints in the same way as it does on those of the mother to produce joint laxity in the pelvis.

3. Breech malposition of the fœtus: for infants who are either delivered in the breech position or who spend a substantial part of the last 2 months *in utero* in this position the incidence of instability of the hip is about 10 times as great as for infants with a vertex presentation. It is possible that in the breech position the uterus presses on the fœtal legs in such a way that, if the hip ligaments are already lax, dislocation may occur.

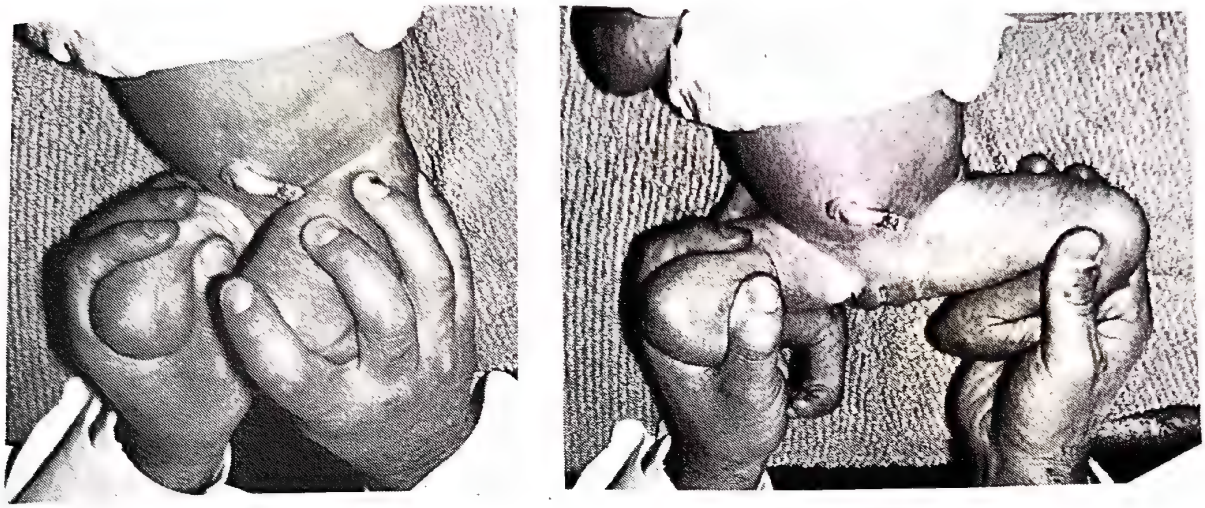
Clinical Features.—It is imperative that this condition be diagnosed in the first few days of life. This will only be done if the physician or midwife attending the delivery is aware of the existence of the condition and knows how to demonstrate its presence.

Diagnosis at Birth.—At birth the appearance of the infant is normal, and the hips can be put through a full range of movement. If the hip is dislocated, telescoping can in theory be demonstrated but in practice it is extremely difficult for the examiner to convince himself that this is occurring in a neonate. Thus conventional clinical examination of the hip reveals no abnormality. Radiologically, the epiphysis of the femoral head does not appear until the first year of life and the acetabulum is largely cartilaginous so that, even if the hip is dislocated (rather than dislocatable), there is no obvious radiological abnormality. Thus there is no way of detecting a dislocatable or dislocated hip at birth save by a specific examination designed to elicit instability. It is imperative that every doctor should be familiar with this physical sign:—

The Demonstration of Instability of the Hip at Birth.—The demonstration consists of eliciting a click from the hip, and is known as Barlow's or von Rosen's sign. The legs are held as shown in fig. 273. The hip is then flexed to 90° and adducted. Whilst adduction is taking place, gentle pressure is exerted by the examining hand in a proximal direction along the long axis of the femoral shaft. As the femoral head rolls over the posterior lip of the acetabulum it may, if dislocatable (but not if dislocated), slip out of the acetabulum. The sensation which the examining hand receives as the hip

Thomas Geoffrey Barlow, 1915–1975. Orthopædic Surgeon, Salford Royal Hospital, Salford, England.
Sophus von Rosen, Contemporary. Orthopædic Surgeon, Malmö General Hospital, Malmö, Sweden.

slips over the posterior lip of the acetabulum is difficult to describe but is composed of a mixture of the feeling of abnormal posterior movement plus a distinct ' clunk ' as the femoral head leaves the acetabulum. If the hip is dislocated by this manœuvre or if it is already dislocated prior to examination, the second half of the physical sign can now be elicited. The hip is kept 90° flexed and, starting from a position of full adduction, is gently abducted. Now



(*a*) (*b*)

FIG. 273.—Von Rosen's or Barlow's sign. (*a*) The hip in full adduction. (*b*) The hip in full abduction: note that the knee touches the couch.

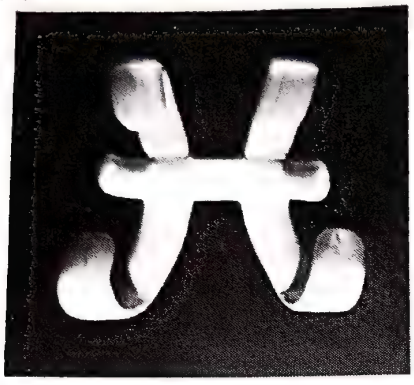
instead of exerting pressure proximally in the long axis of the femoral shaft, the examiner exerts pressure distally in the long axis of the shaft via his little finger placed proximal to the greater trochanter. The femoral head can now be felt to reduce with a soft ' clunk ' into the acetabulum somewhere during the course of movement from full adduction to full abduction. As abduction continues the femoral head remains in the acetabulum, demonstrating that the hip is stable in this position.

Occasionally a soft click can be felt in the hip which is noticeably different to the experienced examiner from the ' clunk ' of an unstable hip. The origin of these clicks is uncertain but they presumably come from soft tissue around the hip. Should the physician attending the delivery detect either a ' click ' or a ' clunk ' the patient should be referred immediately for an orthopædic opinion.

There are perhaps a few dislocated hips which cannot be reduced at birth. The diagnosis of dislocation in these hips at birth appears to be difficult or impossible.

The Treatment of CDH in the Newborn Infant.—The incidence figures quoted above show that in the absence of neonatal treatment only a minority of unstable hips at birth will develop into a persistent dislocation. All that is required to ensure that no unstable hip develops in this way is to place the femoral head in the acetabulum by the method described for the elicitation of von Rosen's sign (p. 252) and to keep it there until the hip is clinically stable and normal development is occurring radiologically.

Various splints have been devised to do this by keeping the hip in a position of 90° flexion and abduction (a position in which the femoral head is stable in the acetabulum) for a period of three months. All are satisfactory. One such splint is the von Rosen splint which is illustrated in fig. 274.



(*a*)

(*b*)

FIG. 274.—(*a*) The von Rosen splint made of padded malleable metal. (*b*) The splint applied.

The Diagnosis of CDH in a child of one year's age or more.—A discussion of the diagnosis and treatment of CDH in this age group used to fill a considerable part of textbooks of orthopædics, but it is very much to be hoped that no medical practitioner in the United Kingdom will ever in future have occasion to concern himself clinically with this problem. Unfortunately, because the method of making the diagnosis in the first week of life is not yet universally appreciated and implemented, it still happens that children present later in life with dislocated hips. This is a tragedy.

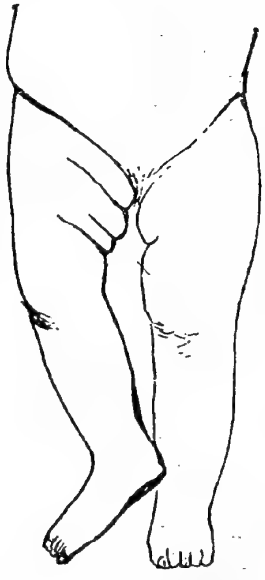


FIG. 275. — Asymmetrical skin creases in CDH.

FIG. 276.—Limited abduction of the left thigh in CDH.
(*J. C. R. Hindenach, F.R.C.S., London.*)

If one hip is dislocated, the skin creases in the groin and around the buttocks are asymmetrical (fig. 275). The affected hip has a full range of flexion, extension and rotation but cannot be fully abducted in 90° of flexion. In the infant, the normal hip will abduct until the knee nearly touches the examination couch. The dislocated hip will abduct only to about 45° (fig. 276). Telescoping may be demonstrated.

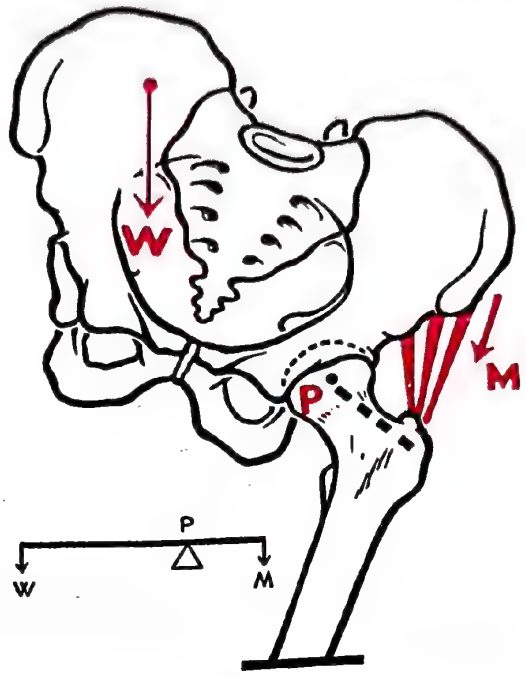

FIG. 277. — The physiological basis of Trendelenburg's sign. Contraction of the gluteus medius elevates the pelvis.

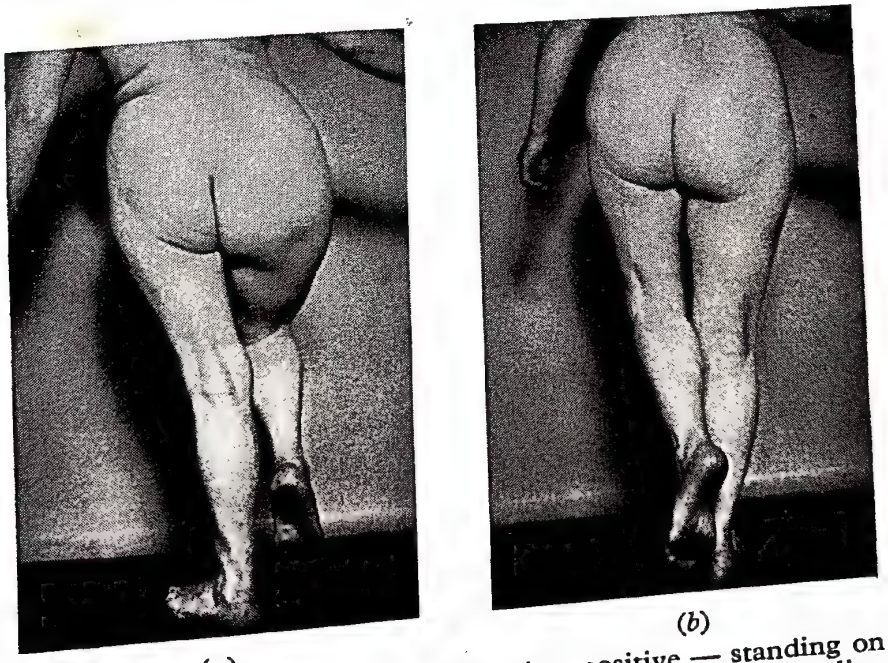
W = weight of body
M = muscle pull
P = pivot (the hip)

If the patient is old enough to stand, Trendelenburg's sign is positive.



(*a*) (*b*)

FIG. 278.—(*a*) Trendelenburg's sign positive — standing on the defective hip. (*b*) Trendelenburg's sign negative—standing on the sound hip.

Friedrich Trendelenburg, 1844–1924 (see footnote, p. 71). Described this sign in 1895.

This sign is elicited by asking the patient to stand on the affected leg and noting the position taken up by the pelvis. If the sign is negative (i.e. the hip is normal), the pelvis rises on the unsupported side (figs. 277 and 278 (*b*)). If the sign is positive, the pelvis drops on the unsupported side (fig. 278 (*a*)). A positive sign is produced by any pathology which interferes mechanically with the abductor mechanism of the hip, for example dislocation of the hip, fracture of the neck of the femur, or paralysis of the abductors. If

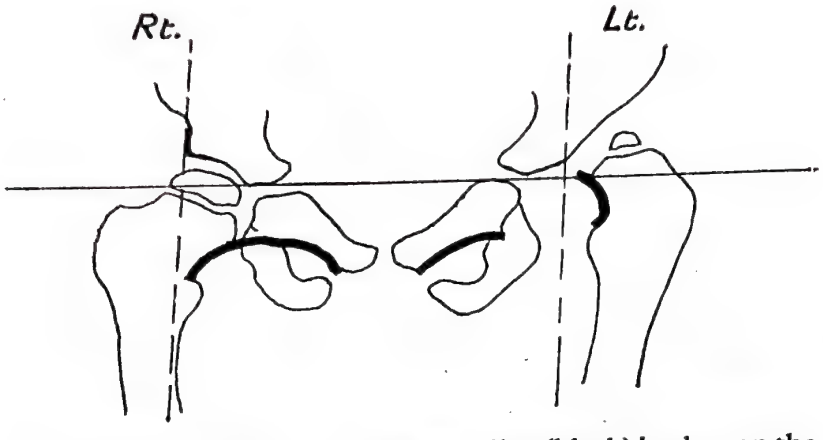


FIG. 279(*a*).—CDH (Lt). Shenton's line (black) broken on the left side. Note the small ossific nucleus on the dislocated side above the horizontal and lateral to the vertical line, and the shallow acetabulum with its undeveloped bony roof.

FIG. 279 (*b*).—Bilateral CDH in a six-year-old girl.

Trendelenburg's sign is positive, the patient has a typical gait lurching downwards towards the unsupported side during the stance phase on the affected leg.

If both hips are dislocated, asymmetry of the groin creases is absent and the symmetry of the 'waddling' gait (there being a Trendelenburg limp on both sides) often misleadingly makes it appear normal. Accordingly bilateral dislocation of the hips in infancy can be missed more easily than can unilateral dislocation.

Edward Warren Hine Shenton, 1872–1955. Surgical Radiographer, Guy's Hospital, London.

X-ray Examination.—In contrast to the situation in neonates, the hip is radiologically abnormal (fig. 279). The significant features are:—

1. Lateral and upward displacement of the epiphysis of the femoral head. This displacement can be demonstrated by drawing 2 lines, one horizontally through the tri-radiate cartilage and one vertically through the superior lip of the bony acetabulum: in CDH the femoral epiphysis lies above the first line and lateral to the second.

2. A break in Shenton's line. Shenton's line is a fortuitous radiological appearance consisting of the continuous curve produced by the inferior margin of the superior pubic ramus and the medial cortex of the femoral neck and shaft. If the hip is dislocated, this line will be broken by a step—because the femur moves upwards.

3. The capital femoral epiphysis is late to develop and when it does so is smaller than that on the unaffected side.

4. The superior lip of the bony acetabulum is also slow to develop so that it appears radiologically that the acetabulum is unduly shallow. If the hip continues to be dislocated throughout childhood, the final bony acetabulum is truly shallow. In infancy, however, the true acetabulum is often not particularly shallow since the cartilagenous development of the superior lip is not grossly abnormal.

Treatment between the ages of 6 months and 7 years (for unilateral dislocation) or 4 years (for bilateral dislocation).—Weight-bearing at the infant hip begins when the infant crawls at about 6 months. From this age until about 7 years for unilateral dislocation, and until about 4 years for bilateral dislocation, it is possible to reduce the hip and finally obtain fair function. Above these age limits, reduction is difficult and it is probably unwise to attempt it for reasons set out below; see Treatment in the Older Child (p. 258).

Treatment aims to replace the femoral head in the acetabulum and to keep it there whilst normal development occurs. Reduction is impeded by the facts that (1) the soft tissues have by this time developed in such a way as to conform with the abnormal position of the femur, and (2) the acetabulum has become filled with a mass of fibro-fatty tissue. Maintenance of reduction is difficult because: (1) the acetabulum is abnormally shallow and vertical, (2) the femoral head is smaller than normal, and (3) the femoral neck is usually retroverted on the shaft.

Closed 'Manipulation'.—It is sometimes possible under general anæsthesia to replace the femoral head in the acetabulum without any force being exerted on the leg. Should force be required the manœuvre is unwise, since it is likely to result in damage to the blood supply of the femoral head. If closed reduction under anæsthesia is thought likely to fail, it should be preceded by a period of traction in progressively increasing abduction, and for this a variety of special splints have been devised. The femoral head may reduce spontaneously during a period of traction, or it may be reduced under anæsthesia after a period of traction. Open adductor, and sometimes psoas, tenotomy is often needed to allow the hip to be fully abducted without forcibly compressing the femoral head.

Open Reduction is indicated if closed reduction fails. It may be difficult to determine if the femoral head has been truly replaced in the acetabulum by closed manipulation, or whether on the other hand it has been brought opposite the acetabulum, but held out from a full reduction by fibro-fatty tissue in the acetabulum or by the presence of a fold of capsule and acetabular labrum (the limbus) intruding between the femoral head and the superior

part of the acetabulum. The presence of such an impediment to reduction may be suspected if the femoral head persistently 'stands off' radiologically after an apparently satisfactory reduction, and may be confirmed by arthrography. The presence of a limbus, or clear-cut inability to reduce the dislocation by conservative means, are indications for open reduction. The hip is exposed and the soft tissues obstructing reduction are excised or released, so that the head can be repositioned in the acetabulum.

FIG. 280.—Plaster-of-Paris spica for the maintenance of the reduction of a bilateral CDH in neutral rotation and 90° abduction.

Maintenance of Reduction.—If the hip has been replaced either by closed or open means it must be maintained in the acetabulum for a period of months by some form of *splintage*. This may be done initially by traction on an appropriate splint or by a double hip spica applied with the hips held in the position of maximum stability. Not all hips are best immobilised in the same position, but stability is usually obtained in a position of abduction and flexion with some degree of external or internal rotation (fig. 280). Extreme internal or external rotation should be avoided since this tends to 'wring out' the vessels in the capsule of the hip and may interfere with the blood supply to the femoral head so that changes similar to those seen in Perthes' disease (p. 278) develop. After 3 to 6 months a hip spica may be exchanged for a Denis Browne splint if the child is under 2 years of age.

If reduction has been deferred until the bones of the hip have developed abnormally, *surgical reconstruction* of the hip may be required in addition to open reduction. The available procedures consist of:

1. *Pelvic Osteotomy* (Salter) which aims to rotate the acetabulum into a more horizontal position to cover the femoral head.

2. A *Shelf Operation* in which the superior lip of the acetabulum is reconstructed (so that it covers the femoral head) by a bone graft or by medial displacement of the acetabulum relative to the ilium after a pelvic osteotomy just above the hip.

3. *Intertrochanteric Rotation Osteotomy of the Femur* in which the proximal fragment is rotated, bringing the femoral head squarely into the acetabulum.

Treatment in the Older Child.—Putti suggested that the results of treatment in bilateral dislocations of the hip over the age of 4 years and in unilateral dislocations over the age of 7 years are worse than the results of the disease itself and thus that no treatment is indicated for these children in childhood. A lower age limit applies to bilateral dislocation because: (1) the limp is less noticeable; (2) as a consequence these patients, although they have a slightly abnormal posture and an abnormal gait, tend to live normal lives until their 40's or 50's when secondary osteoarthrosis may develop; (3) there is a danger that treatment may be more successful in one hip

Sir Denis John Wolko Browne, 1892–1967. Surgeon, Hospital for Sick Children, Great Ormond Street, London.
Robert B. Salter, Contemporary. Professor of Orthopædic Surgery, University of Toronto, Ontario, Canada.
Vittorio Putti, 1880–1940. Professor of Orthopædic Surgery, University of Bologna, Italy.

than in the other so that a bilateral dislocation is converted into a unilateral dislocation and (4) treatment may stiffen the hip, a tolerable outcome in one hip but a significant disability if it affects both.

Club Foot

Nomenclature.—' Club Foot ' is a loose term used to describe a number of different abnormalities in the shape of the foot. If the foot is fixed in a position of plantar-flexion so that it cannot be fully dorsiflexed, the deformity is described as one of ' equinus '. The opposite deformity is described as ' calcaneus '. If the foot is inverted and adducted at the mid-tarsal joint so that it cannot be fully everted the deformity is described as ' varus'. The opposite deformity is described as ' valgus '. Almost invariably two or more of the deformities are combined and by far the most common congenital combination is ' equino-varus '. The Latin synonym for club foot is ' talipes ' and the descriptive nomenclature for a club foot combines this term with the Latin description of the deformity. Thus the most common variety of congenital club foot is known as ' Talipes Equino-Varus ' (fig. 281).

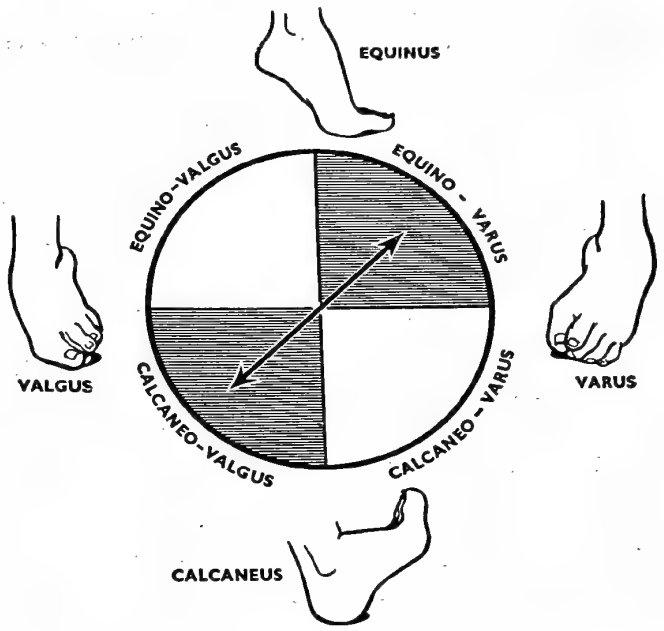

FIG. 281.—Nomenclature of talipes. Shaded quadrants indicate the common varieties.

Ætiology.—In the great majority of patients with congenital club feet the ætiology is unknown, and this group should properly be called idiopathic congenital club foot. But because this variety represents the majority of club feet, it is usually referred to simply as ' congenital club foot '.

It has been suggested that raised intra-uterine pressure forces the lower limbs of the fœtus against the wall of the uterus so as to mould the feet into the position of deformity. The presence of lesions in the skin over the convex aspect of the foot in talipes equino-varus which very much resemble healed pressure sores, lends support to this belief. It has alternatively been suggested that the primary disturbance is in the muscles of the calf or the soft tissues of the foot where some form of contracture, possibly ischæmic in nature, has been visualised as drawing the foot into a position of deformity. Neither of these postulated ætiological mechanisms have received widespread support and the most commonly held view is that the primary disturbance is a developmental defect of the soft tissues of the legs affecting particularly the ligaments on the concave side of the curve, or possibly, in the case of talipes equino-varus, the development of the neck of the talus.

Congenital club foot may be paralytic and secondary to myelodysplasia (Chap. 19). The deformities in arthrogryposis multiplex congenita may also include club feet. The club foot in this disease is gross, and nearly always associated with other deformities, in particular with clubbing of the hand (p. 264).

Morbid Anatomy.—Surprising as it may seem, there are relatively few accurate descriptions of the morbid anatomy of untreated club foot at or before birth and therefore the nature of the original morbid anatomy is un-

certain. Within a few months of birth the morbid anatomical features are as follows:—

1. Adduction and external rotation of the bones of the forefoot. The adduction occurs at the mid-tarsal and tarso-metatarsal joints, but also to some extent affects the bones themselves which are curved so as to be concave medially. The adduction may be so gross as to result in medial dislocation of the navicular from the talo-navicular joint. The external rotation is produced by torsion of the shafts of the metatarsals.

2. Inversion of the os calcis and of the navicular on the talus. The inverted os calcis and navicular carry the rest of the foot into inversion with them.

3. Plantar-flexion of all the bones of the foot including the talus. The talus, although plantar-flexed, is not as plantar-flexed as the other bones so that the head of the talus tends progressively to dislocate from the mid-tarsal joint in a dorsal as well as a lateral direction.

4. There is possibly an early abnormality in the neck of the talus which, it has been suggested, is angulated so that the head of the talus is displaced downwards and medially. Secondary changes occur in the head of the talus.

5. The os calcis may be small. As a consequence the heel is small.

6. All the ligamentous structures on the medial side of the foot and to some extent in the sole are shortened, but are histologically normal.

7. The muscles of the calf are hypoplastic, but histologically normal. As a result, the flexors of the foot and toes and the invertors of the foot are short. As growth takes place, hypoplasia commonly persists in spite of effective treatment for the deformity, so that finally the whole of the foot and calf are smaller than normal.

8. The skin shows adaptive shortening on the concave side of the curve, a fact which may present difficulties in skin closure following surgical treatment. On the convex side of the curve dimples are often present which may in extreme cases resemble scars, especially over the lateral malleolus.

The extent of these deformities is variable. In the mildest cases the deformity consists only of adduction and some rotation of the forefoot. In extreme cases the foot is so deformed that the sole rests on the medial side of the tibia (figs 282(*a*) and (*b*)).

(*a*) (*b*)

FIG. 282.—(*a*) Mild talipes equino-varus. (*b*) Severe talipes equino-varus.

Clinical Features.—The condition should be diagnosed at birth. If the deformity is severe the diagnosis is obvious, but mild deformities may be difficult to distinguish from the normal because the new-born infant tends to posture the foot in a position of equino-varus. The normal new-born foot has a greater range of dorsiflexion and eversion than the normal adult foot: it can be dorsiflexed until the dorsum touches the anterior aspect of the shin. If this is impossible, a minor degree of talipes equino-varus exists. Thus part of the examination of a new-born infant should include putting the foot through a full range of movement. If a club foot is detected, the spine and all other joints should always be examined carefully to exclude myelodysplasia and arthrogryphosis. Since the bones of the foot are at this stage largely cartilagenous, radiography is useless.

FIG. 283. — Untreated talipes equino-varus in an adult.

It must be appreciated that in the world as a whole most deliveries are not supervised by a physician and that therefore a club foot may not present until infancy or later life. By this time the deformity which was present at birth has become fixed and callosities will have developed on the skin of the foot where it bears weight. By adult life (fig. 283) secondary degenerative changes develop in the deformed joints.

FIG. 284.—The technique of manipulation of the foot (in this case the (left in the treatment of talipes equinovarus. Note the range of dorsiflexion at this normal infant's foot. The physician's left thumb everts the heel while his right thumb dorsiflexes and everts the foot by pressing on the base of the fifth metatarsal.

Treatment

Conservative Treatment.—If the deformity is slight, so that the foot can be dorsiflexed to a little beyond the plantigrade position, the mother should be taught to manipulate her child's foot after every feed. The foot is dorsiflexed and everted as shown in fig. 284. Sufficient pressure should be exerted by the mother to blanch her own fingers and this pressure should be maintained for about 2 seconds. The pressure should be released and re-applied over a period of about 5 minutes. Minor deformity can usually be corrected on this regime but the infant should be examined at monthly intervals to ensure that the deformity does in fact steadily diminish.

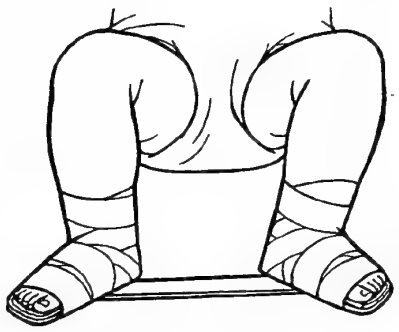
If initially the foot cannot easily be brought beyond the plantigrade position, the maximum correction obtained by manipulation must be main-

tained and gradually increased by serial splintage. The neonatal foot is too small to be treated satisfactorily in plaster-of-Paris but correction can usually be maintained by strapping. The foot may be taped to a padded aluminium splint using zinc oxide plaster by the method shown in fig. 285. The splint is removed and reapplied with a little more correction every week. By this method gradual correction of the deformity may be achieved so that, if all goes well, by 3 months the deformity can easily be corrected to beyond the plantigrade position. Splintage is then discontinued and maternal manipulation substituted. If by the age of 1 to 2 months the position of the foot is not satisfactory, plaster-of-Paris is substituted for the aluminium splint: a padded above-knee cast is applied with the knee at 90° of flexion so that the femur can be used to gain a purchase against which to abduct the foot. The cast is applied with the foot in the position of deformity and the foot is manipulated gently into a position of maximum correction as the plaster dries. The plaster is changed at 3 weekly intervals (a procedure which in an infant may involve sedation) until a satisfactory correction has been achieved.

FIG. 285.—Splintage of the foot in the treatment of mild talipes equino-varus.

On this regime most club feet should have been corrected by the age of about 3 months. If they have been, splintage can be discontinued and maternal manipulation substituted.

Denis Browne splints (fig. 286) may be used throughout the day instead of maternal manipulation until the child walks and thereafter they may be used at night.



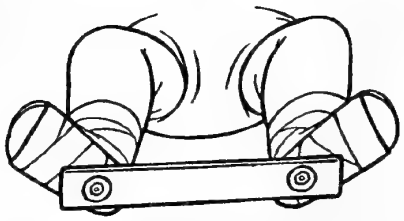


FIG. 286.—Denis Browne splint.

Treatment by Operation

A minority of club feet cannot be satisfactorily corrected by manipulation and splintage by the age of 6 weeks. In this event, the soft tissues on the medial side of the foot should be released surgically, the posterior capsule of the ankle divided, and the Achilles tendon elongated sufficiently to render the foot plantigrade.

The Operation of Medial Release and Elongation of the Achilles Tendon for Talipes Equino-Varus.—Through a curved incision posterior and distal to the medial malleolus the ligaments on the medial side of the ankle, talo-navicular and navicular-cuneiform joints are divided. The tendons of tibialis anterior, tibialis posterior, flexor hallucis longus and flexor digitorum longus are divided and elongated by Z-plasty. Division of these structures should allow the forefoot to be abducted and the foot to be everted. When this is done gaps open at the ankle, talo-navicular and navicular-cuneiform joints. Post-operatively, the cartil-

Achilles (*see footnote p. 316*).

age covering these bones proliferates rapidly so as to fill the gaps. The Achilles tendon is then elongated by Z-plasty. This may be sufficient to produce the required slight over-correction of the equinus deformity, but if it is not, the posterior capsule of the ankle joint is divided. During this operation the neurovascular bundle posterior and distal to the medial malleolus is carefully safeguarded. Closure of the skin may be difficult in the corrected position. Post-operatively the foot is splinted in a position of slight over-correction using an above-knee plaster as described above.

Treatment of 'Relapsed' Club Foot.—No matter what regime is employed for the initial treatment of club foot, there is a tendency for the condition to relapse over the early years of life and therefore children whose feet have been satisfactorily treated in infancy should be supervised until they are adult. If relapse occurs in a child less than 4 years of age, a soft tissue release as described above is usually sufficient, but in children over the age of 6 this procedure is insufficient. Children presenting with unsatisfactory feet at this age require not only medial release but also resection of bone from the lateral side of the foot. The foot may be likened for this purpose to a horse with two reins: the operation aims to pay out the medial rein (by medial release) and to pull in the lateral rein so as to turn the forefoot in a lateral direction. The lateral rein is shortened by resecting the articular surfaces of the calcaneo-cuboid joint and stapling the calcaneum to the cuboid so as to achieve calcaneo-cuboid fusion. Once calcaneo-cuboid fusion has been obtained, growth of the lateral side of the foot is slowed so that the tendency to relapse is diminished.

In adolescent children presenting with an unsatisfactory club foot, the foot may be corrected by the resection of laterally based wedges (followed by fusion of the exposed bony surfaces) from the mid-foot (to correct forefoot adduction) and the os calcis (to correct inversion of the heel).

If the condition presents in adult life, subtalar (triple) fusion with an appropriate resection of bone so as to bring the sole into a plantigrade position is the treatment of choice. Astragalectomy is the alternative if the deformity is severe.

Phocomelia of the Lower Limb may occur as in the upper limb (p. 264), and may be of varying extent up to total absence of the limb.

Absence of the Proximal Femur is rare. Radiologically the proximal third of the bone always appears to be absent, but the condition varies in severity since in some patients a cartilagenous femoral head is present although not radiologically visible. Treatment is difficult and the limb tends to become grossly short.

Absence of the Fibula is associated with forward bowing of the tibia, an equino-valgus deformity of the foot and absence of the 5th toe. The condition has some similarity to absence of the radius and its associated deformities. In both these conditions the fibrous tissue replacing the absent bone appears to grow more slowly than adjacent normal tissue so as to draw the limb into a curve concave on the side of the absent bone.

Absence of the Tibia is exceedingly rare and is inevitably followed by amputation.

Congenital Pseudarthrosis of the Tibia is probably a developmental abnormality although some are associated with neurofibromatosis and the possibility cannot be excluded that it is due to an ununited intrauterine fracture. Clinically the condition presents with marked forward angulation of the tibia at birth. Radiologically, a bony discontinuity can be seen at the junction of the middle and lower thirds of the bone and the adjacent bone is sclerotic and thinned. Treatment is by McFarland's operation in which the angulation is ignored, and a bone graft is placed posterior to the tibia extending from normal bone above to normal bone below the site of the pseudarthrosis.

Bryan Leslie McFarland, 1900–1963. Professor of Orthopædic Surgery, University of Liverpool, England.

Congenital Vertical Talus is a rare condition producing a congenitally flat foot. The long axis of the talus is vertically disposed so that the head of the bone is dislocated ventrally from the talo-navicular joint. The os calcis is in a position of equinus. As a consequence of these deformities the sole of the foot is convex downwards and the foot is rigidly flat. (fig. 287.) The condition must be distinguished from the normal flat foot of infancy in which, although the foot has no medial arch, the sole is flat rather than convex downwards and the foot is mobile. Treatment is difficult and consists of surgical re-position of the talus.

FIG. 287.—Bilateral untreated congenital vertical talus.

Abnormalities in the Toes correspond to those which may occur in the fingers (see below). In addition one toe, commonly the fifth, may override its neighbour. This is a familial condition which gives rise to no disability and which does not respond to simple conservative measures in infancy. No treatment should be given in infancy but the toe may require either correction or amputation in adult life.

THE UPPER LIMB

Phocomelia[1] is a condition in which the limb may totally or partially fail to develop. Although the condition occurs spontaneously attention has been drawn to it recently by the discovery that certain drugs, for example thalidomide, may interfere with the development of the foetus *in utero* to produce phocomelia. Such drugs are known as teratogens.

Treatment.—Under no circumstances should any portion of a phocomelic limb, for example a remnant of a finger attached directly to the trunk at the shoulder, be removed even though it is apparently useless, since such vestiges may enable the child to activate a powered prosthesis if they are capable of the slightest movement.

Minor degrees of phocomelia are represented by the *absence of one or more fingers*. The least rare anomaly of this kind is 'the lobster hand' which has a thumb and only one finger. Function is surprisingly good in hands of this kind and no treatment is indicated.

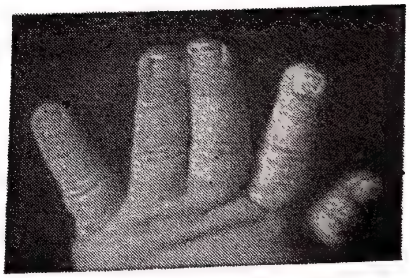

FIG. 288.—Syndactyly.

Syndactyly or Webbed Fingers may be primary, secondary or acquired (fig. 288). Primary syndactyly is often familial and in this condition not only does the skin bridge the two fingers but the bones of the fingers are fused as well. No treatment is successful. Secondary syndactyly is possibly due to amniotic adhesions and in this condition only the skin bridges the fingers. They can be separated by plastic surgical procedures (fig. 289). Acquired syndactyly may follow burns and can also be treated by plastic surgery.

Absence of the Radius is a rare anomaly as a consequence of which there is gross radial deviation of the carpus and hand ('club hand'). The thumb is often absent as well. Treatment consists of splintage to hold the deformity, but this is commonly unsuccessful. Fusion of the carpus to the ulna with an extensive release on the lateral side of the wrist may be required.

[1] Phoco (L) = a seal. i.e. Like a seal's flipper.

Radio-Ulnar Synostosis is an uncommon condition in which the radius and ulna are fused, usually in the proximal 2.5 cm of the bone. Pronation and supination are impossible. No treatment is advised.

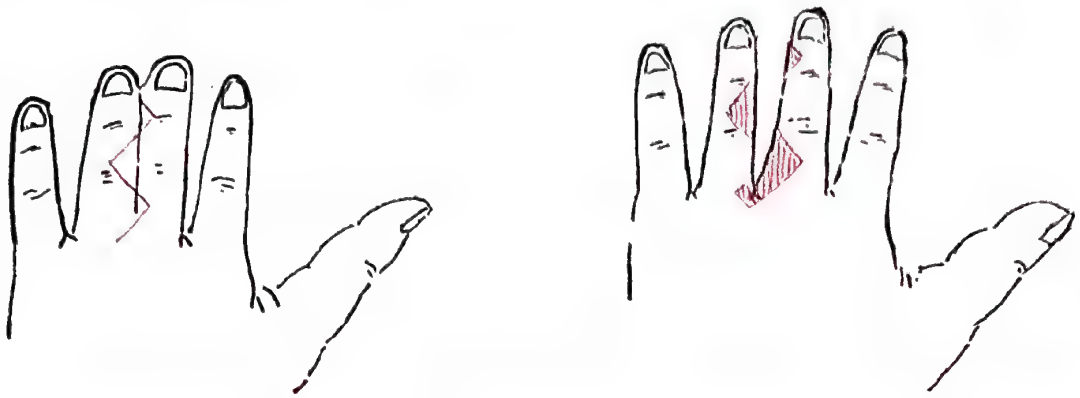

FIG. 289.—Syndactyly. The fingers are divided by means of a modified 'Z' plasty. There is insufficient skin to bridge the gap totally; the defect is therefore covered with a split thickness graft to both fingers. (Simple division with 'Z' plasty will nearly always result in scar contracture across each interphalangeal joint.)

Sprengel's Shoulder is a condition in which the whole shoulder girdle, including particularly the scapula, is higher on the affected side than on the opposite side. No treatment is available.

Webbing of the Neck occurs as part of the Klippel-Feil syndrome.

Congenital Pseudarthrosis of the clavicle is a condition similar to congenital pseudarthrosis of the tibia (p. 263). It is confined to females and only the right clavicle is affected.

Cervical rib is dealt with in Chapter 32.

THE SPINE

Fusion of cervical vertebræ occasionally occurs but is not noticeable clinically unless it is part of a more complex deformity such as the Klippel-Feil syndrome.

Hemivertebræ, especially in the dorsal region, may cause scoliosis (p. 271).

Myelodysplasia may occur in the sacral or more proximal spine.

Spondylolysis at L5 and L4 may possibly be congenital in origin although it is now widely regarded as being a fatigue fracture. The condition may progress to Spondylolisthesis (p. 473).

Sacralisation of the 5th Lumbar Vertebra, Lumbarisation of the 1st Sacral Vertebra and False Joints between the Transverse Processes of L5 and the Sacrum or Ilium are common congenital abnormalities. They may be revealed as a chance X-ray finding, sometimes in patients complaining of back pain. It is uncertain whether or not they themselves are actually responsible for back pain.

BONE DYSPLASIA

These diseases are sometimes referred to as Dysplasias, sometimes as Dystrophies. The term 'dystrophy' strictly implies that the condition is due to faulty nutrition, the term 'dysplasia', to faulty development. Since there is no evidence that any of these diseases have a nutritional basis, the term dysplasia is to be preferred. In some diseases the dysplasia appears to be

Otto Gerhard Karl Sprengel, 1852–1915. Surgeon, Grossherzogliches Krankenhaus (Grand Ducal Hospital), Brunswick, Germany. Described congenital high scapula in 1891.

Maurice Klippel, 1858–1942 and André Feil, 1884– , both of whom were neurologists in Paris. Described this disease in a joint paper in 1912.

genetic in origin but in many the cause is unknown. They may affect the skeleton generally, or may be localised to certain areas.

There are many dysplasias of bone and there is a regrettable tendency to expect the student to remember the names of all of them: very little useful purpose is served by doing so. Many have been given exotic names constructed from a random mixture of Latin and Greek, and in addition have been eponymously named: in this chapter wherever possible a simple English name is used. The majority are rare and only two or three are of orthopædic significance; the rest produce bizarre X-ray appearances, or deformities for which no treatment is available.

Diseases of Orthopædic Significance.

Brittle Bones (Osteogenesis Imperfecta).—This is a disorder in which the bones are unduly fragile (and the sclerotics of the eyes are blue). As a consequence multiple fractures occur following trivial injuries which, because of their multiplicity, result in progressive deformity. The severity of the disease varies; some patients have only one or two fractures, others have many Children prone to a great many fractures may die before reaching adult life but if the child survives, the tendency for the bones to break seems to diminish and even to disappear when skeletal growth ceases.

Radiologically the long bones are often osteoporotic, bent and slender; the bone ends may appear large and sometimes cystic. The blood chemistry is normal. The bones are histologically normal and fractures unite uneventfully.

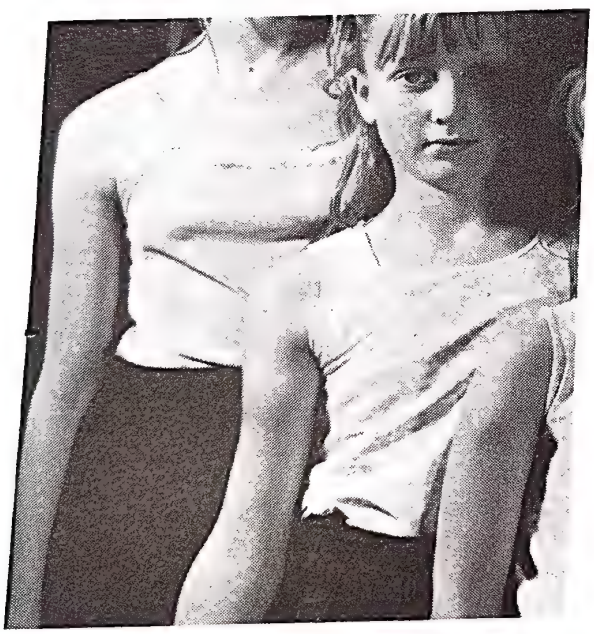

FIG. 290.—Exostoses of the humerus in three sisters.

Treatment.—Individual fractures should be treated on their merits. Should a long bone become unduly deformed it may be cut into several segments and each segment threaded on to an intramedullary nail to correct the deformity.

Multiple Exostoses (Diaphyseal Aclasis) (see also Osteochondroma p. 241).—This is a familial disorder more common in males (but see fig. 290). It appears to be due to a failure of bone remodelling at the metaphysis and perhaps to a failure of the control of circumferential growth at the epiphyseal plate. A variable number of exostoses develop in the metaphyseal region of the long bones. The exostoses usually stop growing at the completion of skeletal growth. They may occasion deformity and interfere with the movement of local soft tissues. Patients are otherwise unaffected by the disease, although they are often a little shorter than normal.

Five per cent of patients develop malignant changes in an exostosis. It is unfortunately impracticable to remove all a patient's exostoses in order to prevent this, but should an exostosis become painful, or should it continue to grow after the completion of skeletal growth, it should be removed *en bloc* and sent for histology.

Multiple Chondromatosis (Dyschondroplasia, Ollier's Disease) (see also Chondroma, p. 242).—This disease is rare and is not familial. Ossification of the cartilage at the epiphyseal plate is faulty and islands of cartilage remain unossified within the shaft and continue to grow. The disease tends to be unilateral and the affected limb is short. Involvement of the hand is common (fig. 266). The involved bones are often expanded by the tumour to produce deformity especially in the fingers. Radiologically the bone can be seen to be expanded by a lytic lesion in which areas of calcification may occur. Pathological fractures occur through the tumours. Malignant change develops in approximately 1% of chondromas.

Marble Bones (Osteopetrosis, Albers-Schönberg Disease).—This is a rare familial disease in which the bones appear excessively dense and structureless on X-ray because the medullary canal is for practical purposes absent. The spine is also affected. The bone is hard but at the same time brittle, and accordingly pathological fractures are not uncommon. Management of the fractures may be difficult since internal fixation is almost impossible.

Diseases of Little Orthopædic Significance

These diseases produce abnormal radiological appearances and often deformity. They do not however call for orthopædic treatment.

Achondroplasia.—This is a familial disease in which the growth of the long bones and of the antero-posterior axis of the skull are defective. Accordingly the patient is dwarfed and has a typical facial appearance. The trunk is less obviously shortened than are the limbs (fig. 291).

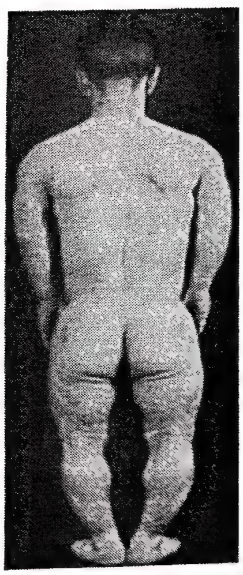

FIG. 291.—Achondroplasia.

Chondro-Osteodystrophy (Morquio-Brailsford's Disease).—This is a rare disease produced by a recessive gene so that consanguinity is important in its ætiology. The disease gives rise to dwarfism. The vertebral bodies may show typical 'tonguing' in the X-ray and the pelvis may be tri-radiate.

Gargoylism (Hurler's Disease).—In this condition a skeletal disorder is combined with a disturbance of lipid metabolism. Dwarfism and a typical facial appearance develop.

Epiphyseal Dysplasias.—There are several forms of epiphyseal dyplasia. Dyplasia epiphysialis multiplex is the least rare and affects all the epiphyses so that the patient is stunted because the limbs are short. The face and skull appear normal. The epiphyses look ill-formed, irregular and mottled radiologically. Dyplasia epiphysialis punctata is a variant of multiplex in which the mottling is more pronounced, but the shape of the epiphysis is more normal. Dyplasia epiphysialis hemimelica is a variant in which only the medial or lateral half of the knee epiphyses, the ankle epiphyses and the talus of one leg are affected.

Tibia Vara (Blount's Disease).—This is probably a mild version of dysplasia epiphysialis hemimelica in which only the proximal tibial epiphyses are involved. The disorder is particularly common in the West Indies and may be treated by early tibial osteotomy.

Cleido-Cranial Dysostosis (Anosteoplasia) (fig. 292).—In this condition there is faulty development of membrane bones, particularly of the clavicle and the skull. The clavicles are almost completely absent so that the patient can bring his shoulders together in front of the chest.

Louis Xavier Édouard Léopold Ollier, 1830–1900. Professor of Surgery, Lyons, France. Described dyschondroplasia in 1899.
Heinrich Ernst Albers-Schönberg, 1865–1921. Professor of Roentgenology, Hamburg, Germany. Described osteopetrosis in 1904.
Luis Morquio, 1867–1935. Professor of Medicine, Montevideo, Uruguay.
James Frederick Brailsford, 1888–1961. Radiologist, Queen Elizabeth Hospital, Birmingham, England.
Morquio and Brailsford reported this condition independently in 1929.
Gertrud Hurler. Pædiatrician, Munich, Germany. Described this disease in 1919.
Walter Putman Blount, Contemporary. Professor of Orthopædic Surgery, Marquette University, Milwaukee, Wisconsin, U.S.A. Described this condition in 1937.

Nail-Patella Syndrome (Osteo-Onychodysplasia).—This is a curious familial disorder in which the nails are hypoplastic or absent and the patellæ small. The radial head may sublux laterally and bony excrescencies may develop on the lateral aspect of the ilium.

FIG. 292.—Cleido-cranial-dysostosis.

Progressive Diaphyseal Dysplasia (Engelmann's Disease), *Spider Finger* (Arachnodactyly, Marfan's Syndrome), *Acrocephalo-syndactyly* (Apert's Syndrome), *Candle Bones* (Melorheostosis, Leri's Disease), *Striped Bones* (Osteopathia Striata), and *Spotted Bones* (Osteopoikilosis) all produce abnormal radiological appearances of the bones and in some cases deformity.

MUSCLE DYSPLASIA

Arthrogryphosis Multiplex Congenita.—This is a rare condition in which there is extensive congenital failure of muscular development. The absent muscles are replaced by fibrous tissue. As a consequence of the mixture of paralysis and contracture, multiple deformities develop in the joints. The skin overlying the joints is strikingly creaseless. The most commonly affected joints are those of the feet and hands in both of which clubbing commonly occurs. No treatment is available for the underlying pathology. The deformities are hard to correct, and even if corrected, function tends to be poor. Excision of the talus may be required to render the foot plantigrade.

'Congenital' Torticollis is not a true congenital abnormality: it is almost certainly attributable to infarction of the central portion of one sternomastoid muscle at the time of birth. At birth the central part of the muscle may be found to be swollen: a 'sternomastoid tumour' (fig. 293). The infarcted muscle is gradually replaced by fibrous tissue which contracts. As it does so the neck is turned so that the face is directed away from the side of the lesion (as if the affected sternomastoid muscle were contracting). This state of affairs is exactly analogous to the development of Volkmann's ischæmic contracture in the limbs and indeed the condition should probably be regarded as an example of ischæmic contracture. Persistent torticollis often results in facial asymmetry.

FIG. 293.—Left sternomastoid 'tumour' in a newborn infant.

Treatment.—If a sternomastoid 'tumour' is noticed at birth, the infant's head should be gently manipulated through a full range of movement every day in the hope that such a range can be maintained whilst the muscle is being replaced by fibrous tissue. More commonly the condition is not noticed until torticollis has developed. At this time the condition is treated by division of the sternomastoid muscle at its distal, or proximal and distal, attachment. Care should be taken at the proximal end of the muscle to avoid damage to the spinal accessory nerve.

Guido Engelmann. Orthopædic Surgeon, Vienna. Described this disease in 1929.

CHAPTER 16

DISORDERS OF THE GROWING SKELETON

CERTAIN disorders affect the epiphyseal plate or the epiphysis itself and hence are peculiar to the growing skeleton. Disorders of the epiphyseal plate usually manifest themselves functionally, as *disturbances of growth*, but some disorders arise because the epiphyseal plate is a point of mechanical weakness in a long bone, so that *displacement of the epiphysis* may occur. Certain other disorders of the epiphysis affect both its bony and cartilaginous portions and hence are termed '*Osteochondritis*'.

DISTURBANCES OF GROWTH

The limbs and spine normally remain straight as they grow because growth on the two sides of the limb or spine proceeds at an equal rate. If the growth rate on one side exceeds the growth rate on the other, the structure will become curved, being convex on the side of more rapid growth. Unequal growth in the leg produces bow-leg or knock-knee, and in the spine is possibly responsible for idiopathic scoliosis. Although it is easy to understand how an imbalance in relative growth rates could produce angulation of a limb, there is at present no understanding of the mechanism of production of torsional deformities. Nevertheless, disorders of growth may not only produce angulation of the limbs or spine, they may also result in torsion. In the legs, torsional disturbances of growth produce in-toeing or splay-foot; in the spine, combined with angular disturbances, they produce scoliosis.

Angular and Torsional Deformities of the Leg. Perfectly normal infants when they first stand and begin to walk may be noticed by their parents to have some degree of knock-knee or bow-leg (fig. 294), in-toeing or splay-foot. These 'deformities' often worry the parents, although they do not upset the child. Typically, medical advice is sought when the child is 3 to 4 years of age.

Both *knock-knee* and *bow-leg* occur as part of the normal pattern of growth and should only be viewed as deformities if they are severe and progressive. Both are usually primary disturbances of growth of unknown ætiology. In countries where malnutrition is common however, knock-knee is a frequent complication of rickets, but in Great Britain Vitamin D deficiency rickets is almost non-existent, save in immigrants. Rickets does occur (rarely) as a consequence of a metabolic disorder or malabsorption syndrome (Chap. 47).

The degree of knock-knee can be measured by noting the distance between the medial malleoli. Bow-leg can be measured by noting the distance between the medial femoral condyles. The severity of both 'deformities' is prone to increase when the child stands, so that a measurement should be

made both non-weight bearing and weight bearing and should be related to the length of the leg. Of the two deformities knock-knee is slightly the more common.

In-toeing is somewhat more common than *splay-foot* and is due to torsion of the bones of the legs. If the child is placed supine on the examination couch with the patellæ pointing directly forwards, the degree of tibial torsion is revealed by the position taken up by the foot (fig. 295). Most of the torsion is usually in the tibia but some may be in the femur where it affects particularly the angle made in the coronal plane between the femoral neck and the back of the femoral condyles (the ' angle of femoral anteversion ').

FIG. 294.—Infantile bow-leg. This appearance is within the limits of normal at this age.

FIG. 295.—Internal tibial torsion (the patellæ are ringed) causing in-toeing, and associated knock-knee.

Treatment.—No form of splintage, or adjustment to the footwear, has any effect upon any of these deformities. No treatment is indicated until the age of 6, since the deformity is usually self-correcting before that age. The parents should therefore be reassured and the child left to live a normal life. If significant deformity persists after the age of 7, the legs can be straightened by osteotomy or by slowing growth on the convex side of the curve. Growth can be slowed either by placing staples across the epiphyseal plates at the knee on the convex side of the limb or by excising this portion of the epiphyseal plate and fusing the epiphysis to the metaphysis with a bone block. The latter operation (epiphyseodesis) has the advantage over stapling of being more reliable, but the disadvantage of being irreversible. These operations must be carefully timed in relation to the child's growth potential so as to avoid over-correction and under-correction.

Torsional deformities very rarely require correction, but in girls severe in-toeing, as well as being a slight functional disability, may represent a significant cosmetic defect. Should it be severe enough to merit treatment, the only treatment available is to divide the proximal shaft of the femora and de-rotate the bones at the osteotomy site. If the deformity really merits operations of this magnitude, they should be carried out when the child is about 11 years of age.

SCOLIOSIS

Scoliosis is defined as a lateral curvature of the spine, but the lateral curvature is always complicated by a rotational deformity which, in the thoracic region, is transmitted to the ribs and produces asymmetry of the thorax (fig. 296). Scoliosis is classified according to its ætiology.

1. Idiopathic Scoliosis.

This is the most common form of scoliosis, and next to the paralytic form is responsible for the most severe curves, usually in the dorsal spine.

The fundamental cause of idiopathic scoliosis is, as the name implies, unknown. It has been attributed to paralysis of the intrinsic muscles of the spine caused by subclinical poliomyelitis, but its incidence appears to have been unaffected by the control of poliomyelitis, and girls are more commonly affected than boys (whereas poliomyelitis affects both sexes equally). The absence of paralysis in any other muscle group is also against the presence of a paralysing disease. It is, in fact, the complete normality of the rest of the body which distinguishes this condition from paralytic and other forms of scoliosis. A genetic element is almost certainly involved since the disease has a slightly increased familial incidence. Whatever the ultimate cause of the deformity, the proximate cause is a disturbance of vertebral growth.

FIG. 296.—Scoliosis: the appearance of the back.

Clinical Features.—In order that the patient may stand upright, the primary curve in the spine is balanced by secondary curves in the opposite direction above and below it. These compensatory curves bring the shoulders over the pelvis so that in mild primary curves, no gross abnormality may be visible when the patient is dressed. On the other hand, a severe scoliosis is very disfiguring for two reasons: firstly there is a loss of as much as 15 cm. of height as the spine becomes 'concertinaed', and secondly a rib hump

develops which gives the appearance of a hunchback. Thus the adult picture is that of a dwarfed hunchback. The curves in the spine in a child are to some extent fixed (structural) and to some extent mobile. The latter are caused by the spine collapsing like a concertina under the influence of gravity: if the child is picked up by the head or the axillæ, the mobile part of the curve straightens so that only the structural component remains.

The rib hump is characteristic of idiopathic scoliosis and early in the disease is best demonstrated by standing behind the unclothed patient and asking her to touch her toes. Even in the absence of any very marked clinical deviation of the spine, this test will show the asymmetry of the chest (fig. 297). The rib hump is produced by rotation of the dorsal vertebræ (when they are involved in the curve) and, with them, of the ribs. The vertebræ rotate in such a way that the tips of the spinous processes move towards the concave side of the curve and hence, clinically, diminish its apparent severity. On the convex side of the curve, vertebral rotation displaces the ribs posteriorly to form the rib hump. Thus the appearance of the back is a poor guide to the severity of the spinal curve: rotation of the spine diminishes the appearance of the deformity in so far as it brings the spinous processes nearer the midline, but increases it in so far as it produces a rib hump. The only way that the

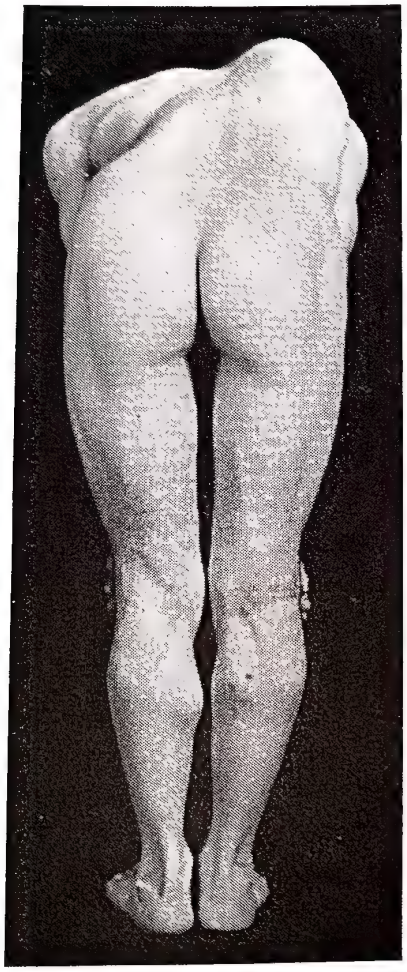

FIG. 297.—Scoliosis showing 'rib hump' revealed in flexion.

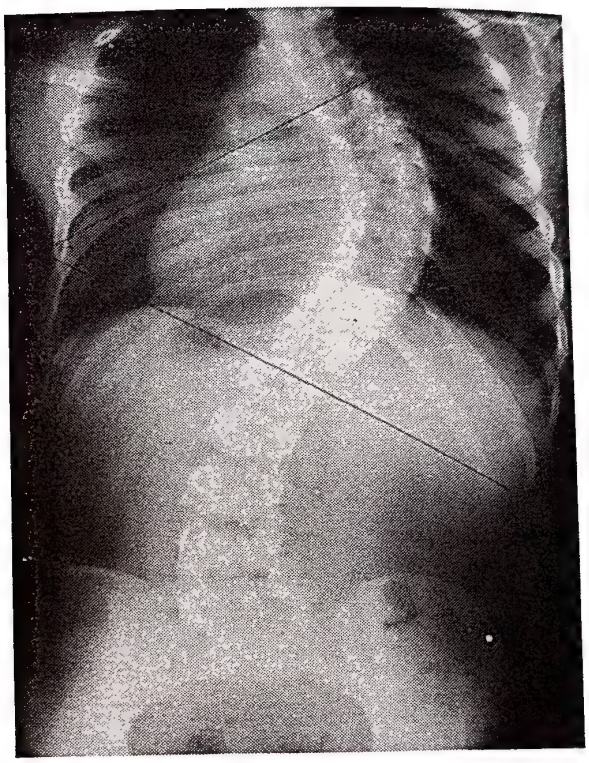

FIG. 298.—The radiological appearance of the spine in scoliosis. The angle of the curve is measured by the angle subtended by the upper surface of the first and the lower surface of the last vertebra in the primary curve.

spinal curve can be assessed accurately is by the measurement of X-rays (fig. 298).

Because of the deformity of the ribs and dorsal spine, a dorsal scoliosis reduces the vital capacity, often seriously so. As a consequence the patient may eventually die of pulmonary infection. Alternatively, secondary pulmonary fibrosis may lead to Cor Pulmonale and right sided heart failure.

Clinical Management.—Idiopathic scoliosis may appear in infancy, in childhood, or during adolescence. In infancy it may resolve spontaneously but a few curves become progressive. All curves, once established as structural and irreversible, may deteriorate rapidly, particularly during periods of skeletal growth. After the completion of spinal growth (which coincides with the fusion of the iliac crest apophyses), deterioration may continue at a slower rate, or, more commonly, will come to a halt. Once advanced structural deformity has developed, nothing can be done to restore the spine to normal. Thus untreated, the condition may rapidly progress until the patient is an irrevocably dwarfed hunchback. Early diagnosis and, if necessary, treatment are therefore essential.

The rate of progression of deformity is hard to predict when the patient is first seen, so that the patient must be examined frequently once the deformity has been noticed. Comparable anteroposterior X-rays of the entire spine should be taken every 3 months during the first year and thereafter at longer intervals until skeletal growth is complete. The curves are measured accurately on these X-rays (fig. 298); it is useless to depend upon clinical impressions of the appearance of the spine. Without careful radiological supervision a deformity may develop, within a year of the curve first being noticed, which is too severe for full correction.

Treatment.—In most patients who develop a severe curve, a rapid deterioration takes place in the 2 or 3 years prior to skeletal maturity. Mild curves under 20° may be treated *expectantly*, the spine being checked regularly by comparable anteroposterior radiographs, taken in the erect position, until growth is complete.

Conservative or non-operative treatment by the Milwaukee brace[1] and exercises may be successful in preventing deterioration or even producing improvement in curves which advance beyond 20° but do not exceed 40° to 45°. It may be used in more severe deformity, particularly in young children as a holding device until the child reaches the age of ten to twelve years, when definitive surgical treatment can be carried out.

Operative treatment is reserved for those patients who deteriorate during conservative treatment or who have severe curves (over 50°) when first seen. It is preferable to defer surgery until near skeletal maturity because of the unpredictable effects of further growth after spinal fusion. Fusion of the spine is also more difficult to achieve in the young child. Nevertheless correction and fusion in a young child is sometimes carried out where deterioration cannot be controlled in any other way.

[1]The Milwaukee brace was introduced in 1946 by Walter Putnam Blount and his associates at Milwaukee, Wisconsin, U.S.A.

The aim of all surgery for scoliosis is correction and fusion of the primary curve. Correction may be pre-operative or it may be part of the surgical procedure.

Techniques of Pre-operative Correction

1. *Risser Turnbuckle Cast.*—This is the most widely used method of obtaining correction. A plaster cast is applied, including the head and one thigh, with the patient's spine flexed laterally to produce the maximum correction of the mobile portion of the curve which can be tolerated. The cast is heavily padded with sorbo rubber at the points where pressure is encountered. When the cast is dry it is cut at the level of the apex of the primary curve and angulated so as to produce progressive correction. The new position is held by means of metal turnbuckles incorporated into the plaster. In this way a slow correction can be obtained from week to week and checked by X-ray. When the primary curve has been sufficiently corrected from the

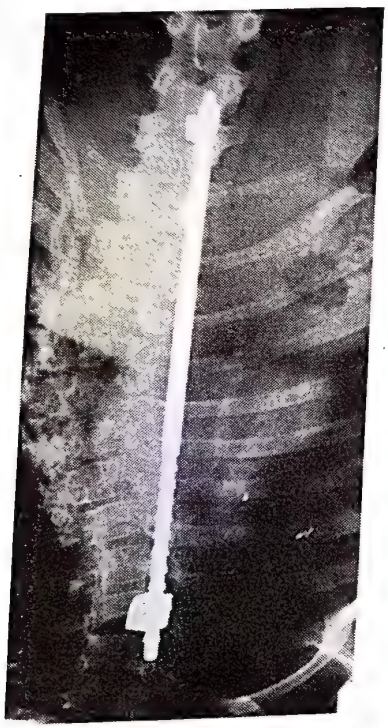

FIG. 299.—A single Harrington rod used to extend and internally fix the concave side of the curve.

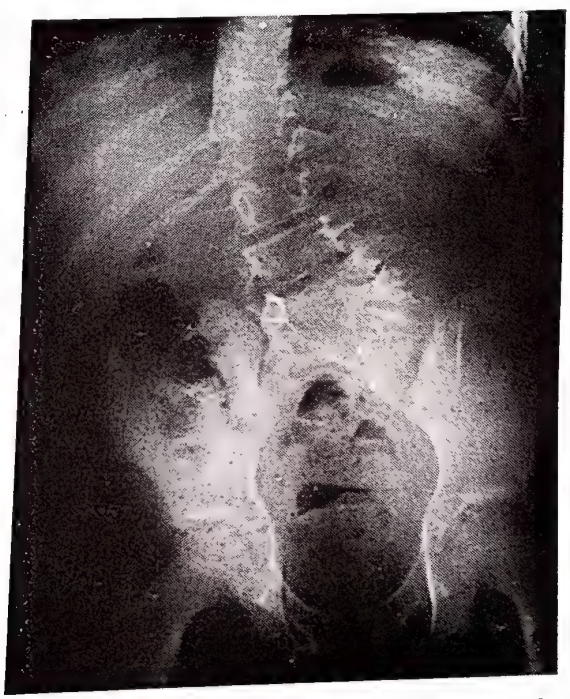

FIG. 300.—Congenital lumbar scoliosis due to a hemivertebra at L.3 fused to L.4. Note associated spina bifida, in this case occult.

cosmetic and functional standpoints (which may not be the point of complete correction in an originally severe curve), a window is cut in the back of the plaster over the primary curve and through this the spine is fused posteriorly. The fusion must extend to include the vertebræ immediately above and below the primary curve. The bone used is generally taken as small chips from the patient's own spine and iliac crests, but the volume can be increased by adding banked bone. If the primary curve is very long, the operation may be performed in stages. After operation, the patient remains in the Risser jacket for 6 months whilst the fusion consolidates. The following year is spent in a carefully moulded corset or Milwaukee brace so that the soft new graft is not subjected to severe bending forces.

2. *Risser Localiser Cast.*—This is applied on a special frame. The patient lies on a narrow strip of canvas and correction is obtained by a combination of longitudinal traction and the localiser which applies pressure over the rib hump to correct the angular and rotation deformities. A well fitting plaster cast is applied in the corrected position. A series of such casts may be used to obtain gradual correction.

3. *Cotrel Dynamic Traction.*—Mobilization of a rigid curve and some correction

Joseph Charles Risser, Contemporary. Professor of Orthopædic Surgery, Loma Linda University, Los Angeles, California, U.S.A.

Cotrel, Contemporary. French Orthopaedic Surgeon.

may be obtained by this method. The pelvis is anchored to the foot of the bed by a leather harness. A leather head halter is connected via a pulley at the head of the bed to a pair of stirrups through which the child applies longitudinal traction by extending the legs.

4. *Skeletal Traction* may be applied to the skull by means of a 'halo'. This may be combined with skeletal traction to the femora or pelvis. Great forces can be applied by this means and the method requires most careful supervision to avoid neurological and other complications.

Operative Correction

Harrington Instrumentation is the most widely used method of operative correction of scoliosis. After exposure and stripping of the posterior elements of the spine, hooks are applied to the vertebræ beyond the end vertebræ on the concave side of the primary curve. These hooks are connected by a rod which has a ratchet device so that gradual distraction can be applied to produce correction. A compression rod and hooks is sometimes used on the convex side of the curve.

Dwyer's Procedure.—Through an anterior approach the vertebral bodies are exposed on the convex side. A wedge of disc and body is removed at each level of the primary curve. The gaps so created are closed by means of a series of screws in the vertebral bodies. A tension cable passes through the heads of the screws. As each level is corrected the screw head is crimped on to the cable.

Technique of Fusion.—Correction, whether pre-operative or intra-operative, is always combined with spinal fusion. This may be anterior between the vertebral bodies, or posterior fusion of the laminæ and transverse processes. Or a combination of the two is sometimes used. Additional bone preferably autogenous bone from the ilium is commonly used.

Standard posterior fusion consists of meticulous stripping of the primary curve from the midline to the tips of the transverse processes. This is followed by excision of the apophyseal joints and decortication of the laminæ and transverse processes. Additional bone is packed into the bed so prepared and the wound is closed.

Following spinal fusion a corrective plaster is maintained until the graft is mature and solid. This may take about a year.

2. Congenital scoliosis is associated with congenital spinal anomalies, such as hemivertebra (fig. 300), errors of segmentation, spina bifida, diastematomyelia etc. Associated anomalies are common particularly of the spinal cord and kidneys. A myelogram and intravenous pyelogram are therefore indicated if surgery is contemplated.

3. Paralytic Scoliosis (Chapter 19).

4. Postural Scoliosis

This affects children of school age and is characterised by being a simple C curve without rotation of the vertebræ. The deformity is fully mobile and correctable. Formerly quite common, the condition is now almost non-existent, possibly because of the improvement in the general health of the population, the provision of physical education in schools and the avoidance of bad posture when sitting at school desks. Treatment is by gymnastics and lessons in deportment.

5. Pulmonary Scoliosis

Pulmonary disease may produce scoliosis if disease of one lung results in contraction of the chest wall on that side. In the past the most severe deformities followed the

Paul R. Harrington, Contemporary. Associate Professor of Orthopædic Surgery, Baylor University, Houston, Texas, U.S.A.

treatment of empyema by prolonged drainage through tubes in the chest wall, but the modern treatment of chest disease has made this one of the rarer causes of scoliosis.

DISPLACEMENT OF EPIPHYSES

Slipped Femoral Epiphysis

Displacement of the proximal femoral epiphysis may occur in the face of the loads imposed by normal activities—possibly because the normal loads applied to this epiphysis are high, because the epiphyseal plate may not be disposed at right angles to the line of action of the resultant force applied to it, or because the epiphyseal plate is not mechanically normal. The latter possibility is entirely hypothetical. No other epiphysis is liable to displacement in this way. Rarely the normal epiphysis may be displaced by significant violence: this is really a fracture of the femoral neck which happens to involve the epiphyseal plate.

The condition affects children between the ages of 10 and 18 years. It is particularly common in boys in a ratio of 3:2 and in over-weight 'hypogonadal' children. It is bilateral in about 20% of patients, the two sides being affected at about the same time. Dunn has observed that, when unilateral, the side of the dominant hand is usually affected first. Relative to the neck, the epiphysis slips downwards and posteriorly. This is the equivalent of the femoral shaft and neck moving into adduction and external rotation in relation to the head.

Two varieties of slipped epiphysis are encountered: 1. acute (i.e. sudden) displacement and 2. chronic (i.e. slow) displacement.

1. Acute Slipped Epiphysis.—Careful questioning will often reveal that the acute slip is really a final episode in what has been a slow slip, but the symptoms prior to the acute slip can be so slight as to pass without notice. The acute slip often follows an injury of some magnitude, such as a fall off a bicycle or at football, after which the patient is unable to move the hip and

FIG. 301.—Slipped femoral epiphysis.

FIG. 302.—Internal fixation of a slipped femoral epiphysis with 3 Moore's pins.

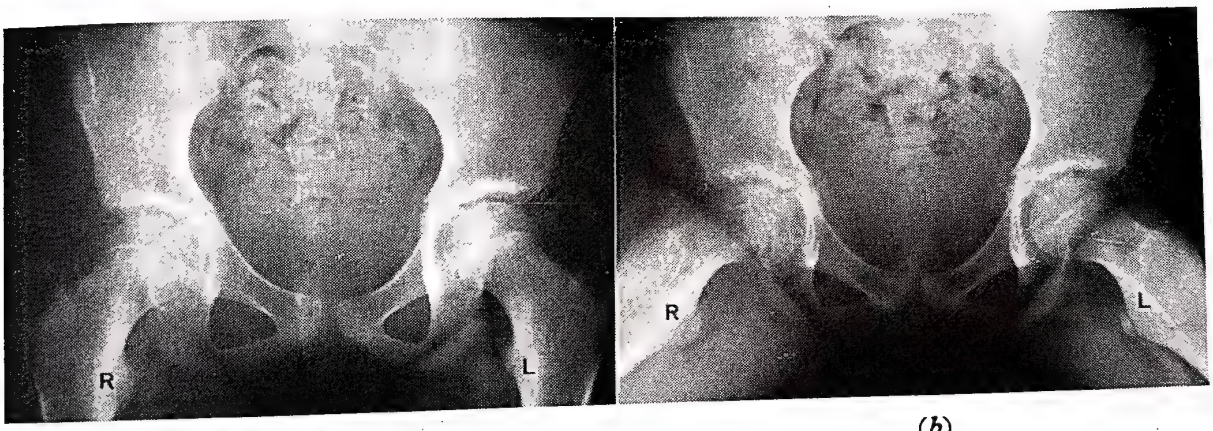
Denis Michael Dunn, Contemporary. Orthopædic Surgeon, Essex County Hospital, Colchester, Essex, England.
Austin Tally Moore, 1899–1963. Orthopædic Surgeon, Columbia Hospital and the Moore Clinic (which he founded in 1939), Columbia, South Carolina, U.S.A.

experiences severe pain. The clinical signs are identical with those of a subcapital fracture in an adult, and indeed this condition is a subcapital 'fracture' through the epiphyseal plate. X-rays show complete displacement of the epiphysis (fig. 301).

Treatment is similar to that of a subcapital fracture of the femur in a young adult: the epiphysis should be reduced under anæsthesia without undue delay (by internal rotation and abduction) and fixed internally with 3 Moore's pins (fig. 302) under X-ray control.

2. Chronic Slipped Epiphysis.—In this condition the child complains of pain in the hip and of a limp, but is able to walk. On first examination muscle spasm usually causes limitation of movement in all directions, suggesting an inflammatory process in the hip (for example early tuberculosis). Rest in bed for a day or two relieves the pain and spasm: isolated limitation of internal rotation and abduction, and slight apparent shortening of the leg, are then demonstrable.

X-rays will reveal the displacement of the epiphysis (figs. 301 and 303) although if only a small slip has occurred it is very difficult to detect in an anterio-posterior view. In a lateral view of the hip, however, the posterior displacement of the epiphysis is obvious. Therefore a *lateral view of the hip should always be obtained if a slipped femoral epiphysis is suspected clinically.*



(*a*) (*b*)

FIG. 303.—A minimal slip of the right femoral epiphysis. (*a*) Apparently normal antero-posterior X-ray. (*b*) Minimal slip revealed on a lateral X-ray of the femoral neck.

In the absence of treatment there is a period of disability during which the slip progresses. This may be followed by spontaneous remission if healing occurs at the epiphyseal plate so that the head of the femur 'unites' with the neck in the slipped position. The patient then recovers almost full function, though with the permanent physical signs of limited abduction (due to the adduction element in the deformity) and limited, or absent, internal rotation (due to the external rotation element in the deformity). Later in life, osteoarthrosis may be expected to develop. Alternatively the period of slow, progressive slipping may culminate in an acute slip.

Treatment.—Attempts to reduce a chronic slipped epiphysis are difficult or impossible, and the attempt may damage the blood supply to the head. If

the slip is slight, the position should be accepted and treatment should aim only to prevent further displacement by internal fixation of the epiphysis as for an acute slip. Because this condition is commonly bilateral, the other hip should be watched for any sign of a slip or should be pinned prophylactically.

Once internal fixation has been obtained, the child should remain in bed for 3 weeks, use crutches for 6 weeks, and then walk normally. Contact sports and physical education should be avoided for 1 year. If the child is overweight, he should diet.

If gross slipping has occurred by the time the patient is first seen, an osteotomy, either in the neck or trochanteric region of the femur, should be performed to correct the external rotation and adduction deformity.

Displacement in Response to Significant Violence.—This may occur at any epiphysis: the condition is really a fracture through or adjacent to a previously normal epiphyseal plate and is described in Chapters 22 and 23.

Subclinical Displacement

It has recently been suggested by Murray that children, especially athletic boys, may sustain subclinical slips which are responsible in later life for many examples of so-called primary osteoarthrosis of the hip.

OSTEOCHONDRITIS

It is a confusing misfortune for the medical student that this one term is used to describe widely differing pathological processes all of which affect epiphyses. The exact nature of the pathological process occurring in the diseases which are given the title 'Osteochondritis' is uncertain because adequate human histological material has rarely been available. It is only possible here to state that three pathological processes appear to be at work: infarction of epiphyses, traction injuries to epiphyses, and transchondral fractures in epiphyses.

Infarction of Epiphyses

This disorder affects particularly the proximal femoral epiphysis where it is known as Legg-Calvé-Perthes' disease, the distal epiphysis of the second metatarsal bone, where it is known as Freiburg's disease, and the navicular where the whole bone may be regarded as the epiphysis and where it is known as Köhler's disease. Of these, Perthes' disease is the most common and has the most serious consequences for the patient.

Perthes' Disease

Pathology.—Since this disease is not fatal and there is no therapeutic indication for removal of the femoral head in patients suffering from the disease, there have been very few observations of the morbid anatomy of this disease in man. On the basis of the histology obtained from epiphyses infarcted experimentally in animals, the little human histological material that is available, and the radiological appearances of the epiphysis in experimental animals and in man, it may be speculated that the sequence of events in Perthes' disease is as follows:—

Ronald Ormiston Murray, Contemporary. Radiologist, Royal National Orthopædic Hospital, London.
Arthur Thornton Legg, 1874–1939. Orthopædic Surgeon, The Children's Hospital, Boston, Massachusetts, U.S.A.
Jacques Calvé, 1875–1954. Orthopædic Surgeon, La Fondation Franco-Américaine, Berck-Plage, France.
Alban Köhler, 1874–1947 *(see p. 281).*
Albert Henry Freiberg, 1868–1940 *(see p. 281).*
Georg Clemens Perthes, 1869–1927. Professor of Surgery, Tübingen, Germany. Legg, Calvé and Perthes all described osteochondritis of the head of the femur independently in 1910.

The presence of an epiphyseal plate results in a peculiarity of the blood supply to the bone of the epiphysis, for blood vessels do not cross the epiphyseal plate. Thus the blood supply to the epiphysis is derived entirely from vessels passing around the periphery of the plate and along the ligamentum teres. (In the adult on the other hand blood not only reaches the head of the femur by the original route, but also by a route within the bone itself across the fused epiphyseal plate.) Since the epiphysis is entirely intra-articular, all the epiphyseal vessels run beneath the synovial membrane before entering the epiphysis itself, and thus the epiphysis could be infarcted if, for example, fluid collected in the joint under sufficient pressure to occlude the vessels. It has been suggested that this is in fact the mechanism of infarction in Perthes' disease. (Why certain small bones such as the navicular may also infarct, is uncertain.)

That the spontaneously occurring variety of the disease is caused by infarction of the epiphysis is supported by the fact that similar changes in the femoral head may follow events which would clearly be expected to interrupt its blood supply such as traumatic dislocation of the hip and fractures of the femoral neck in children, immobilisation of the hip in positions in which the capsule is twisted tightly around the femoral neck (as for example occurs in the treatment of congenital dislocation of the hip by immobilisation of the hip in positions of extreme internal or external rotation), and tense hæmarthroses in the hip in hæmophiliacs.

When the blood supply to the epiphysis has been interrupted the bone dies but the cartilage, nourished from the synovial fluid, survives and proliferates. Thus the bony epiphysis on the infarcted side appears smaller (because it fails to grow) and the radiological joint space appears larger (because the cartilage grows, and possibly because an effusion is present in the joint).

Although the cartilage survives for some weeks upon synovial nutrition, some chondrocytes eventually die, especially in the basal layers, perhaps because proliferation of the overlying cartilage makes it impossible for them to receive an adequate supply of nutrients by diffusion from the synovial surface. Dead cartilage (1) is probably softer than normal so that it may deform under normal loads, and (2) may not ossify.

Granulation tissue invades the infarcted epiphysis by overgrowing the margins of the epiphyseal plate. The dead bone is partly resorbed and partly entombed in new bone deposited on a scaffold of the old: a process known as creeping substitution. Before it is replaced, the dead bone may fail mechanically (i.e. may fracture) especially if the cartilage is soft, perhaps because it fatigues. Thus the bony nucleus of the epiphysis, like the cartilaginous position, may deform in response to normal loads.

All these changes can be seen in the femoral head of the puppy after one experimental infarct but they do not result in significant deformity of the head. In contrast two experimental infarcts disturb the normal pattern of growth in the epiphysis and as a consequence produce deformity of the head. Recent histological studies in man show that in most if not all cases of Perthes' disease the capital epiphysis has been infarcted more than once and hence it seems very likely that, although deformity of the femoral head in man may be partly mechanical in origin, it is mainly due to a disturbance of growth. Even mechanical deformation seems to be more likely after two infarcts since experimentally the old ossific nucleus may then fail to become revascularized, fragment and eventually be replaced by fibrous tissue.

Experimentally the epiphyseal plate may be damaged when the epiphysis is infarcted on two occasions and vessels sometimes gain access to the epiphysis not only around the margins of the plate but also by breaching its centre. The resulting disturbance of epiphyseal growth may contribute to the deformation of the femoral head and may be responsible for the metaphyseal changes seen in clinical X-rays. Experimental work also suggests that growth of the epiphysis (i.e. of the femoral head) may be disturbed by repeated episodes of infarction. It is not known, however, if clinical Perthes' disease is due to a single, or to repeated, episodes of infarction.

As the bone is revascularised the deeper layers of the overlying cartilage are progressively, but patchily, converted into bone by endochondral ossification. The combination of creeping substitution of the bony nucleus and patchy endochondral ossification in the cartilage makes the epiphysis appear radiologically dense, fragmented, and deformed. Although the bony nucleus of the epiphysis always appears to be deformed radiologically, the femoral head itself may not be so: a fact which can be observed experimentally with the naked eye or clinically by arthrography.

Clinically, true deformation of the femoral head (due to the mechanisms suggested above) is, however, the usual outcome.

Gradually the whole epiphysis is revascularised and replaced by normal bone and cartilage. The epiphysis is then no longer liable to deform, but any deformation which has already occurred is permanent and is revealed by the radiological outline of the bony nucleus.

Clinical and Radiological Features.—Boys are more commonly affected than girls in a ratio of 4 to 1 but why this is so is unknown. The condition usually presents between the ages of 3 and 10 years. The child complains of pain in the hip and is seen by the parents to limp. Occasionally there is a history of injury, but if so there is often a silent interval between the injury itself and the pain and limp which bring the patient to hospital. When first examined the muscles around the hip are in spasm so that all movements are slightly limited and painful at extremes. If the child is put to bed and light skin traction applied to the limb, these signs gradually disappear so that a full range of movement can usually be obtained after 1 or 2 weeks. All hæmatological investigations are normal.

The diagnosis is made upon the history, upon the transient physical signs, upon the absence of any evidence of tuberculosis or other infective disease, and upon the X-ray appearances.

FIG. 304.—Radiological appearance of Perthes' disease of one year's duration.

The *X-ray appearances* go through a series of phases. At first the ossific nucleus appears normal save that it is smaller than that on the other side. This appearance is attributable to the fact that it has ceased to grow. The radiological joint space on the other hand is greater than that on the unaffected side, partly because there is often an effusion in the hip and partly because the cartilaginous portion of the femoral head continues to grow at a normal rate. In spontaneously occurring Perthes' disease, this phase is rarely seen; presumably because the disease does not usually give rise to symptoms at this time. This phase is followed by one in which the ossific nucleus appears to fragment, to flatten, and to become more dense than normal (fig. 304). Although these appearances always suggest deformation of the femoral head, true deformation of the cartilagenous epiphysis and of the femoral head at maturity does not in fact always occur (see Pathology). Radiologically, the whole of the femoral head usually appears to be involved but occasionally the changes seem confined to a part of the head only.

Metaphyseal changes often accompany those in the epiphysis and consist of circumscribed lytic lesions (so-called ' cysts ') and broadening of the neck.

Finally the femoral head returns to its normal bony texture and at this time it may or may not be truly deformed but is usually larger than normal.

Prognosis.—The prognosis depends upon the age of the child at the onset of the disease and perhaps (but this is speculation) upon the number of times that the epiphysis has been infarcted. The younger the child, the smaller is the epiphysis and thus the greater is the chance of its being totally revascularised before it has deformed. Accordingly the younger the child at the age of onset of the disease the better is the prognosis.

Sequelæ.—If the femoral head, when fully revascularised, is of a normal shape, there are no sequels to this disease. If however the femoral head is irregular in outline, osteoarthrosis may occur in adult life.

Treatment.—There is no specific treatment for the underlying pathological process. All that can be offered is an attempt to reduce the chances of significant deformation. The most effective way of achieving this is at present believed to be to improve the mechanical environment of the epiphysis (but treatment aimed at preserving its blood supply may in fact be more rational). One extreme way to off-load the affected hip is to confine the child to bed for the 2 or 3 years required for revascularisation to occur. This represents a massive interference with the child's life which most orthopædic surgeons prefer to avoid. An alternative, but less effective, method of reducing the load on the femoral head is to fit the child with a caliper in which weight is supposed to be borne through the pelvis rather than through the hip. Alternatively, advantage can be taken of the fact that if the femoral head is entirely contained in the acetabulum, any moulding of the head that occurs may not result in deformation since the head will tend to take up the spherical shape imposed by the acetabulum. Complete containment of the femoral head in the acetabulum may be achieved by an adduction osteotomy of the femur at the inter-trochanteric level, by innominate osteotomy of the Salter type (p. 258), or by special splintage in which the child bears weight on the abducted hips. None of these forms of treatment is predictable in outcome and none can be guaranteed to prevent deformity.

Infarction of the Navicular (Köhler's disease).—This condition presents with physical signs and radiological appearances analogous to those of Perthes' disease (fig. 305). The

affected bone becomes painful and tender and apparent radiological deformation occurs. Treatment consists of relieving weight from the affected foot until revascularisation and a normal bony radiological appearance have been achieved.

Infarction of the Head of the Second Metatarsal (Freiberg's disease).—This condition (fig. 306) is not entirely similar to the two foregoing diseases in that infarction occurs in a rather older age group, namely in adolescents aged between fifteen and twenty-five years. It would seem, however, that the underlying mechanism is entirely similar. Treatment is difficult and consists of attempting to weight-relieve the affected bone by an appropriately placed insole. If pain persists, the head of the second metatarsal may be excised.

Traction Injuries to Epiphyses

Pathology.—Because the epiphyseal plate represents a point of weakness in the long bones, mechanical failure may occur in the region of the epiphyseal plate which is impossible in the adult. Slipped femoral epiphysis (p. 276) is one example of mechanical failure of this kind. Certain epiphyseal plates may be loaded in tension, a mode of loading which they do not appear to be well able to withstand, so that traction injuries form another example of such lesions. These injuries produce physical and radiological signs which in some ways resemble those associated with other disorders of the epiphysis and which for this reason have been attributed to 'Osteochondritis'.

Clinical Features.—These injuries occur in the knee, the heel, and the spine. In the knee the tibial tubercle, which is part of the proximal tibial epiphysis, may gradually be avulsed from the shaft, which is part of the metaphysis. This condition is known as '*Osgood-Schlatter's disease*' (fig. 307). A corresponding condition may occur at the distal pole of the patella where the condition is known as '*Sinding Larsen's disease*'. At the heel the posterior epiphysis of the os calcis may be partially avulsed by the Achilles' tendon. This condition is known as '*Sever's disease*'.

FIG. 307.—Osgood-Schlatter's disease; decalcification, fragmentation, and partial separation of the tongue-shaped portion of the epiphysis from the upper tibial shaft. (*Robert Maguire, M.R.C.S., Myrtleford, Vic., Australia.*)

In the spine the disease may occur in the vertebral bodies where it is known as '*Scheuermann's disease*'. The disease affects particularly the 6th to the 10th thoracic vertebræ, and the lumbar spine. To understand this condition two facts must be appreciated: firstly, that in the normal hydrated intervertebral disc the nucleus pulposus functions as a fluid and accordingly is positively pressurised when the disc is loaded in axial com-

Robert Bayley Osgood, 1873–1956. Professor of Orthopædic Surgery, Harvard University, Boston, Mass., U.S.A.

pression. The pressure generated in the nucleus pulposus is applied to the annulus fibrosus which is therefore under tension when the disc is loaded. Secondly, the annulus fibrosus is attached to ring-shaped epiphyseal plates on the superior and inferior surfaces of the vertebral body. Thus traction injuries may occur at the cartilagenous attachment of these epiphyses to the vertebral body. This occurs particularly in the anterior portion of the epiphysis and results in interference with the growth of this portion of the vertebral body. The vertebral bodies become narrowed anteriorly, especially in the thoracic region, to produce a smooth, rigid kyphosis. In the lumbar region slight anterior narrowing occurs but is not clinically evident since the normal lumbar spine is lordotic. The epiphysis may fail to fuse with the rest of the vertebral body and thus appears as a separate island of bone in the adult. Probably because the disease is associated with a disturbance of the intervertebral disc, the corresponding disc spaces are narrowed. It may even be that this condition is not strictly a traction injury to the epiphysis at all, but rather represents an extrusion of nuclear material through the epiphyseal plate, separating the epiphysis from the metaphysis. Whatever their cause, these events alter the mechanics of the spine and thus may cause back pain.

Treatment.—No matter where these conditions occur, treatment consists of resting the involved epiphysis until pain and tenderness have subsided. This usually takes about 6 weeks.

No persistent disability follows these conditions save in the spine where there may be a permanent increase in the normal dorsal kyphosis, sometimes accompanied by back pain.

Transchondral Fractures. (Osteochondritis Dissecans.)

Pathology.—A transchondral fracture is one in which the fracture line runs entirely in articular bone, that is to say in bone covered by articular cartilage. Because articular cartilage is more elastic than bone, strains which fracture the bone may not break the cartilage. Thus the bony fragment may be held in its bed by an intact bridge of cartilage. The cartilage is nourished from the synovial fluid and hence remains healthy. In contrast the bone dies because its blood supply is completely interrupted at the fracture line. If the cartilage all round the fracture breaks at the time of injury, the fragment separates to form a *loose body* in the joint. If the cartilage remains partly or completely intact, the fracture may unite and the fragment may become revascularised. Sometimes, however, especially if the fragment is large, revascularisation fails and the dead fragment of cartilage-capped bone may then separate to form a *loose body* long after the injury. Such injuries may occur in adults as well as in children, but in the latter, if the bone has an epiphysis, it is the epiphysis which is involved.

The connection between the injury and the formation of the loose body is often unprovable because the violence required to produce the fracture is slight and because the injury and the formation of the loose body are widely separated in time. The suspicion therefore arises that the formation of some loose bodies may not be due to injury at all. This suspicion is strengthened by the occasional spontaneous development of loose bodies in several joints of the same patient. It has been suggested that this may be due to thrombosis of an end-artery supplying the involved bone. In these cases of uncertain ætiology, it is reasonable to retain the term *Osteochondritis Dissecans.*

Clinical Features.—The condition may affect any convex articular surface but is particularly common in the femoral condyles, and the capitel-

lum. Less commonly it occurs in the head of the femur and the dome of the talus (fig. 385 (*b*)). An unseparated fragment causes aching pain and an effusion in the joint. The lesion can be displayed radiologically but only if views are carefully chosen so as to place the lesion on the 'skyline' (fig. 308). Tomographs may be required. A separated fragment forms a loose body which may lock the joint. Radiologically the loose body and its parent cavity can be seen.

FIG. 308.—Osteochondral fragment separating from the medial femoral condyle. *(Professor Carl Krebs, Aarhus, Denmark.)*

Treatment.—If the fragment separates totally, the loose body must be removed. The crater from which it was derived should be ignored and will gradually be filled with fibro-cartilage. If the fragment is not displaced from its parent cavity when first detected, a state of affairs which applies particularly to the knee, it should be held in place by two pins (Smillie pins) in the hope that it will eventually re-unite. If the end-result of a transchondral fracture is an irregular articular surface, osteoarthrosis is likely in later life.

Ian Scott Smillie, Contemporary. Emeritus Professor of Orthopædic Surgery, Dundee, Scotland.

CHAPTER 17

GENERALISED DISEASES OF BONE

DISEASES OF UNKNOWN ÆTIOLOGY

Paget's Disease (syn. Osteitis Deformans)

This disease was described in 1877 by Sir James Paget. In three classical papers (1877, 1882 and 1889) he described the advanced polyostotic form of the disease and most of the known complications.

The disease is rare under the age of 40 but becomes progressively more common as age advances, finally reaching an incidence of about 10% in people over 90 years of age. Males are slightly more commonly affected than females. The condition can affect any bone in the body and many bones may be affected in the same patient. The spine, the skull, the pelvis, the femora and the tibiæ are the most commonly involved bones.

The pathological process begins with osteoclastic resorption of existing bone. This is followed by osteoblastic regeneration of a primitive coarse-fibred bone which is highly vascular. This process affects both cortical bone, which becomes increasingly thick and less well demarcated from adjacent cancellous bone, and cancellous bone where massive ill-formed trabeculæ replace the normal structure. Finally the affected bones assume the mosaic pattern of lamellar bone.

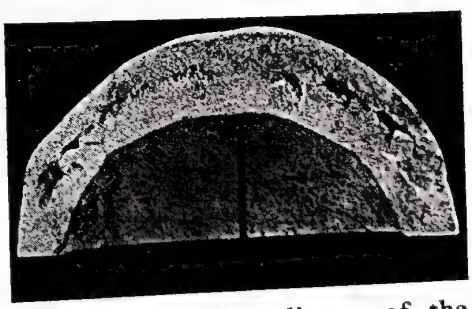

FIG. 309.—Paget's disease of the skull. (*R.C.S. Museum.*)

Clinical Features.—The majority of cases of Paget's disease are discovered incidentally in patients attending a physician for some other reason; relatively rarely a patient presents with a complaint arising directly from the condition. The disease gives rise to visible thickening of the involved bones and a complaint of increased thickness may be the presenting symptom. This applies particularly to the skull (fig. 309) where an inability to wear his normal size of hat may draw the patient's attention to the first changes. The pathological process may be painful, especially in the weight-bearing bones where deformity is taking place: the patient will then present complaining of a dull, continuous aching pain localised in the involved bone. The new bone formed is less strong than normal bone and, either because it deforms under load or because its deposition is irregular, it tends to bend under load producing typical bowing of the involved bones especially in the leg (fig. 310). The consequent deformity may be noticed

Sir James Paget, 1814–1899. Surgeon, St. Bartholomew's Hospital, London.

by the patient. Attention is not infrequently drawn to the presence of the disease by the development of one of its complications (see below).

Physical Signs.—Subcutaneous bones may be obviously thickened and bowed, but otherwise there are no significant findings. Because of the massive increase in vascularity of the bones, the involved parts of the skeleton may become the functional equivalent of arterio-venous fistulæ and as a consequence lead to left ventricular failure (p. 287).

FIG. 310.—Paget's disease affecting the skull, which is large, and the legs (especially the right tibia) where the bones are thickened and bowed.

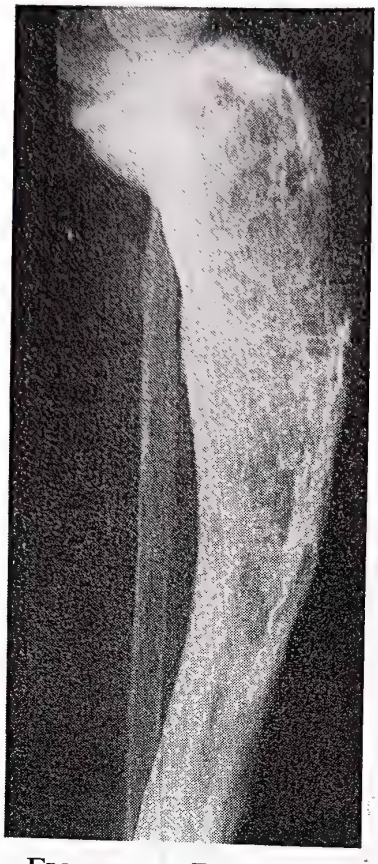

FIG. 311.—Paget's disease involving the tibia showing thickening of the bone, bowing, a pathological fracture anteriorly, and mottled sclerosis.

Radiological Appearances.—The involved bone is thickened, and patchily sclerotic. The normal clear line of demarcation between cortex and medullary canal becomes blurred. The long bones may be deformed. The final appearance of the bone is one of predominant sclerosis with a typical mottled appearance (fig. 311).

Special Investigations.—The serum calcium and serum phosphorus are usually within normal limits. The serum alkaline phosphatase is often very high, but this finding is in no way specific for it is a feature of most diseases in which osteoclasis is taking place.

Treatment.—The pain of Paget's disease can now be relieved by treatment with calcitonin. The extent to which this hormone also reverses the pathological process is uncertain but current evidence suggests that it does so to a significant extent. Whether or not it affects the incidence of complications, especially of malignant change, remains to be seen.

Complications

1. **Osteogenic sarcoma** develops in approximately 5% of patients with Paget's disease. The neoplasm is extremely malignant and death is almost invariable once this complication has developed. Treatment should be along the lines described for osteogenic sarcoma in general (p. 247).

2. **Pathological fracture** may occur through long bones involved with Paget's disease. The fractures are usually transverse and the appearance of a transverse fracture in the tibia or femur in a patient over the age of 40 whose bone looks a little

thickened should raise the suspicion of Paget's disease. Union of these fractures usually occurs uneventfully whether they are treated by internal fixation or by external splintage. Internal fixation may be indicated because of the age of the patient, but is usually difficult since the medullary canal has been lost and the bone is extremely vascular.

3. **Osteoarthrosis** occasionally develops in joints adjacent to deformed bone, but it is by no means certain that the incidence of osteoarthrosis is in fact higher than in the uninvolved population of similar age.
4. **Paraplegia** is a rare complication of involvement of the vertebræ.
5. **Heart failure** (high output) may occur due to the arteriovenous shunts within the affected bones.
6. **Deafness** may occur due to bony involvement of the middle ear.

Osteoporosis

This condition may occur in a localised form following local inflammation or disuse (due for example to paralysis or immobilisation). A generalised form may develop either primarily, and as such represents an almost invariable concomitant of increasing age, or secondarily following endocrine disorders.

Senile osteoporosis first becomes manifest in women shortly after the menopause and in men at around the age of 65, but it is rarely a clinical problem in women before the age of 65, and in men before the age of 85. There is no precise dividing line between normality and osteoporosis and the latter can be detected radiologically only when about 40% of the skeleton has been lost. There is now evidence that the major cause of osteoporosis in ageing women is the change in their hormonal environment after the menopause. Disuse (secondary to the generally reduced level of activity in the elderly) may also play a part. It is also suggested that loss of bone in the elderly may be due in part to osteomalacia (p. 288) as well as to osteoporosis.

The condition is characterised by a reduction in the amount of bone in the skeleton, which is only radiologically manifest when approximately 40% of the skeleton has been lost. At this time the cortices of the long bones are noticeably thinner and cancellous bone less dense than normal. As a consequence of the latter change, the invertebral discs may intrude into the centres of the vertebral bodies to produce a typical 'fish head' appearance. Histologically the bone is perfectly normal and there are no demonstrable metabolic changes.

The disease itself is symptomless and only constitutes a clinical problem in so far as osteoporotic bone is more liable to fracture than normal bone. The fractures commonly associated with senile osteoporosis are Colles' fracture, fractures of the proximal humerus, crush fractures of the vertebral bodies, fractures of the femoral neck and intertrochanteric fractures of the femur. The first two and the last of these fractures are always associated with a clear-cut history of a fall and as such are perhaps as much due to the unsteadiness of the elderly as to their osteoporosis. Fractures of the vertebral bodies and of the femoral neck, on the other hand, may occur without a history of injury and there is now evidence that they represent the end-result of progressive fatigue fracture of isolated trabeculæ. Such fractures can be attributed to the increased stresses which osteoporotic bone must encounter because of its reduced mass.

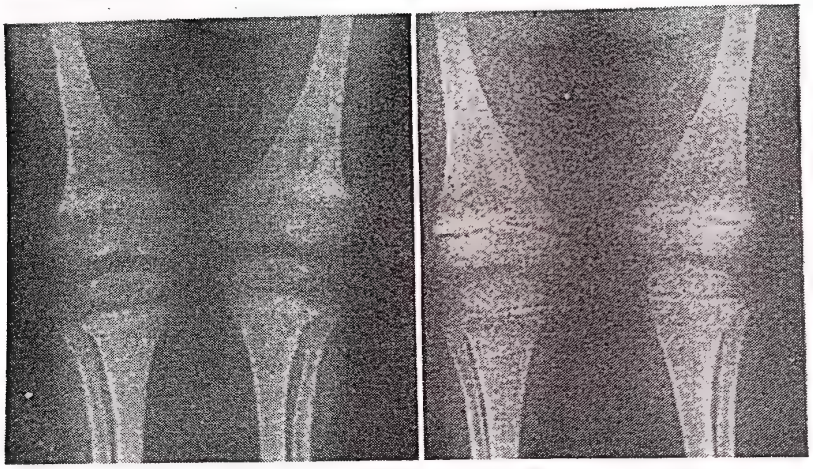
Fractures present either obviously, in the case of the Colles' fracture or fracture of the femoral neck, or as back pain in the case of compression fractures of vertebral bodies. The fracture should be treated on its own merits, ignoring the presence of osteoporosis, which does not interfere with healing. No specific treatment is available for osteoporosis itself.

DEFICIENCY DISEASES AFFECTING BONE

A deficiency of certain vitamins may lead to abnormalities in the skeleton. In this section these diseases will be mentioned only in the briefest outline in so far as the bony complications demand orthopædic treatment. The student is referred for a more detailed treatment of the diseases themselves to appropriate textbooks.

Rickets.—Rickets is due to a dietary or absorption deficiency of Vitamin D. Uncalcified bone matrix is deposited normally but fails to calcify. Histologically, the bone contains large areas of uncalcified matrix which is known as osteoid. The disease affects both bones formed by endochondral ossification and bones, such as the skull, which ossify in membrane.

The disease usually presents in infants, but may develop at any time during the period of growth if the diet becomes deficient in vitamin D. Clinically, characteristic abnormalities develop in the skeleton: the costochondral junctions enlarge to cause the 'ricketed rosary', the long bones bow under the body weight, the skull develops frontal bosses, and the pelvis becomes triradiate. In general the stature is stunted (figs. 312–314).



(*a*) (*b*)

FIG. 312.—Rickets: (*a*) The active state; (*b*) The healing state.

FIG. 313.—Rickets, showing the deformed legs and pot-belly.

Treatment.—The treatment of the disease itself consists of the administration of vitamin D. Early bony deformities may respond to appropriate splinting, but if they are more than trivial they will require correction by manual osteoclasis in the third and fourth year of life, or osteotomy thereafter. The tibia is the bone most commonly requiring orthopædic treatment.

Osteomalacia is the analogue of rickets occurring in the adult skeleton. Once again excessive osteoid is demonstrable histologically and the bones become unduly soft so that they deform under the body weight. Treatment consists of correction of deformities by osteotomy where necessary and practicable, together with the administration of vitamin D.

Other Causes of Excessive Osteoid in Growing and Adult Bones.—In children phosphaturia (synonyms—renal tubular rickets, vitamin D resistant rickets), and Fanconi's syndrome (amino acid-uria) both produce the changes of rickets. In adults renal tubular acidosis produces the changes of osteomalacia. Renal failure occurring from whatever cause in children may produce dwarfism and occasionally the appearance of rickets, whilst in the adult it occasionally produces osteomalacia and/or osteitis fibrosa. Osteoid tissue is often present in excess in hyperparathyroidism, together with the more specific lesion of osteitis fibrosa.

Scurvy.—Scurvy is a deficiency disease attributable to a lack of vitamin C. In the skeleton endochondral ossification ceases but chondrocyte proliferation continues. As a consequence a chaotic state of affairs develops in the epiphyseal line: fractures may occur following insignificant trauma and hæmorrhages are common. Hæmorrhages occurring either around the epiphyseal line or subperiostally in the shaft, may ossify to give rise to bony swellings.

Treatment consists of the administration of vitamin C.

FIG. 314.—Rachitic tibia showing abrupt curvature in the lower third of the bone, and well-marked buttress formation.

ENDOCRINE DISEASES AFFECTING BONE

Adrenalcorticosteroids in excess produce osteoporosis. This may occur either secondarily following increased stimulation from the pituitary or primary as a consequence of an adrenal cortical tumour. High doses of steroids may be administered therapeutically and have the same effect of reducing skeletal mass. This complication occasionally develops during the course of the treatment of rheumatoid arthritis and greatly increases the disability due to the disease itself.

Disorders of the pituitary may affect the skeleton not only indirectly via the adrenal cortex, but also directly. A deficiency of growth hormone developing during the growth phase produces pituitary dwarfism. Excessive growth hormone consequent upon the development of a pituitary adenoma produces pituitary gigantism if the tumour develops before the epiphyses have closed, and acromegaly if it develops after the epiphyses have closed. No orthopædic treatment is available for any of these conditions.

Hyperparathyroidism affects the skeleton. The disease itself is dealt with in Chap. 34. The bone changes in hyperparathyroidism retain the name (osteitis fibrosa cystica) which they were given when they were thought to represent a separate disease entity. Histologically, marked osteoclastic activity can be seen and the resorbed bone is replaced with fibrous tissue to produce the so-called 'brown tumours' (see Giant Cell Tumour, p. 246). As a consequence, patchy osteolytic lesions develop throughout the skeleton and pathological fractures may occur through them. It is of particular diagnostic importance that resorption affects the terminal phalanges in the hand and the alveolar margins in the jaws, so that the radiological appearances of the hands and jaws are characteristic. The blood chemistry is abnormal: the serum calcium is raised, the

Guido Fanconi, Contemporary. Emeritus Professor of Pædiatrics, Zürich, Switzerland. Described this syndrome in 1936.

serum phosphorus lowered, and the alkaline phosphatase usually somewhat raised.

Orthopædic treatment is required only for pathological fractures. These are treated on their merits. They unite satisfactorily provided the underlying endocrine disease is treated.

CHAPTER 18

DISEASES OF MUSCLES, TENDONS AND FASCIÆ

NON-ARTICULAR RHEUMATISM

'NON-ARTICULAR RHEUMATISM' is a poor, but not easily abandoned, name for a group of common conditions the pathology (or pathologies) of which are not understood. The conditions present as pain localised to the aponeurotic attachment of muscle to bone. The commonest sites for this to occur are 1. the attachment of the extensor muscles of the forearm to the lateral epicondyle of the humerus (where the condition is called 'tennis elbow'), 2. the attachment of the flexor muscles to the medial epicondyle (' golfer's elbow '), 3. the attachment of the rotator cuff of shoulder muscles, especially the portion made up by the tendon of the supraspinatus muscle, to the greater tuberosity of the humerus, 4. the attachment of the ligamentum patellæ to the patella or the tibia, 5. the attachment of the Achilles' tendon to the os calcis, 6. the attachment of the plantar fascia to the os calcis. Similar symptoms commonly develop in the muscles of the back and it is possible that here they are due to the same pathological process affecting the bony attachment of one of the back muscles. In the back, however, localised pain of this kind has been attributed to reflex muscular spasm arising from some (unknown) deep-seated lesion in the spine or alternatively to ' fibrositic nodules '. (The terms ' fibrositic nodule ' and ' fibrositis ', like the term used here ' non-articular rheumatism ', are meaningless and do not advance our understanding of the condition but at least the latter does not imply a knowledge of the pathology.)

The tender area, especially at the lateral epicondyle of the humerus and at the attachment of the rotator cuff, has been explored on various occasions but significant morbid anatomical features have not always been demonstrated. It seems that the condition is caused by a tear in the collagen fibres attaching the muscle to the bone which, because it is repeatedly loaded does not heal satisfactorily. The tear may be caused by overt injury, by the loads imposed in excessive but normal activity (as for example, at the elbow, by typing) or by weakening of the tissues following an interruption of their blood supply (as for example happens in the rotator cuff and possibly the Achilles' tendon).

The specific features of these lesions are as follows:

Tennis Elbow.—The patient complains of pain in the elbow at rest and in particular when he uses the hand and hence contracts the wrist and finger extensors. The attachment of the extensor muscles of the forearm to the lateral epicondyle is tender, and active resisted contraction of the extensor muscles of the fingers or the wrist provokes pain at the elbow.

Golfer's Elbow.—This is a precisely similar condition to tennis elbow,

save that it affects the attachment of the flexor muscles of the forearm to the medial epicondyle. Tenderness is often less well localised than in tennis elbow (and treatment is even less satisfactory).

Supraspinatus Tendonitis.—In this condition pain is felt in the shoulder, especially on abduction and rotation, and localised tenderness is present over the insertion of the supraspinatus tendon.

A feature of supraspinatus tendinitis or of any painful pathological process around the shoulder is the rapid onset of shoulder stiffness. This is probably to be attributed to the close proximity of the humerus to the acromion so that adhesions readily form between the two bones which limit movement of the humerus on the scapula.

In supraspinatus tendonitis, the pathology is a little more clearly understood than in other examples of this condition. Injection studies of post-mortem material have shown that the blood supply to the supraspinatus tendon commonly becomes defective in middle and later years—probably because of compression of the tendon between the acromion and the proximal humerus. As a consequence the tendon is prone to degenerate and may even rupture spontaneously (see Tendon Ruptures, p. 293). Progressive calcification of the tendon may develop and be obvious radiologically (fig. 315).

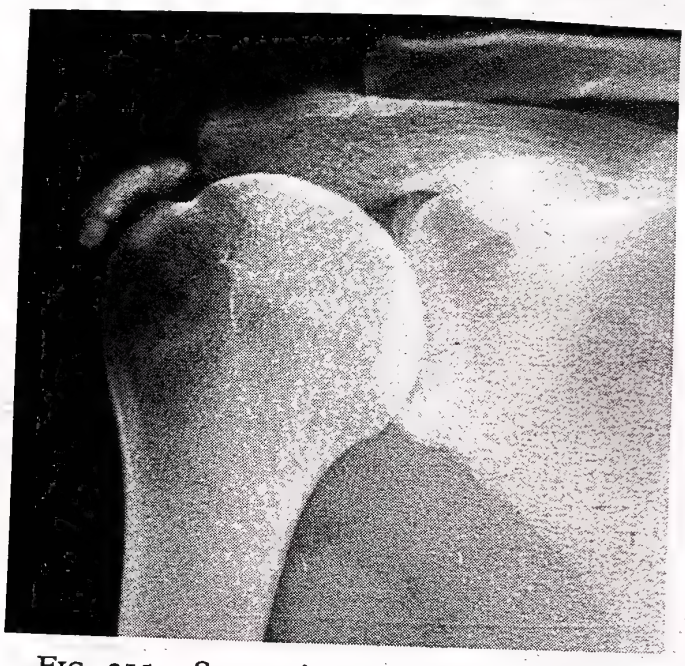


FIG. 315.—Supraspinatus calcification. Faint shadow of calcium seen lying above the head of the humerus just lateral to the outer margin of the acromion.

Pain occurs on moving the humerus, especially as the inflamed portion of the supraspinatus tendon passes between the head of the humerus and the acromion: this occurs in the middle third of the abduction arc so as to give a typical clinical picture, described as the *painful arc syndrome* in which the patient is freely able to abduct his arm through the initial 30°, has pain raising the arm through the next 30°, but thereafter is able to abduct the arm painlessly. Pain recurs as the arm is brought down to the side through the same mid 30° of abduction. As a consequence of the pain provoked by movement, such patients naturally tend to protect the shoulder by holding it still. Adhesions now form which limit shoulder movement mechanically. Thus the patient initially complains of pain in the shoulder and soon thereafter notes stiffness. The pain and stiffness tend, in the absence of treatment, gradually to increase for 3 months but thereafter remain static—usually for a further period of 3 months. During the latter half of this second period pain gradually settles in the shoulder so that now the patient finds it is more

comfortable to move it. Probably as a consequence of increasing comfort, the range of movement gradually increases until by about the end of 9 months the whole cycle is completed and the joint returns essentially to normal. This sequence of events has been given several names of which probably the best is *frozen shoulder*. It should be clearly understood that a frozen shoulder is not a specific clinical or pathological event: it is merely a response of the shoulder to any locally painful pathological process.

Patellar Tendonitis.—Occasionally the ligamentum patellæ may become painful and tender in adults either at its attachment to the patella or at its distal attachment to the tibia. Pain is felt on active extension of the knee.

Plantar Fasciitis is discussed on p. 316.

Achilles' Tendonitis is described on p. 316.

Treatment.—No satisfactory treatment is available for these conditions. The patient should be advised that the condition is normally self-limiting and that he should, so far as possible, avoid powerful contraction of the involved muscles without keeping the joint itself still: movement in the absence of powerful muscular activity is the objective. Local injections of 25 mg. of hydrocortisone and local anæsthetic into the tender area sometimes bring about dramatic relief. When the supraspinatus tendon is calcified it may suddenly become excruciatingly painful. Such pain can be relieved by incision and evacuation of the calcareous deposit. Surgical treatment is required, rarely, if these conditions persist and are severely painful. The procedures aim to release or decompress the involved tendon but, like conservative measures, they do not always bring symptomatic relief.

PATHOLOGICAL TENDON RUPTURES

The supraspinatus tendon may rupture spontaneously following interruptions in its blood supply in middle aged or elderly adults. The tear may include only the supraspinatus tendon or may extend throughout the rotator cuff. The rupture often occurs following insignificant violence or even as part of normal everyday activities. The patient complains of sudden pain in the shoulder the severity of which usually masks the important physical sign: an inability to initiate abduction. For this reason and because once abduction has been started passively (for example by the patient tilting his body to the affected side so that abduction is initiated by gravity) the deltoid can continue abduction in a normal way, the diagnosis is frequently missed.

The disability, even if the lesion is left untreated, is very slight. This is fortunate since the only form of treatment available is suture of the tendon and this is frequently unsatisfactory—partly because the tendon holds sutures poorly, and partly because the operation often results in adhesion formation and hence in a stiff shoulder. Thus if the patient is prepared to accept the disability, it is probably best to leave the condition untreated.

The long head of biceps brachii may rupture in the bicipital groove. This is probably an attrition rupture and again occurs spontaneously. The

patient complains of sudden pain in the upper arm followed occasionally by a little bruising. The diagnosis is made by asking the patient to flex the elbow against resistance whereupon the affected biceps muscle bunches distally leaving a gap proximally (fig. 316).

Once again the disability is usually trivial and if the patient is prepared to accept it no treatment should be offered. Should the patient miss the slight loss of elbow flexor power which follows this injury, it is feasible to reattach the proximal end of the biceps to the humerus itself.

FIG. 316.—Spontaneous rupture of the tendon to the long head of the left biceps muscle. Note that when the muscle contracts the long head bunches near the elbow.

The rectus femoris muscle may be ruptured by normal loads at its attachment to the patella. This condition is discussed on p. 379.

The Achilles' tendon may rupture after insignificant violence—probably because it is weakened by vascular insufficiency as is the supraspinatus tendon. This condition is discussed on p. 370.

TENDON SHEATHS

Simple Tenosynovitis.—This condition follows excessive or unaccustomed use, and is commonly seen in connection with the extensor tendons of the hand and the Achilles' tendon. Pain and local œdema are present and a characteristic soft crepitus (like the rustling of tissue paper) is sometimes palpable when the fingers are moved. The condition is treated by resting the tendons involved, which in the case of the extensors of the hand must of course involve the fingers. A minimum of 3 weeks absolute rest on a splint is usually required, followed by a period of gentle but progressive activity.

Suppurative Tenosynovitis.—This condition affects particularly the flexor tendons of the hand since these sheaths are far more commonly injured than those elsewhere in the body. The condition is discussed on p. 193.

Stenosing Teno-Vaginitis.—This is a condition of unknown ætiology in which the sheath of a tendon thickens, apparently spontaneously, so as to entrap the tendon. Pain and limitation of movement result. The condition is most common at the common sheath of the abductor pollicis longus and extensor pollicis brevis tendons of the wrist (*de Quervain's disease*) and at the retinaculæ of the flexor tendons of the fingers and thumb in the palm ('*trigger finger*'). In the palm, the flexor muscles are sufficiently strong to continue forcing the tendon through the diminished gap in the flexor reticulum. The flexor tendon as a consequence gradually develops a constriction under the retinaculum and a bulge distal to it. Finally, the flexor muscles may force the bulge through the retinaculum but the extensor muscles may be insufficiently powerful to extend the finger thereafter. The finger now snaps as it passes through the constriction and finally locks in a

Fritz de Quervain, 1868–1940. Professor of Surgery, Berne, Switzerland. Described Stenosing Teno-Vaginitis in 1895.

position of flexion from which attempts passively to extend the finger are painful.

Both de Quervain's disease and trigger finger can be cured by dividing the appropriate retinaculum surgically. It might be expected that following this operation the involved tendon would subluxate but in practice this never occurs.

Carpal Tunnel Compression of the Median Nerve.—The carpal tunnel is formed by the flexor retinaculum anteriorly and by the distal row of the carpus posteriorly (fig. 317). The median nerve and the flexor tendons pass through it. Sometimes as a consequence of some clearly demonstrable pathology such as rheumatoid arthritis involving the synovial sheaths of the flexor tendons, the contents of the tunnel increase in bulk and compress the median nerve. Usually, however, signs of median nerve compression develop without any obvious increase in bulk in the contents of the tunnel. The ætiology of this condition is unknown but it may be an example of *stenosing teno-vaginitis*, in this case affecting the flexor retinaculum. The condition usually occurs in otherwise normal individuals but is associated with myxœdema (Chap. 33) and pregnancy.

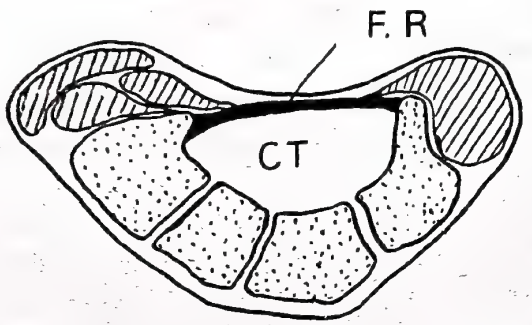

FIG. 317.—Carpal tunnel formed in the cavity of the carpus by the flexor retinaculum.

The patient complains of pain which classically is localised to the distribution of the median nerve in the hand but which may be felt anywhere in the arm. The poor localisation of the pain may make the diagnosis difficult since it is easy to confuse the condition with other causes of pain in the arm, for example with cervical spondylosis. Commonly the pain is worse at night and the patient may notice that he is then relieved by hanging the hand over the edge of the bed, a feature of the history which is almost diagnostic of carpal tunnel compression of the median nerve. As the compression increases in severity more obvious neurological symptoms develop including paræsthesæ, numbness, inco-ordination, and finally frank weakness in the muscles of the hand innervated by the median nerve (of which the easiest to examine is abductor pollicis brevis, wasting of which is obvious). The fingers, apart from being inco-ordinated, may also feel stiff, especially first thing in the morning, a symptom which is probably attributable to compression of the flexor tendons themselves. Examination of the hand is frequently negative but may demonstrate slight tenderness over the carpal tunnel, an increase in pain if the fingers and wrist are held fully flexed for a few moments, and the presence of abnormal neurological signs in the distribution of the median nerve in the hand. Conduction studies on the median nerve demonstrate delay at the carpal tunnel.

Treatment.—Whatever may be the pathology, simple decompression of the tunnel by longitudinal incision of the flexor retinaculum cures the condition, often in a dramatic fashion. Rheumatoid tenosynovitis may in addition require synovectomy.

FASCIÆ

Dupuytren's contracture is a localised thickening of the palmar, and rarely the plantar, fascia. The fascia thickens to form nodules and contracts so that eventually the affected fingers are drawn into flexion. The overlying skin of the palm adheres to the fascia. Most commonly the disease starts near the base of the little finger and soon draws that finger into the palm of the hand (fig. 318). Later it involves the ring finger and, less often, the long and then index fingers, in the same way. In long-standing cases permanent changes take place in the metacarpo-phalangeal and the proximal interphalangeal joints which render futile any attempt to straighten the fingers.

The pathology of the condition is unknown. In the past it was believed to be due to repeated trauma to the palm. However, it is known to be familial and is frequently seen in patients who have never experienced such trauma. That it is so often bilateral and may involve the feet is also against any traumatic origin. It is more common in men than in women and may be seen in cirrhotics and epileptics who take sodium hydantoin.

Treatment.—Early cases can be treated by night splintage and gentle stretching by the patient. More advanced changes require excision or (less satisfactorily) multiple division of the affected fascia. This operation can give excellent results in all but severe longstanding cases where permanent joint changes have developed. In these cases it may be advisable to amputate the affected finger.

FIG. 318. — Dupuytren's contracture; note puckering of adherent skin in the palm.

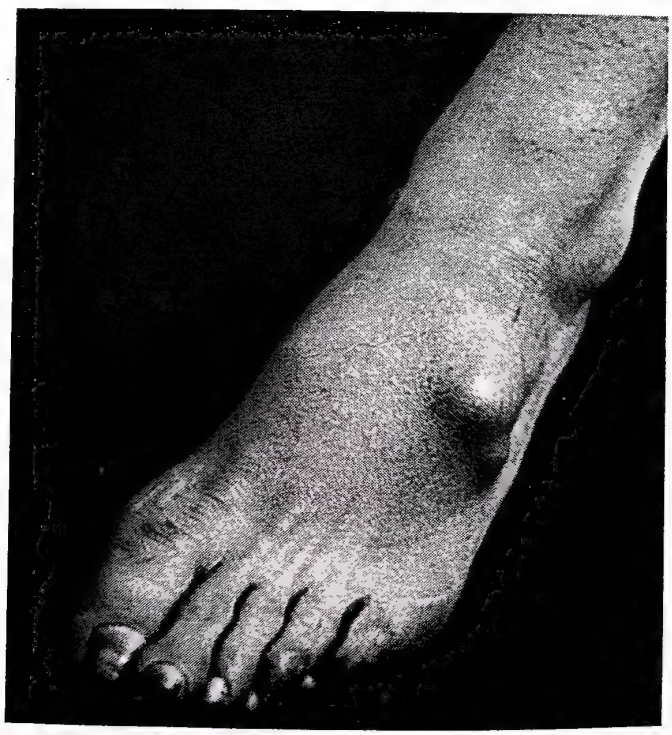

FIG. 319.—Simple ganglion on the tendon of the peroneus brevis muscle.

Baron Guillaume Dupuytren, 1777–1835. Surgeon, Hôtel Dieu, Paris. Described Contracture of the Palmar Fascia in 1831.

GANGLIA

Ganglia are localised, tense (but often painless) cystic swellings containing clear gelatinous fluid. They often communicate with, and are always adjacent to, a tendon sheath or the capsule of a joint. Their origin is uncertain but they are probably caused by leakage (and subsequent fibrous encapsulation) of synovial fluid through the capsule of a joint or tendon sheath. They are sometimes predisposed to by injury. Simple ganglia are most commonly found on the dorsum of the wrist and the foot (fig. 319). Occasionally minute ganglia develop on the flexor aspect of the fingers which although small, are exquisitely painful and tender.

BURSÆ

Simple Bursitis.—Acute traumatic bursitis follows injury or unaccustomed exercise, for example inflammation of the bursa anterior to the Achilles' tendon may follow a cross-country run.

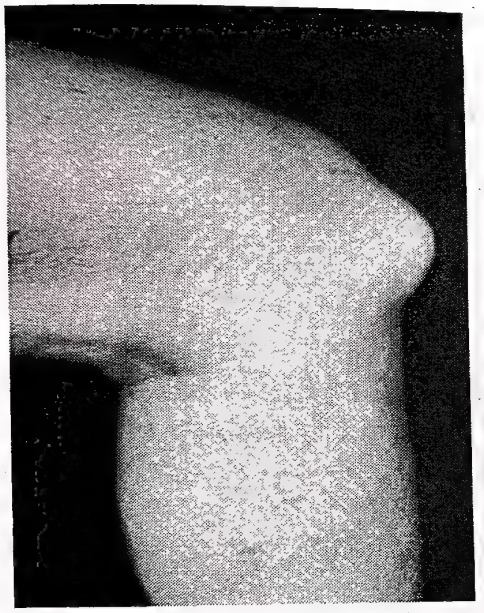

FIG. 320.—Housemaid's knee.

FIG. 321.—Chronic olecranon bursitis.

Chronic Bursitis.—This is the result of repeated pressure or slight injuries, to anatomical bursæ. Examples are involvement of the *prepatellar bursa* (housemaid's knee, fig. 320) or *olecranon bursa* (students or miner's elbow, fig. 321), and subsartorial bursitis (fig. 322).

Enlargement of the *semimembranosus bursa* is common in children (fig. 323). The cyst is aspirated if it causes disability, but most cysts disappear spontaneously. Semimembranosus bursæ, if they communicate with the knee joint, sometimes enlarge when there is an effusion in the joint, for example as a result of osteoarthrosis, and form one variety of *Baker's cysts*. (In general, synovial cysts in the popliteal fossa, which are known as Baker's cysts, may arise as described above from the semimembranosus bursa or, in rheumatoid arthritis of the knee, from a posterior rupture of the capsule of the joint.)

William Morrant Baker, 1839–1896. Surgeon, St. Bartholomew's Hospital, London. Described these cysts in 1877.

Acute Suppurative Bursitis.—This is due to direct infection by penetrating wounds, or by the spread of local cellulitis. The prepatellar bursa is the most commonly involved. A 'sympathetic' effusion in the knee joint sometimes follows. Confusion with infective arthritis should be avoided,

FIG. 322.—Subsartorial bursitis.

FIG. 323.—Semimembranosus bursitis.

as in the latter condition any attempt to move the joint is painful, and at the knee pain is elicited by pressure in the popliteal space (see p. 212). The infection usually responds to chemotherapy, but if pus is already present incision and drainage will be necessary.

Excision of Bursæ.—Persistent trouble with a subcutaneous bursa (e.g. olecranon, prepatellar) may only be resolved by complete excision of the whole of the endothelial lining and surrounding 'capsule' under a general anæsthetic.

Adventitious bursæ form as a result of prolonged pressure over bony prominences. The term 'adventitious' means that no anatomical bursa was present at the site of the newly formed cyst, and that it was generated in connective tissue as a result of repeated shearing motion in the tissue. One of the commonest of such bursæ is that over the medial aspect of the head of the first metatarsal in hallux valgus (p. 312). Like anatomical bursæ, adventitious bursæ can become infected.

CHAPTER 19

NEUROLOGICAL DISORDERS AFFECTING THE MUSCULO-SKELETAL SYSTEM

In spite of the wide variety of diseases which affect the nervous system the consequences for the locomotor system tend to follow a common pattern so that it is possible to lay down certain principles of management which have a general application. The loss of motor power and sensory faculty require separate consideration, although obviously both are commonly present together.

PARALYSIS

The consequences of paralysis are twofold:—

1. *Loss of Function.*—This results from the failure of action of the affected muscles and, while many of its consequences are self evident, the loss of joint stability is of particular importance.

2. *Liability to Deformity.*—In the adult this is seldom a serious problem for although there is a tendency for contractures to develop in the non-paralysed muscles these are relatively easily controlled by passive movements and splintage. In the growing child however the problem is much more serious for here there is a disturbance of growth. For reasons not well understood the non-paralysed muscle becomes relatively shorter than its paralysed fellow so that the joints concerned become fixed in the direction of the acting muscles. These changes may be followed by secondary bony deformity leading to even greater fixity of the joint. In addition to these particular deformities there may be an overall shortening of the limb, again for reasons which are not readily apparent.

It is important to appreciate that these forces of unbalanced growth are almost irresistible and just as a solid pavement yields before the persistence of a penetrating weed so also will splints and calipers fail if they are used alone in an attempt to correct or even to control these deformities. On the other hand it must be remembered that a totally paralysed limb has no tendency to deform since there is no imbalance to distort it, although its overall dimensions are usually reduced. In these circumstances gravitational force may have some distorting effects particularly in the production of equinus deformity of the foot, but this is easily resisted.

The Management of Paralysis

This has 3 main objectives as follows:

1. The Elimination of Deformity

In the adult the emphasis should be on prevention, with the institution of passive movements and splintage as soon as possible. If fixed deformity does develop simple tenotomy will usually be sufficient to bring it under control.

In the child splintage alone will not suffice and it will usually be necessary surgically to divide the contracted structures and in particular the tendons of the unopposed muscles acting on the joint. Once these deforming forces have been eliminated it may be possible to complete the correction by serial casts and splintage. Bony deformity may also be corrected at this stage providing that the epiphyses are not interfered with.

2. The Prevention of Recurrent Deformity

In the child this implies the restoration of muscle balance across the joint. This can be achieved either by reinforcing the paralysed group or by weakening the non-paralysed muscles, although in practice the methods are often combined.

Reinforcement of the Paralysed Group.—This may be achieved by *tendon transfer* in which the tendon of a normally acting muscle is inserted in a new site while preserving the origin of the muscle and its nerve supply thereby altering its mode of action. If this is to be undertaken there are certain principles which must be observed.

(i) The transferred tendon should itself be working to full power. Tendon transfer results in a significant loss of power so that if the tendon of a partially paralysed muscle is transferred it may be reduced to total impotence in its new situation.

(ii) Deformity in the joint must have been previously eliminated. Tendon transfer alone cannot be relied upon to correct an established deformity.

(iii) The action which is expected of the transferred tendon should be as close as possible to its original action to facilitate re-education. This is of particular importance in the lower limb where the powers of re-education are limited.

(iv) The path of the transferred tendon should be as direct as possible.

(v) The transferred tendon should if possible be re-inserted into bone rather than into another tendon.

Weakening of the Non-paralysed Group.—This is the only method available if tendon transfer is not possible. It must always be remembered that a flail joint will not deform, so that if only one muscle is left acting across a joint muscle balancing will be impossible and it is better to eliminate all activity. Methods for weakening an active group are:—

(*a.*) *Tenotomy.*—Spontaneous reconstitution is possible so that if permanent loss of power is required it is better to resect a length of tendon.

(*b.*) *Elongation.*—Z-elongation of a tendon results in a considerable but not total loss of power.

Both of these procedures may be indicated for correction of the deformity and it is often convenient to carry out the rebalancing procedures at the same time.

Denervation.—Division of the motor nerve to the overacting muscle is sometimes indicated (for example, the soleus and adductor group).

3. The Re-establishment of Joint Stability and the Restoration of Function.

Joint stability may already have been achieved by tendon transfer together with some restoration of function, but if not, then the choice lies between arthrodesis of the joint, which is normally possible only in the adult, or external splintage which is the solution usually adopted in children until they are old enough for bony procedures. The methods commonly employed in the lower limb are as follows:—

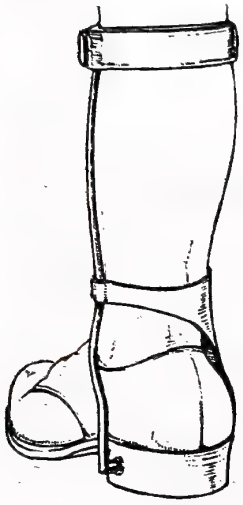

FIG. 324.—Outside iron and inside 'T' strap to control valgus deformity.

Subtalar Instability.—Below knee iron and T strap (fig. 324). The iron is usually placed on the side of greater weakness. Thus if the foot tends to valgus an outside iron and inside T strap is normally used. In many instances it is better to use a double iron. When skeletal maturity of the foot is attained (about 12 years) arthrodesis of the subtalar complex (triple fusion) can be undertaken (fig. 325) and the appliance discarded. Stabilisation at an earlier age can be achieved by means of an extra-articular graft between talus and calcaneum inserted across the sinus tarsi (Grice). Since this does not interfere directly with joint cartilage the disturbance to growth is minimised.

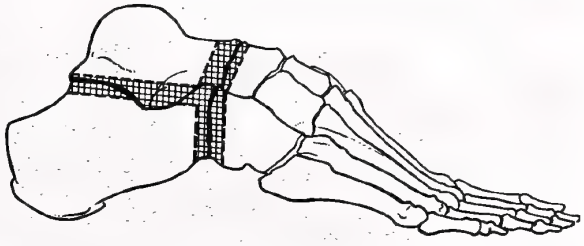

FIG. 325.—Shaded areas denote the bone to be removed in triple arthrodesis (triple fusion).

Ankle Instability.—A double leg iron is used. If there is a tendency to equinus this is resisted by a torsion bar in the heel or a toe raising spring (fig. 326). An appropriate stop can be incorporated if there is calcaneous deformity. A cosmetically more attractive solution for drop foot has become available more recently with the development of new plastic materials. This consists of a flexible back splint which is worn inside a normal shoe. Ankle arthrodesis is usually inadvisable and definitive correction of equinus or calcaneous deformity of the foot is usually obtained at the subtalar level by a modification of triple fusion.

FIG. 326.—Toe raising spring used in conjunction with a below knee iron to control equinus deformity.

Knee Instability.—This can be controlled by a double leg iron extending up to a thigh corset and may be provided with an unlocking device to permit sitting. The

David Stephen Grice, 1914–1960. Professor of Orthopædic Surgery, University of Pennsylvania School of Medicine, Philadelphia, U.S.A.

stability of the knee is dependent on the quadriceps muscle and if this is paralysed the patient cannot normally stand without a brace. If the knee is entirely flail, however, some patients can achieve stability by a trick action in which the knee is forced into hyperextension (fig. 327). Note that in this position the ankle is in some equinus. Arthrodesis of the knee is seldom indicated for paralysis.

FIG. 327.—Complete quadriceps palsy in the right leg. The patient is able to stabilise the knee by bracing it back into hyperextension.

Hip Instability.—This is usually caused by paralysis of the glutei. Loss of the abductors results in a lurching gait which may be improved by the use of sticks but if the gluteus maximus and hamstrings are paralysed the patient is usually unable to stand upright without the trunk falling forwards. In these circumstances the bracing may need to be carried above the waist. Some patients with flail hips are able to stand by hyperextending the joints relying on the strong anterior capsule of the joint to support them. Arthrodesis is never indicated for paralysis affecting the hip.

Gluteal paralysis creates a special problem for the hip if it arises within the first few years of life. In the presence of functioning adductor and flexor groups dislocation is likely and must always be looked for when there is flexion and adduction deformity.

Tendon Transfer.—The use of tendon transfer in the prevention of deformity has already been mentioned and these procedures may also be used for the restoration of function. The very fact that a joint has been arthrodesed may liberate certain muscles for this purpose.

On the whole tendon transfers are very satisfactory in the upper limb where each muscle appears to have separate cortical representation so that rapid re-education can be expected. In the lower limb, however, there appears to be central representation of whole joint movements rather than of individual muscles so that re-education of a single muscle within a group is more difficult. The expectation of useful function from a lower limb transfer is therefore much less than in the upper limb particularly if it is expected to act in a different phase of the gait than formerly and the ability to convert shows much individual variation. The chief value of such transfers is probably the prevention of deformity although certain operations, such as the lateral repositioning of the tibialis anterior and forward transfer of tibialis posterior through the interosseous membrane can usually be relied on to produce worthwhile function.

PARALYSIS FOLLOWING PERIPHERAL NERVE INJURIES (p. 482)

Approximately 18 months after nerve division irreversible changes will have occurred in the motor end plates unless re-innervation has occurred, so that further recovery cannot be expected after this time and secondary reconstruction may be indicated. The procedures which are commonly carried out are as follows:—

Circumflex Nerve.—Loss of shoulder abduction is the complaint and a useful range of this can be restored by arthrodesing the shoulder providing that the scapular rotators are intact. It must be remembered that this will entail a loss of rotation of the arm.

Musculocutaneous nerve.—The brachioradialis may provide sufficient flexor power at the elbow to make reconstruction unnecessary but if not, additional flexor power can be obtained by advancing the origin of the forearm flexors further up the humerus (Steindler).

Radial nerve.—Various combinations of tendon transfers are available depending on the level of the lesion but at least one wrist flexor should be preserved to prevent hyperextension. A suitable combination for a high lesion is as follows:—

Pronator teres into extensor carpi radialis, longus and brevis.

Flexor carpi ulnaris into long finger extensors.

Palmaris longus into long thumb extensor.

Median Nerve.—In the more common low lesions of the nerve the main disability results from the sensory loss and weakness of opposition. The latter may be improved by tendon transfers, the simplest of which employs the flexor sublimis tendon to the ring finger. The direction of pull of the tendon is made appropriate by causing it to pass first through a pulley constructed on the ulnar side of the wrist. In high lesions the disability is much greater but some improvement in hand flexor function can be achieved by transfers using the brachioradialis and one of the wrist extensors.

Ulnar Nerve.—The disability from a lesion of this nerve is often slight and reconstruction may not be called for. However, paralysis of the adductor pollicis results in weakness of the pinch grip which may be reinforced by tendon transfer usually with one of the radial wrist extensors which has been suitably prolonged.

Brachial Plexus.—A wide variation in the pattern of residual paralysis can result from this and some of the above procedures may be appropriately combined. A total unrecovered paralysis results in a flail arm which is usually best treated by amputation through the humerus, together with the arthrodesis of the shoulder. If the scapular rotators are preserved some abduction at the shoulder will then be possible and may be used to activate a prosthesis. The decision to carry out this procedure should not be too long delayed or the patient will have become permanently adapted to the one-armed way of life.

Lateral Popliteal Nerve.—Many patients are content to control their foot drop with a toe-raising spring (p. 301) or orthosis[1] but some active dorsiflexion may be achieved by a transfer of the tibialis posterior through the interosseous membrane on to the dorsum of the foot.

MENINGOMYELOCELE (see also p. 461)

This is the commonest of the severe forms of spina bifida and is almost invariably accompanied by some paralysis in the lower limbs which is often extensive and comprises a mixture of both upper and lower motor neurone types. Deformities are often present at birth particularly flexion adduction contractures at the hips, which may be dislocated, and deformities of the

[1]Orthosis = a form of splint.

Arthur Steindler, 1878–1959. Professor of Orthopædic Surgery, State University, Iowa City, Iowa, U.S.A.

foot (fig. 328). These are not to be regarded as separate associated abnormalities; they are secondary deformities and usually correspond with the distribution of the paralysis. Without treatment progressive deformity corresponding with the imbalance can be expected.

FIG. 328.—Child with meningomyelocele. There is fixed flexion and adduction of the hips, extension of the knees and calcaneous deformity of the feet. Voluntary innervation was absent below the fourth lumbar segment.

Management.—The management follows general principles with the object of providing straight limbs with plantigrade feet at the same time preserving joint mobility and the important ability to sit comfortably. Certain special features should be mentioned.

Foot Deformity.—This has the first priority in the orthopædic management. Corrective splintage may be used as in non-paralytic talipes but caution must be used since the feet are anæsthetic. In very resistant cases it may be wise to perform early division of the deforming tendons. Once the deformity has been corrected muscle rebalancing should be carried out if possible but in many instances there will be insufficient muscles under voluntary control to do this. Spastic muscles should not be used for transfer and in these circumstances it may be better to abolish all muscle activity in the foot and to support it in a caliper until 11 or 12 years of age when it can be stabilised by triple fusion.

Hip Deformity.—Gluteal palsy is common in this condition. Where the flexor and adductor groups are strong the hips will either be dislocated at birth or will dislocate in the first few months. By the end of the first year about half of all untreated children with the condition will have dislocated hips. The deformity should be reduced as soon as possible by open tenotomy of the adductors, holding the hip reduced by some form of splintage in abduction and extension. As soon as the child is old enough (about 1 year) the muscle imbalance must be corrected. The adductors have already been weakened and the flexors must now be treated similarly by dividing the tendon of the iliopsoas which is the most important deforming force. At the same time an attempt may be made to reinforce the missing abductors and extensors by transferring the iliopsoas tendon to the back of the greater trochanter (Sharrard.)

Rotation and other deformities at the hip may be corrected by femoral osteotomy at any age since the epiphyses are not interfered with.

CEREBRAL PALSY (Spastic paralysis)

This condition which presents in childhood is the result of intracranial damage involving the cerebral hemispheres or the basal ganglia. It sometimes results from a congenital malformation of these structures, whilst in

William John Wells Sharrard, Contemporary. Orthopædic Surgeon, Sheffield Royal Infirmary, Sheffield, England.

others the damage is acquired either during birth or soon after. The result in all is a varying degree of limb paralysis of the upper motor neurone type in which spasm is prominent, together with difficulties in co-ordination (ataxia) and uncontrolled purposeless movements (athetosis).

The pattern is very varied and one or all limbs may be involved. The commonest pattern is of a symmetrical spastic paresis of the lower limbs with a tendency to flexion and adduction of the hips with flexion of the knees and equinus of the feet. In the upper limb there is typically flexion of the wrist and fingers with adduction of the thumb and pronation of the forearm but ataxia and athetoid movements are often present in addition.

The mechanism of deformity and disability is very complex and is by no means exclusively due to the overactivity of the spastic muscles. Some muscle groups may exhibit normal tone and yet be significantly weakened and, particularly in younger children, the limbs may be held in particular attitudes due to the persistence of primitive reflexes such as the tonic neck reflex. Many children have serious difficulties with balance and orientation in space and these may have an over-riding effect on their locomotor performance.

Management.—Physical therapy is important, particularly in the reinforcement of weak muscle groups by exercise. Passive stretching of muscles and splintage may help to lessen deformity but their limitations should be recognised. Severe fixed deformity can only be corrected by surgery.

When operations are planned the objectives must be clear. Deformity may require correction in order to assist with the child's general management as for example when tight adductors interfere with dressing and toilet care. If, on the other hand, improved function is the aim then this must be realistic, taking into account the child's I.Q., overall muscle power, co-ordination, etc. Failure to do this will lead to unduly ambitious and unnecessary surgery.

The objects of treatment are as before: the elimination of deformity and the restoration of muscle balance, but in the latter tendon transfer can play only a limited part because of the difficulty in finding wholly normal muscles to transfer. Rebalancing therefore has to be confined to procedures which weaken the stronger groups.

Hip.—Adduction deformity and spasm is the commonest problem and if it interferes with walking or toilet care is an indication for adductor tenotomy.

Adductor Tenotomy.—A skin crease incision is made close to the inguinal ligament and the tendons of adductor longus, brevis and gracilis divided through their tendinous parts as close to the pelvis as possible. It may also be necessary to divide the pectineus and even part of adductor magnus. Both branches of the obturator nerve should be identified. If spasm is prominent it may be justifiable to divide the anterior branch but the posterior branch must be preserved at all costs. If there is also flexion deformity the tendon of the iliopsoas can be divided or elongated through the same wound. The legs are immobilised in an abduction and extension cast for 3 weeks post-operatively.

Flexion and adduction predominance predisposes to hip subluxation which will proceed to full dislocation over a number of years, and strict radiological vigilance is required in its presence. Adductor/abductor imbalance may be restored by weakening the adductors by adductor tenotomy and anterior branch neurectomy and in this way the tendency to dislocate controlled.

Once dislocation has occurred restabilisation is extremely difficult. Another common problem at the hip is produced by internal torsion of the femur tending to an ungainly intoeing gait. This may require a rotation osteotomy for its correction.

Knee.—Flexion deformity is the usual problem and is best dealt with by a transfer of some of the hamstrings to the back of the femur (Eggers). In this way their extensor action on the hip is preserved.

Foot.—Equinus of the heel is extremely common and the child walks on his toes. Sometimes the contracture involves only the gastrocnemius in which case the deformity disappears on flexing the knee. In these circumstances division of the gastrocnemius part of the Achilles' tendon is required. If the entire group of calf muscles is involved an elongation of the Achilles' tendon is indicated. This must be done cautiously as overcorrection may lead to intractable calcaneous deformity.

POLIOMYELITIS (Infantile Paralysis)

This is an acute febrile disease caused by a neurotropic virus whose permanent effect is an irregularly distributed flaccid paralysis caused by injury to the anterior horn cells. New cases of the disease have been practically eliminated in the United Kingdom as a result of mass immunisation. Occasionally cases of paralysis present without a clear history of the acute infection. These are recognisable by the distribution of the flaccid paralysis and the wasting which is almost invariably asymmetrical, involving particularly the proximal part of the lower limbs and the spine and trunk musculature. Sensory disturbance is absent.

Management.—In the initial and recovery phases of the disease orthopædic management is confined to simple splintage to minimise deformity, but after 2 years or so no further recovery can be anticipated and definitive reconstruction can begin. Although almost any pattern of paralysis is theoretically possible a number of deformities occur with some regularity.

Foot.—Pes equinus due to paralysis of the dorsiflexors of the foot. This can be corrected in childhood by a Z elongation of the Achilles' tendon possibly accompanied by a posterior capsulectomy of the ankle. Anterior transfer of tibialis posterior will help to control recurrence.

Pes calcaneus due to calf paralysis.—This can be treated by a transfer of the peronei and the tibialis anterior through the interosseous membrane to the heel. This is useful in preventing deformity but will probably provide no useful active function. Triple fusion will be required eventually in most cases (fig. 325).

Knee.—The ability to stabilise a knee with a paralysed quadriceps has already been mentioned (fig. 327), and if present represents a strong contraindication to correction of equinus deformity of the foot which may result in a loss of power to hyperextend the knee. If the knee flexors are strong it will again be impossible to hyperextend the joint, when transfer of the hamstrings into the back of the lower end of the femur may be helpful.

Hip.—If the paralysis occurs in infancy and affects the abductors subluxation or dislocation may occur. After dividing the adductors transfer of the

George William Nordholtz Eggers, 1896–1963. Professor of Orthopædic Surgery, University of Texas, Galveston, Texas, U.S.A.

iliopsoas to the great trochanter to act as an abductor (Mustard) will prevent progressive subluxation and may also improve the Trendelenburg gait. There is a tendency for the femoral neck to become valgus in these circumstances, further unstabilising the hip. Varus osteotomy may therefore be indicated.

Leg Length Discrepancy.—This may amount to many centimetres, so some correction is required. The normal limb may be shortened by driving staples across the growth plates of the upper tibia and lower femur so that normal growth is slowed, or in an adult the bone shortened by excising a segment of diaphysis. Alternatively the short limb may be lengthened up to 6 cm. by dividing the tibia or femur and producing gradual distraction with skeletal fixation and a screw apparatus. This procedure is contraindicated above the age of 12 years because of the risk of non-union. Whenever possible, the lengthening should be carried out in the tibia where the risk of complications is very much less than in the femur.

Scoliosis.—Muscle imbalance around the vertebral column may produce severe scoliosis with rotary changes as in idiopathic scoliosis (p. 271). However, the curve usually remains a good deal more mobile than in the latter condition. In its most severe form there is a collapsing spine so that the patient cannot even sit up and respiration is embarrassed.

Treatment.—Treatment follows the same lines as in idiopathic scoliosis with correction usually in plaster casts followed by fusion to maintain the correction attained. It should be recognised that this represents a conflict with the basic rules of management since the muscle imbalance remains uncorrected, but there is no alternative in this situation. It is not surprising therefore that there is often recurrence of deformity.

DISSEMINATED SCLEROSIS

This is a slowly progressive disorder resulting from patchy demyelination of the central nervous system. It results in progressive spastic paralysis, usually of the lower limbs. There is a tendency to deform and in particular to develop flexion of the knees and flexion and adduction of the hips. Treatment should therefore be prophylactic with the use of splints and passive joint movement. Unfortunately late cases are often seen and although no growth forces are involved deformity is often severe as it may represent the end result of many years of neglect.

The knees may be treated by tenotomy of the hamstrings followed by serial plasters to increase extension. Flexion and adduction of the hips may be so extreme that surgery in the groin is physically impossible. In these circumstances division of the psoas in the pelvis through a retroperitoneal approach with an intrapelvic division of the obturator nerve will make the situation more manageable. Tendon transfer is never indicated in this condition.

HEMIPLEGIA FOLLOWING A CEREBROVASCULAR ACCIDENT

The pattern of deformity here is very similar to that in cerebral palsy but since the patients are adult it is more easily controlled particularly if physical therapy and splintage are instituted early enough. Occasionally fixed deformity of sufficient severity to require surgery is encountered. Equinovarus of the foot is the commonest problem and this can very satisfactorily be dealt with by elongation of the Achilles' tendon and a division of the tibialis posterior through the same incision. Hamstring tenotomy may sometimes be needed for knee flexion deformity.

William T. Mustard, Contemporary. Orthopædic Surgeon, Hospital for Sick Children, Toronto, Canada.

SENSORY LOSS

This has consequences for both skin and the bones and joints.

Skin.—Because of the lack of protective sensation ulceration is likely particularly in weight bearing areas of which the classical illustration is the penetrating ulcer over the metatarsal heads (fig. 64). The latter is particularly liable to occur if there is accompanying equinus deformity from associated motor loss. In the fingers sensory loss is of particular significance for, apart from the liability to damage, an insensitive finger will not be used even if its motor function is perfect. All attempts at finger reconstruction therefore must make provision for restoration of some innervation. If nerve repair is impossible sensation to the pulp may be restored by a pedicle graft of innervated skin from the tip of another finger, the pedicle including an intact digital neurovascular bundle.

Neuropathic Joints.—Tertiary syphilis was formerly the commonest cause of this condition but as this disease disappears an increasing proportion have become due to other causes including syringomyelia, peripheral neuritis and the rare condition of congenital indifference to pain.

Clinical diagnosis is usually easy due to the remarkable combination of a joint showing obvious gross disorganisation with deformity, swelling and grotesque hypermobility together with the absence of pain (fig. 329) —the so-called Charcot joint.

Function is often astonishingly well preserved. The accompanying features of the underlying disease will also be present. Radiography shows a grossly disorganised joint with destructive features and irregular areas of new bone formation (fig. 330).

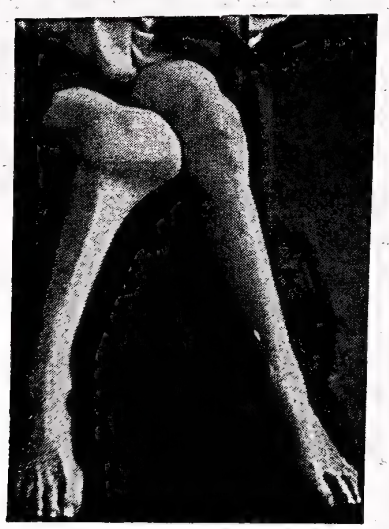

FIG. 329.—Charcot's disease of the right knee. *(Dr. Worster-Drought, London.)*

FIG. 330.—Charcot's knee joint. Hypertrophic type.

Treatment.—Although arthrodesis would appear to be the logical treatment this is often difficult to achieve in this condition and it is usually sufficient to stabilise the joint with a suitable appliance—a brace in the lower limb or a moulded leather support in the upper limb.

Jean Martin Charcot, 1825–1893. Physician, La Salpêtrière, Paris. Described tabetic arthropathy in 1868.

CHAPTER 20

DISORDERS OF THE FOOT

THE common causes of pain in the adult foot are set out in fig. 331.

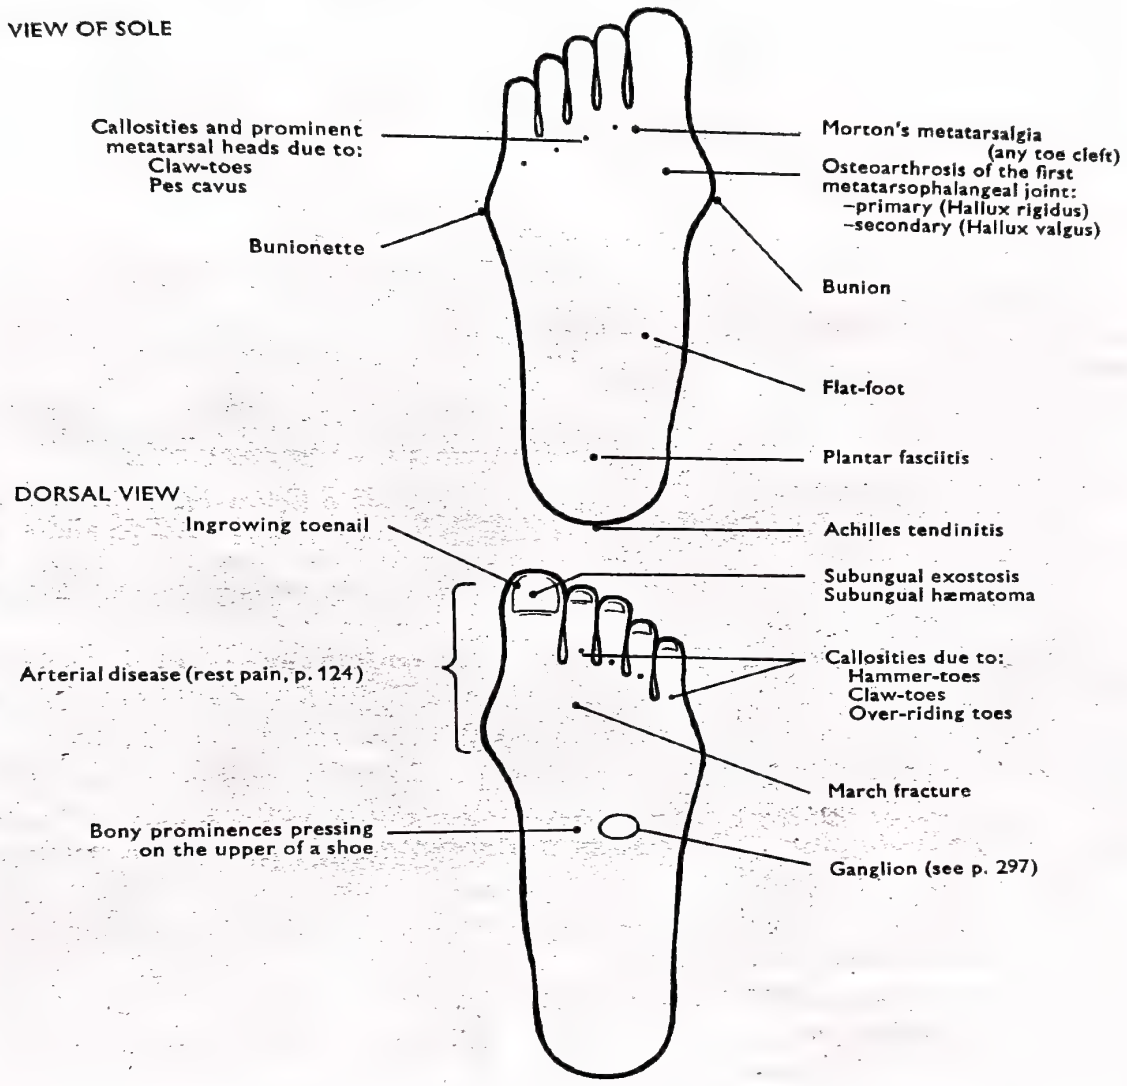

FIG. 331.—The causes of pain in the foot.

Flat-foot (*syn.* Pes Planus)

At birth the foot is flat, and the normal arch is only acquired when the infant stands. The arch is maintained in adult life by the shape of the bones of the foot, by their connecting ligaments and by the action of the muscles of the calf and sole. Flat-foot in adult life (fig. 332) may be due either

to the collapse of once normal arches, or to the persistence of the infant shape.

It is often difficult confidently to attribute a complaint of pain in the foot to anatomical pes planus. Under conditions of active service in first-class infantry regiments, for example, great variations in the shape of the foot, including flat-foot, are observed in unselected groups of men not complaining of painful feet. On the other hand patients will be found complaining of significant pain in the foot who have well-formed arches.

The presence of anatomical 'flatness' is not the most important aspect of pes planus, and two other physical signs should be sought in order to decide whether a patient's symptoms can be attributed to it. These are: (1) limited mobility of the tarsal joints and (2) localised tenderness. In general, only patients with painful limitation of movement at the sub-talar, mid-tarsal, or tarso-metatarsal joints are likely to have a mechanical disorder in the foot. Similarly, consistently localised tenderness in one part of the foot is strong evidence of a local source of organic pain.

There are 4 varieties of flat-foot:

1. **Infantile.**—This is physiological.

2. **Peroneal Spastic Flat Foot.**—An uncommon, painful condition which presents insidiously in adolescence. The foot is everted and hence the medial arch appears flat. The tendons of the peronei and long toe extensors can be seen standing out apparently in continuous contraction. Attempts passively to invert the foot are resisted by these muscles and are painful. In about 50% of cases special radiological views of the foot reveal a congenital bar of bone between the talus and the navicular, but in the remainder no abnormality is to be found. In these, the ætiology is unknown.

Treatment is unsatisfactory. Under general anæsthesia a below-knee plaster cast is applied with the foot plantigrade (muscle relaxation may be required to allow the foot to be placed in this position). The cast is worn for 2 to 3 months. Persistent recurrence, especially if a talo-navicular bar is present, may require subtalar fusion or excision of the bar.

3. **Idiopathic Adult Flat-foot.**—This is the commonest form of symptomatic flat-foot in the adult. It may be the end result of repeated episodes of 'foot-strain': an ill-defined, uncommon condition in which the foot becomes acutely painful following excessive use. More commonly, the condition is gradually progressive and presents with aching pain in the foot after long-continued standing. It is seen most commonly in people such as waitresses and hairdressers who spend long hours standing (rather than walking). The medial longitudinal arch gradually collapses causing pain centred in the medial part of the sole. Local tenderness may be found in the sole under the apex of the arch, probably because the plantar ligaments are over-stretched. Pain is provoked if these ligaments are stressed by dorsiflexing the forefoot. In the later stages the feet become painless and the gait shuffling and inelastic. In its final stages this type of foot can be painless, though rigid and flat.

Treatment.—Treatment is only indicated if the flat-foot is symptomatic: 'prophylactic treatment' is often prescribed (mistakenly) in schoolchildren. The pain of 'foot-strain' is relieved by rest. Its prevention may require arch supports or a change of occupation. Chronic flat-foot can only be treated during the years when the foot is progressively breaking down. At

this stage, arch supports moulded to the corrected shape of the foot may bring symptomatic relief but imply an acceptance of the disability. Exercises to improve the function of the intrinsic muscles of the sole and of the toe flexors may prevent further deterioration if the patient co-operates.

When the foot has finally collapsed, little can be done to improve its appearance or function and the patient should, therefore, be advised to accommodate his life to his feet by taking a sedentary job.

4. **Traumatic Flat-foot.**—This is caused by fractures which abolish the longitudinal arch. Fractures of the os calcis may produce a severe flat-foot with a rigid sub-talar joint. Fractures involving the sub-tarsal and mid-tarsal joints may lead to degenerative changes in these joints and hence to pain, the severity of which is out of proportion to the flatness of the foot.

Pes Cavus (*syn.* Claw-foot)

Pes cavus is an uncommon condition in which there is an increased concavity of the arch of the foot, so that the instep is unduly high (fig. 332). It is typically accompanied by clawing of the toes.

FIG. 332.—Imprints of the foot in: (*a*) Pes cavus. (*b*) Normal foot. (*c*) Pes planus. (*d*) The appearance of pes cavus.

Pes cavus is sometimes caused by neurological disease, for example poliomyelitis or Friedreich's ataxia, but in most cases it is idiopathic. The condition can perhaps be explained on the basis of weakness of the intrinsic muscles of the foot. These muscles flex the metatarsophalangeal joints and extend the interphalangeal joints. Without this mechanism the pull of the long flexors of the toes may cause the toes to assume the claw position and the foot to 'bunch'. Another factor which perhaps causes the deformity of pes cavus is shortening of the plantar fascia, which can be felt as a tight band stretched across the arch.

Treatment.—The treatment of pes cavus is unrewarding.

In childhood the foot is very rarely symptomatic so that the child is often not taken to a doctor or else is taken only because the parents have difficulty obtaining shoes. In such feet intrinsic exercises may be tried and, if unsuccessful, the relatively minor procedure of subcutaneous plantar fasciotomy carried out. It is difficult to justify more major procedures in a foot which is symptomless and may always remain so.

Nikolaus Friedreich, 1825–1882. Chief of the Medical Clinic, Heidelberg, Germany. Described this form of ataxia in 1863.

Fortunately many adult patients with pes cavus are able to play games and walk long distances. Such symptoms as are present are usually due to painful callosities under the metatarsal heads due to the ' high loading ' to which a small area of skin is subjected in this shape of foot and to the difficulty of getting a shoe which fits. Therefore before considering surgical treatment of the anatomical deformity, the surgeon must satisfy himself that the patient has sufficient disability to warrant surgery and that such disability as he has cannot be corrected by making his life more sedentary and by moulding insoles to support his high arch, thus relieving weight from his metatarsal heads. In practice surgical treatment is rarely required. If it is, in adolescents or young adults with a supple foot it may take the form of an attempt to abolish the ' tie-bar ' of the plantar fascia by Steindler's operation in which the plantar fascia and all the muscle attachments are erased from the lower surface of the os calcis by an open operation. The long extensor of the great toe may be transplanted to the neck of the first metatarsal to elevate this bone and so reduce the arch. In older adults with more rigid feet the metatarsals may be shortened and elevated by osteotomies through their shafts.

The treatment of claw toes in the absence of pes cavus is considered on p. 315.

Hallux Valgus

Hallux valgus consists of lateral deviation (valgus) of the big toe (figs. 333 and 337). It is initiated by wearing footwear which is too narrow for the fore-

(*a*) (*b*)

FIG. 333.—(*a*) The appearance of the feet with hallux valgus. A bunion is present in both feet, a bunionette only in the right. Note the variation in over-riding of the second toes: in both there is a callosity on the dorsum of the proximal interphalangeal (pip) joint. (*b*) X-ray of the foot with hallux valgus and metatarsus primus varus.

foot and which, therefore, tends to force the great toe laterally. Because women's shoes normally have a narrower forefoot than do men's, hallux valgus is much more common in women, especially the middle-aged. An abnor-

Arthur Steindler, 1878–1959 (*see footnote, p. 303*).

mally broad forefoot predisposes to the condition and may be caused by a congenitally varus position of the first metatarsal (metatarsus primus varus) (fig. 333(*b*)). Once the valgus position of the great toe has developed, it tends to be progressive, because the direction of pull of the extensor and flexor hallucis longus tendons further increases the deformity by a 'bowstring' mechanism.

The following conditions are often associated with hallux valgus:

1. An exostosis on the medial side of the head of the first metatarsal, probably caused by pressure on the periosteum.

2. A *bunion*, which is an inflamed adventitious bursa, produced over the prominent head of the first metatarsal by pressure and friction. Infection of the bursa (to produce suppurative bursitis) is common and the metatarsophalangeal joint of the big toe may be secondarily infected. A similar lesion, called a '*bunionette*', may develop over the lateral aspect of the head of the fifth metatarsal (fig. 333(*a*)).

3. Osteoarthrosis of the first metatarsophalangeal joint secondary to the malalignment of the proximal phalanx.

4. *Over-riding* or *under-riding* of the second toe by the first. In the latter condition (fig. 333(*a*)) a painful callosity may develop on the dorsum of the second toe. The second toe may be displaced laterally by the hallux to under-ride or over-ride the third (fig. 333(*a*)).

The patient may complain of an unsightly deformity, but more commonly the presenting symptom is pain caused either by pressure, infection or osteoarthrosis.

Treatment.—The conservative treatment of hallux valgus is unsatisfactory. As the patient is almost invariably a woman, it is usually useless to advise the wearing of shoes with low heels, wide fronts and straight inner borders since no such shoe is available in ordinary shoe shops, and since such shoes are unsightly. A small rubber pad can be worn in the cleft between the first and second toes, but this also demands the use of a wide-fronted shoe.

Most young adults with hallux valgus will eventually require operative treatment no matter what conservative techniques are tried, but it is important not to operate merely for cosmetic purposes if the foot is reasonably comfortable. A possible exception to this rule is hallux valgus associated with significant metatarsus primus varus and without degenerative changes in the metatarsophalangeal joint: in such a foot a 'prophylactic' osteotomy of the first metatarsal so as to reduce the varus is worthwhile. The most satisfied patients after operation for the correction of hallux valgus are those in whom severe pain (as well as gross deformity) were present preoperatively: the indication for surgery in hallux valgus is pain.

Operation.—Local removal of the bunion together with the underlying osteophytes, without interference with the metatarsophalangeal joint, is not a satisfactory operation because symptoms almost always recur, and a more radical operation is later required. Exceptionally this operation may be performed in young people if the valgus deformity is slight, but the exostosis prominent.

The standard operation for hallux valgus is excision arthroplasty of the base of the proximal phalanx (Keller's operation) or of the head of the first metatarsal (Mayo's

William Lordan Keller, 1874–1959. U.S. Army Surgeon, who became Head of Department of Surgery at the Walter Reed General Hospital, Washington, D.C., U.S.A. Described this operation for hallux valgus in 1904.

Charles Horace Mayo, 1865–1939. Surgeon, The Mayo Clinic, Rochester, Minnesota, U.S.A. Described this operation for bunion in 1908.

operation). The Keller procedure in younger patients can be augmented by osteotomy of the base of the first metatarsal to abduct the first metatarsal and close the enlarged gap between it and the second metatarsal (Stamm). The corrected position is maintained by inserting excised bone to hold the osteotomy open on the medial aspect.

After the operation, at least 3 months will elapse before the foot will tolerate an ordinary shoe, and the patient may not feel the full benefit of the operation for as long as 6 months.

Hallux Rigidus

This condition occurs as two distinct varieties, both more common in men. In both the metatarsophalangeal joint of the great toe is stiff and painful.

FIG. 334.—Metatarsal bar on shoe.

(1) The adolescent type is due to synovitis of the metatarsophalangeal joint following injury, and is associated with muscular spasm. There are no radiological changes. It is relieved by wearing a metatarsal bar 2 cm wide and 1·25 cm thick (fig. 334). Conservative treatment may fail to arrest the condition which then progresses gradually to present as the adult type.

FIG. 335.—Hallux rigidus.

(2) The adult type is nothing more than monarticular osteoarthrosis (fig. 335), sometimes precipitated by injury. The limitation of movement is due to capsular fibrosis, deformation of the articular surfaces, and the interlocking of osteophytes.

Treatment.—The condition may be treated by fitting a metatarsal bar or by operation. The Keller procedure is the most widely employed operation, although arthrodesis is perfectly satisfactory in men, especially if hyperdorsiflexion has developed at the interphalangeal joint of the great toe.

FIG. 336.—Second hammer-toe.

Hammer-toes

This condition, which may affect the second, third and fourth toes, consists of hyperextension of the metatarsophalangeal and distal interphalangeal joints, and flexion of the proximal interphalangeal joint (fig. 336). Callosities form over the bony prominence on the dorsum of the proximal interphalangeal joint, and in long-standing cases adventitious bursæ develop. The tendons and ligaments become secondarily contracted.

Hammer-toes sometimes develop

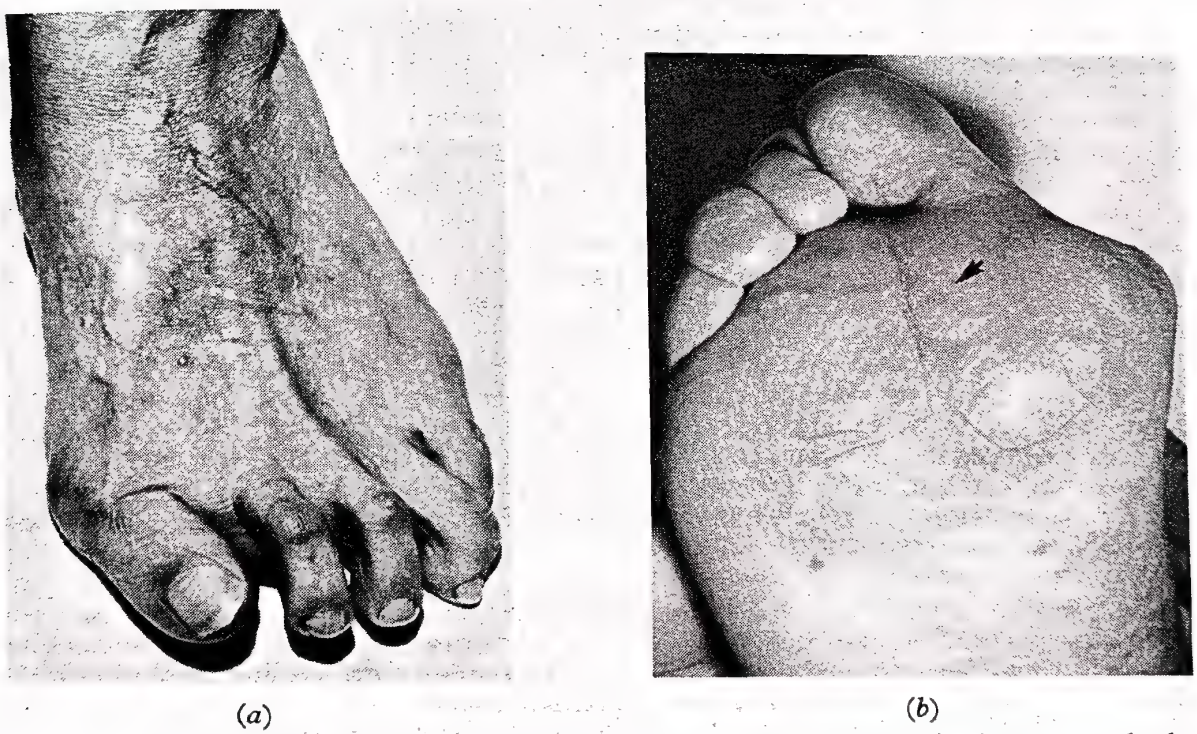
Temple Theodore Stamm, Contemporary. Consulting Orthopædic Surgeon, Guy's Hospital, London.

from overcrowding, either by small or pointed shoes, or as a result of hallux valgus. Often there is no obvious cause.

Treatment consists of correcting any predisposing cause and wearing a corrective splint or a corn plaster. If the deformity is established, arthrodesis of the proximal interphalangeal joint by the 'spike' method (Higgs) combined with extensor tenotomy and dorsal capsulotomy of the metatarsophalangeal joint is the treatment of choice. The spike operation consists of drilling the base of the middle phalanx and impaling it on the shaft of the proximal phalanx after shaping the condyles into a spike. Alternatively, the proximal phalanx may be excised.

Claw-toes

This condition differs from hammer-toes only in that (1) the toe pads do not contact the ground when the patient stands and (2), probably as a consequence of the loss of contact, the distal interphalangeal joint is flexed, not extended (fig. 337(*a*)). Because the toe pads are not weight-bearing, an increased proportion of the body-weight is borne by the corresponding metatarsal head. Because the metatarsophalangeal joint is hyperextended, often to the point of dorsal dislocation, the toes are prominent dorsally and press on the upper of the shoe causing painful callosities on the dorsum of the toe and downward pressure on the metatarsal head. These two factors tend to



(*a*) (*b*)

FIG. 337.—(*a*) Second and third claw-toes. Note that the toe pads do not touch the ground. (*b*) Plantar callosity (arrowed) under the second metatarsal head. Note that the pad of the second toe does not touch the ground.

compress the skin and soft tissues between the ground and the metatarsal heads and so cause pain and callosity formation in the skin of the sole. Eventually the fibro-fatty tissue under the metatarsal head atrophies or is dis-

Sydney Limbrey Higgs, Contemporary. Consulting Orthopædic Surgeon, St. Bartholomew's Hospital, London.

placed distally so that the metatarsal head becomes subcutaneous and easily palpable in the sole. A callosity then develops in the skin under the metatarsal head which is painful to stand on and tender when pressed (fig. 337(*b*)).

The condition is often associated with hallux valgus and pes cavus but may occur as an isolated entity. Its ætiology is unknown, but it is probably related to the wearing of high heels and to poor function in the intrinsic muscles of the foot. Severe claw-toes may be caused by rheumatoid arthritis affecting the metatarsophalangeal joints.

Treatment consists of exercises for the intrinsic muscles of the foot if the metatarsophalangeal joints are fully mobile. If they are not, the foot can be made comfortable by the provision of well-fitting footwear, an insole to relieve weight from the metatarsal heads, and a corn plaster on the callosity.

If conservative measures fail, the deformity can be corrected by arthrodesis of the interphalangeal joint (see hammer-toes) combined with dorsal capsulotomy and extensor tenotomy of the metatarsophalangeal joint and transfer of the flexor digitorum profundus tendon into the dorsum of the proximal phalanx. Alternatively, the affected toes may be amputated through the metatarsophalangeal joints. If pain under the metatarsal heads is the main complaint, the head of the metatarsal may be elevated by osteotomy of the shaft or one or all the metatarsal heads may be excised. The latter operation is particularly useful in rheumatoid arthritis.

Morton's Metatarsalgia.—This syndome was thought to be due to the development of a neuroma on the interdigital nerve between the metatarsal heads, possibly caused by local compression of the nerve. It is now known that the true cause is intermetatarsal bursitis which does compress the nerve but does not cause a neuroma. The condition is rare and presents clinically with well-localised pain and tenderness between the metatarsal heads, together with paræsthesiæ and hypoæsthesia in the related interdigital cleft.

Treatment is by excision of the bursa.

Plantar Fasciitis.—The ætiology is uncertain. Pain and localised tenderness occur under the heel. The pain is often severe, is felt especially at heel-strike, and interferes with walking. It is probably caused by a tear in the attachment of the plantar fascia to the os calcis, but seems sometimes to be associated with gonoccocal and non-specific urethritis. The pain is not caused, as was once supposed, by bony spurs on the plantar surface of the os calcis.

Treatment consists of advising the patient to avoid walking and standing as much as possible for 6 weeks, fitting rubber heels, and supplying insoles to weight-relieve the tender area and to take tension off the plantar fascia by supporting the medial arch. If these measures are ineffective, local injections of 25 mg. of hydrocortisone and 1 ml. of 1% procaine may bring relief.

Achilles' Tendonitis.—The loose connective tissue in which the Achilles' tendon slides becomes inflamed, thickened and painful. Pain may also originate, as in other forms of tendonitis, from the attachment of the tendon to the bone. The condition is often caused by a period of greatly increased walking or by the wearing of shoes with an ill-fitting heel. Occasionally it appears to be spontaneous.

Treatment consists of rest, if necessary in a below-knee plaster cast, for up to 6 weeks.

Subungual Exostosis.—Occurs on any toe but is most common on the great toe. The toe-nail is lifted from its bed and becomes painful and often infected.

Treatment is by removal of the nail and exostosis.

Congenital abnormalities of foot and toes are described in Chapter 15.

Thomas George Morton, 1835–1903. Surgeon, The Pennsylvania Hospital, Philadelphia, Pennsylvania, U.S.A. Described this condition in 1876.

Achilles, the Greek hero, was the son of Peleus and Thetis. When he was a child, his mother dipped him in the Styx, one of the rivers of the Underworld, so that he should be invulnerable in battle. The heel by which she held him did not get wet and was therefore not protected. Achilles died from a wound in the heel, which he received at the Siege of Troy.

CHAPTER 21

INJURIES TO BONE, CARTILAGE, LIGAMENTS AND TENDONS: GENERAL PRINCIPLES

INJURIES TO BONE (FRACTURES)

TUBULAR BONE

Pathology. A fracture of the shaft of a long bone disrupts the bone matrix, the periosteum and endosteum, the blood vessels in the medullary canal, in the cortex and in the periosteum, and the neighbouring soft tissues. The matrix, being inert, does not contribute to subsequent bone healing, but the blood vessels, periosteum and endosteum, and possibly the osteocytes in the involved bone do so.

As a consequence of the disruption of blood vessels, the soft tissue spaces around the fracture site, the space between the fractured bone ends, and the medullary canal, become filled with extravasated blood which clots to form a hæmatoma as elsewhere in the body and is invaded by granulation tissue. Macrophages remove the hæmatoma at the apices of the capillary loops of which the granulation tissue is composed. Cells which probably originate from the endothelium of the capillaries lay down a loose connective tissue composed of collagen fibres embedded in a dilute gel of proteoglycan. The periosteum and endosteum, torn by the fracture, may be avulsed from their attachment to the surfaces of the bone. The cells of which these membranes are composed are stimulated, possibly by the act of avulsion, or possibly by contact with humoral agents arising in the medulla, to proliferate and to lay down new bone. Thus at least 2 cell series, one arising from the endothelial cells of the blood vessels and one arising from the periosteal and endosteal cells are at this stage (that is to say approximately 2 weeks after the injury) contributing to connective tissue formation round the fracture site. It is possible that 2 other groups of cells play a similar role. These are: histiocytes which are believed to represent undifferentiated primitive mesenchyme cells present in all connective tissues, and, doubtfully, the osteocytes in the fractured bone itself. Many of the latter cells die as a consequence of infarction of the bone ends adjacent to the fracture, and such cells certainly contribute nothing to the healing process.

As the fracture hæmatoma becomes progressively organised and replaced by fibrous tissue, the bone ends come to be connected to each other but by a tissue which has very little rigidity and very little strength. From approximately 3 weeks onwards, cells around the fracture site not only lay down collagen in a proteoglycan matrix to form fibrous tissue and cartilage, but in addition they calcify the matrix and subsequently ossify it. Thus the tissue connecting the bone ends becomes osseous, and as such is visible radiologically and confers increasing rigidity and strength on the fracture site. The resulting tissue, known as *callus*, is distributed throughout the area once occupied by the fracture hæmatoma, and thus by 4 to 5 weeks after the fracture the bone ends are surrounded by a randomly distributed mass of fibrous tissue, cartilage and woven bone.

The process of vascular invasion by capillary loops, to which the original hæmatoma was subject, continues throughout this period and cells arising from the capillaries continue to lay down bone. Thus the callus, initially randomly organised, comes to be replaced by bone which progressively takes on an Haversian structure.

The original cortex is subject to the same process of osteoclasis and subsequent new bone formation as is the woven bone of the callus. In this way the anatomical dividing line between callus and cortical bone becomes increasingly blurred. Eventually the mass composed of callus and cortical bone is replaced by fully differentiated Haversian bone bridging the fracture site. At this point the bone returns to its original strength and rigidity but its anatomy and radiological appearance are still

Clopton Havers, 1657–1702. General Practitioner and Anatomist, London. Published his lectures on the anatomy of bone in 1691.

not normal. Over the ensuing years, the mass of bone in the medullary canal and surrounding the fracture site is remodelled so that the anatomy of the bone gradually returns towards the normal, although in the adult some internal or external irregularity commonly persists indefinitely.

Clinical and Radiological Features

Immediately after the fracture has occurred the patient complains of local pain and inability to use the injured part. The site of the fracture is tender, and within a few hours swelling and bruising appear. If the bone ends have been displaced in relation to each other, deformity may be visible. It is possible to elicit abnormal movement at the fracture site, but this physical sign should be sought with gentleness since such movements are painful. Crepitus (a sensation of grating when the bone ends are moved against each other) may also be elicited at the fracture site, but should never be sought deliberately since its demonstration adds nothing to the diagnosis and merely causes pain.

Radiologically, the bone can be seen to be fractured and the details of the fracture anatomy can be discerned. The first radiological examination of a fracture is only complete when the whole of the involved bone together with the joints in which it participates have been X-rayed in 2 planes at right angles to each other, since only in this way can the full extent of the bony injury be demonstrated and the presence of associated joint injuries be detected.

As the fracture hæmatoma becomes organised to form fibrous tissue and subsequently woven bone, the abnormal movement originally demonstrable at the fracture site diminishes. Slight movement can, however, still be elicited, stressing the fracture site is painful, and local tenderness persists. At this stage the fracture is described as being ' sticky '. Between the third and sixth week following injury, the calcification and subsequent ossification occurring in the callus become visible radiologically (fig. 338(*a*)) and as this process progresses the fracture site becomes decreasingly tender and increasingly rigid and strong.

By approximately 6 weeks (the exact time varies with the age of the patient and the nature of the fracture—see Table 1) healing has progressed so that

TABLE 1

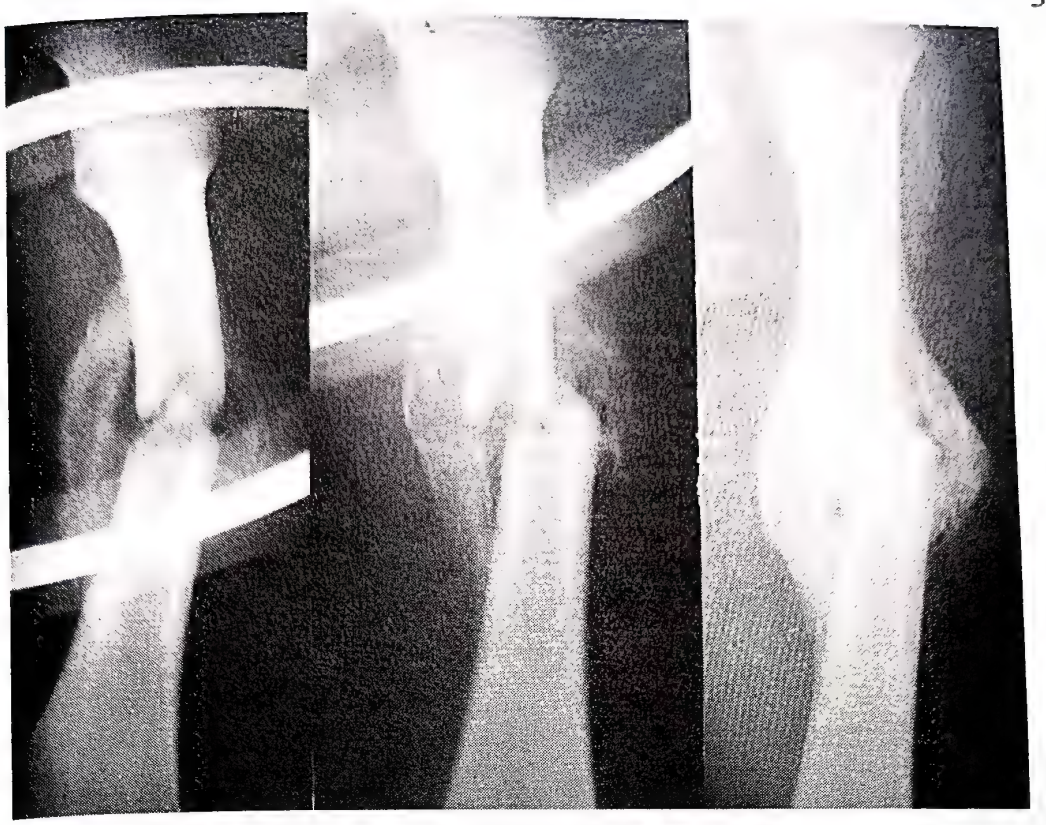
The Rules:

(1) Lower limb fractures take twice as long to unite as upper limb fractures.
(2) Fractures in adults take twice as long to unite as fractures in children.
(3) Transverse fractures take longer to unite than oblique or spiral fractures.
(4) Compound and comminuted fractures are particularly slow to unite.
(5) No fracture unites in less than 3 weeks.

Thus, for example:

(1) An oblique fracture of the humerus in a child takes 3 weeks to unite.
(2) The same fracture in an adult takes 6 weeks,
(3) A transverse fracture of the tibia in an adult takes 12 weeks, and
(4) A comminuted fracture of the tibia in an adult may take 12–24 weeks.

(1) no abnormal movement can be detected when the fracture is stressed, (2) stressing the fracture site is scarcely painful, and (3) local palpation provokes little or no tenderness. At this stage the fracture is described as being



(*a*) (*b*) (*c*)

FIG. 338.—(*a*) Early callus formation. The calcified material does not have a bony texture and does not bridge the fracture site. (*b*) Union. The callus now has a bony texture and bridges the fracture site but the fractured bone is easily visible, distinct from the callus. (*c*) Consolidation. The callus has a bony texture and is no longer clearly distinguishable from the femoral shaft.

'united'. Radiologically, bone can be seen to bridge the fracture, but since the bone is partly woven rather than Haversian in structure, it does not have a normal radiological texture (fig. 338(*b*)).

As the woven bone of the callus is replaced by normal Haversian bone the fracture site becomes entirely painless irrespective of the patient's activity and the radiological texture of the bony mass surrounding the fracture site gradually becomes identical with that of the rest of the bone (fig. 338(*c*)). Such a fracture is described as 'consolidated' and at this point the healing process can be regarded as having come to an end.

Mechanism of Injury

A tubular bone may be broken either by direct or indict violence. For example the tibia may be fractured by direct violence if the bumper of a motor car strikes the bone or by indirect violence if a skier twists his body whilst the ski is held fixed. A bone fractured by direct violence is likely to be broken into several small pieces. Such a fracture is described as 'comminuted'. Indirect violence may be applied to a bone as a twisting force, in which case a spiral fracture results, or as a bending force, in which case a transverse or oblique fracture is produced. Double oblique fractures may

occur so as to leave a 'butterfly' fragment separated from the two main pieces of the bone (fig. 339).

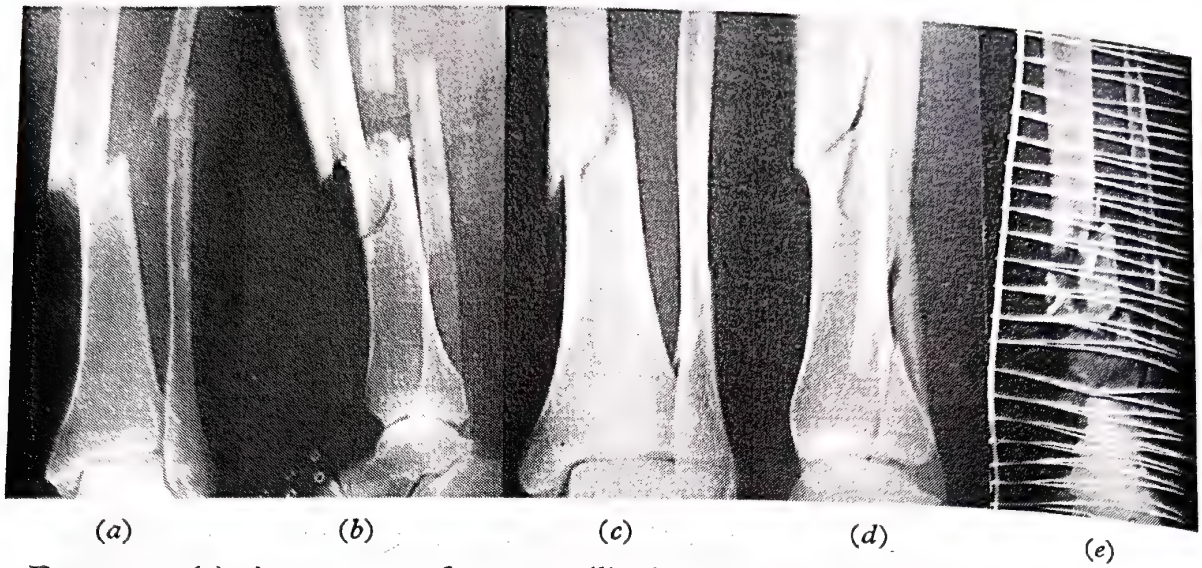


FIG. 339.—(*a*) A transverse fracture. (*b*) A transverse fracture with an undisplaced butterfly fragment. (*c*) An oblique fracture. (*d*) A spiral fracture. (*e*) A comminuted fracture.

CANCELLOUS BONE

Pathological, Clinical and Radiological Features

The pathological events following a fracture of cancellous bone are similar to those following a fracture of a tubular bone save that now the healing process occurs around a multitude of small fractures—one in each trabecula of the involved bone—rather than between the 2 large fracture fragments of the tubular cortex. Thus, although the histological events are similar, the clinical and radiological appearances are somewhat different because the fracture callus is spread evenly throughout a honeycomb of cancellous bone. Clinically, the principal difference is that abnormal motion and crepitus may never be present if the honeycomb structure is interlocked by the chance arrangement of the trabeculæ at the fracture site. Such a fracture is said to be 'impacted'. Radiologically, the callus no longer appears as a bony mass surrounding the fracture site but instead may only be seen as a zone of increased radio-density (known as sclerosis) at the fracture site (fig. 340).

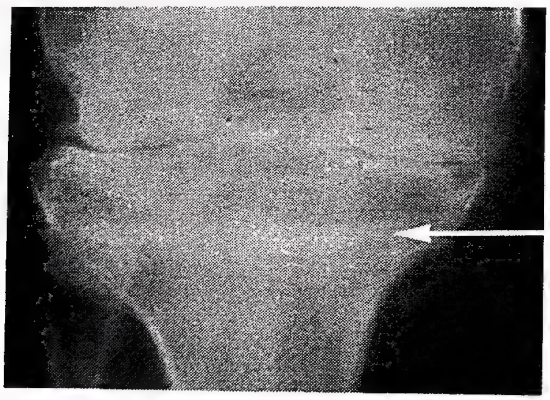

FIG. 340.—A uniting cancellous surgical fracture (an osteotomy) through the tibial condyles. All that is to be seen is a zone of sclerosis (arrow). Compare this with the appearance of the femoral shaft fracture in fig. 338 (*c*).

Mechanism of Injury

Cancellous bone may be fractured either by compression or by tension.

Compression fractures may occur for example if a patient falls from a height and lands on his heels: the compressive force travelling up the leg and through the trunk may produce a crush fracture of a vertebral body, of the tibial or femoral condyles, or of the os calcis. Such fractures are often impacted.

Traction injuries only occur in cancellous bone to which a ligament or tendon is attached, for example the medial malleolus. The bone is stressed by traction on the ligament. The fracture represents an avulsion of the bony attachment of the ligament and as such it is functionally equivalent to a rupture of the ligament. Such fractures are never impacted.

DISTURBANCES OF NORMAL HEALING IN BONE

Delayed and Non-Union

The times by which fractured bones have usually united have been listed in Table 1, but these times are often exceeded. When a bone still displays abnormal movement, pain when the fracture site is stressed, and tenderness over the fracture site at a time when union should have occurred, the fracture is said to display ' delayed union '. Because ossification of the callus has been delayed, the callus in such a bone may be invisible or poorly visible on an X-ray and, if visible, it may not bridge the fracture site (fig. 341). A fracture displaying delayed union may continue slowly to heal until finally it unites. The healing process may, however, come to a halt before union has occurred, so that abnormal movement and a radiologically visible fracture site persist permanently. Such a fracture is said to display ' non-union '. Histologi-

FIG. 341.—Delayed union—no sclerosis.

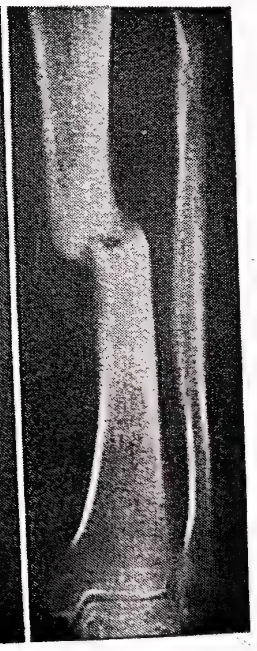

FIG. 342.—Non-union—sclerosis.

FIG. 343.—A pseudarthrosis following an un-united fracture of the shaft of the humerus.

cally a fracture displaying non-union is bridged by fibrous tissue, the bone ends are sclerotic and the medullary canal may be obliterated (fig. 342). The fibrous tissue bridging such a fracture site may be dense and short, so that the bone ends are in close apposition to each other and little abnormal movement occurs between them. On the other hand the scar may be a long one and may contain within it a cavity occasionally displaying all the tissue elements of a synovial joint. Such an abnormal joint is known as a ' pseudarthrosis ' (fig. 343). Persistent abnormal movement at a fracture site interferes with the function of a limb and the fibrous tissue in an un-united fracture is usually painful when stressed. Non-union is therefore usually unacceptable, to the patient. Occasionally, however, a very firm fibrous scar forms so that, if the bone is not heavily loaded, as in the upper limb, the result is indistinguishable clinically from bony union.

The Causes of Delayed Union

1. **Excessive movement** at the fracture site during the healing phase may produce delayed union because the callus bridging the fracture site is constantly ' re-fractured ' by the movement occurring in the healing tissue. It may be speculated that shear, for example produced by torsion, is more harmful in this respect than is bending at the fracture site. Certainly minimal bending movements, such as occur in a fractured rib, are perfectly compatible with normal healing and may even promote it.

2. **Infection** of the fracture hæmatoma usually leads to non-union and, if it occurs, is a disaster (p. 324). Healing fails because the cellular elements which are required for the production of bone at the fracture site are diverted to the production of pus.

3. **A poor blood supply at the fracture site** interferes with healing since the invasion of the hæmatoma by blood vessels is slow or absent. Cells with osteogenic potential are therefore slow to appear in the fracture hæmatoma. Furthermore there is some evidence that a low oxygen tension produced by a poor blood supply interferes with the production of bone by undifferentiated mesenchyme cells so that even such osteogenic cells as are present may fail to produce bone, and instead produce cartilage or fibrous tissue.

The anatomy of the fractured bone may result in a complete loss of the blood supply to one of the fracture fragments. For example in fractures of the neck of the femur, the vessels ascending in the neck of the femur to the femoral head may be ruptured by the fracture. The femoral head may then be completely infarcted, so that the healing process does not consist of the union of two vascularised bone fragments but, instead, involves the bridging of the fracture site from oneside only, followed by revascularisation of the whole of the infarcted fragment. As might be expected, such injuries are either slow to unite or fail to unite altogether.

4. **Interposition of soft tissues** between the fracture fragments may so separate them that it is physically impossible for them to unite. For example, at the medial malleolus the tendon of tibialis posterior may come to lie between the medial malleolus itself and the rest of the tibia, or in spiral

fractures of the femur a spike formed by one of the fracture fragments may become impaled in the muscles of the thigh. Such a fracture cannot be reduced (i.e. the bones ends cannot be accurately apposed) and healing by bone is obviously impossible.

5. **Systemic disease,** for example uræmia developing as a consequence of renal failure secondary to blood loss following injury, may interfere with healing generally.

FIG. 344. — Mal-united fractures of the radius and ulna as a consequence of which this patient was unable to pronate and supinate the forearm.

Mal-union

A fracture which unites in a position of deformity is said to be *mal-united*. For example a long bone shaft fracture may unite with significant angulation at the fracture site. This complication of normal healing is due to imperfect reduction. Mal-union usually, but not always, results in impaired function and cosmetic loss (fig. 344).

Joint Stiffness.—Healing may be imperfect in the functional rather than the anatomical sense. For example *adhesion formation* may occur between the fracture site and the muscles or other soft tissues adjacent to the bone even though reduction has been perfect, so that movement at the adjacent joints is limited and muscle power reduced.

Following a fracture, there is normally an increase in the blood flow through the injured area associated with a loss of bone matrix (i.e. osteoporosis, p. 287) in the skeleton adjacent to the fracture. Immobilisation also causes these changes so that if an injured limb has to be immobilised, they may be severe. Occasionally very marked osteoporosis, associated with thickening of the soft tissues, vascular stasis, pain and joint stiffness complicates a fracture irrespective of its severity. This syndrome is known as *Sudeck's Atrophy* (fig. 345). Its ætiology is unknown but it is thought to have either a reflex vascular basis or possibly to be due to the extreme reluctance of some patients to use the limb after the removal of splintage, a reluctance which accentuates the changes normally produced by immobilisation. The patient should be encouraged, with supervision in a physiotherapy department, to use the limb. No other specific treatment is available.

FIG. 345. Sudeck's atrophy.

Paul Hermann Martin Sudeck, 1866–1938. Professor of Surgery, Hamburg, Germany. Described this type of osteoporosis in 1900.

Compound Fractures

A compound fracture is one in which a laceration in the skin (or mucous membrane) com-

municates with the fracture hæmatoma. Bacteria can therefore reach the fracture site. It may not always be possible to tell pre-operatively whether a laceration adjacent to a fracture actually communicates with the fracture hæmatoma or not, but a combination of a laceration and a fracture should always be regarded as a compound fracture until surgical exploration proves otherwise. If the laceration proves not to communicate with the fracture, the latter may be termed 'technically compound'.

Lacerations associated with fractures may be caused either by a fracture fragment penetrating the skin from its deep surface (in which case the fracture is said to be compound 'from within'), or by the object causing the fracture, e.g. the bumper of a car, breaking the skin as well (in which case the fracture is said to be compound 'from without'). The chances of significant bacterial contamination of the fracture are greater in the latter and hence fractures which are compound from without have a poorer prognosis. A break in the skin surface may be due to skin death from ischæmia rather than to a laceration. Fractures of subcutaneous bones with displacement may lead to pressure on the deep surface of the skin by a bony fragment and thus endanger the circulation to the skin. The reduction of such a fracture is urgent in order to preserve the skin. Injuries causing fractures by direct violence may crush the blood vessels in the skin but this may not be obvious at the time of the first examination. During the following 2 to 3 weeks the skin may slough and if this possibility is not borne in mind, a fracture may be encased in a plaster-of-Paris splint in which the skin may slough unnoticed.

It must be assumed that any fracture in which the overlying skin is broken is contaminated with bacteria, either from the skin itself or from the surrounding environment. Such bacteria remain dormant in the fracture hæmatoma for a few hours following injury but soon thereafter start to multiply so that their number rises rapidly as time goes by. An inflammatory response develops locally and the fracture, from being contaminated, becomes infected. The chances of sterilising the fracture hæmatoma become increasingly remote as the number of bacteria at the fracture site rises. Therefore the treatment of a compound fracture is a matter of urgency (p. 331).

TREATMENT

The management of a fracture can be considered under two headings: (1) the management of the patient as a whole, and (2) the local management of the fracture itself.

General Management of the Patient

(1) *Pain.*—All fractures are painful and it should never be forgotten that the immediate responsibility of the physician is to relieve pain. This can be done by local splintage and by analgesics such as morphia, pethidine, paracetamol or salicylates.

(2) *Blood Loss.*—All fractures are associated with some blood loss. This may be negligible, but in fractures of the major long bones, the spine, and the

pelvis it can be considerable. Its loss, however, may not be immediately obvious. For example a patient suffering a fracture of the pelvis or of the shaft of the femur can lose 2 litres of blood into the surrounding tissues without any obvious swelling or bruising. Such blood loss must be replaced.

(3) *Associated Injuries.*—Fractures are commonly associated with other injuries, for example fractures of the pelvis may be associated with injuries to the bladder, or fractures of a long bone shaft may be associated with injuries to the blood vessels or nerves in the limb. The possibility of such injuries must always be borne in mind since they may be missed unless they are deliberately sought at the time of the first examination.

Local Management of the Fracture

The local management of a fracture is concerned with the management of the injured bone itself and the associated soft tissues. So far as the bone is concerned there are two objectives:

(1) *Reduction* of the fracture (strictly, reduction of the deformity at the fracture site) and (2) *Immobilisation* of the fracture. Reduction restores the normal anatomy. Immobilisation—(*a*) maintains the reduction whilst healing takes place and (*b*) promotes union.

For the soft tissues the objectives are: (1) to maintain muscle power and (2) to promote joint mobility. To some extent there is a conflict between these objectives and that of immobilising the fracture.

Severed blood vessels and nerves, and lacerations of the skin, require specific treatment.

Reduction of the Fracture.—Restoration of the normal anatomy at the fracture site is termed ' reduction ' of the fracture. If the original injury did not produce significant displacement, as for example in the fracture of the metacarpal displayed in fig. 346, no reduction is required. Should reduction be required it may be accomplished in one of two ways: (1) by closed manipulation or (2) by open operation.

FIG. 346.—An undisplaced fracture of the shaft of 3rd metacarpal. The fracture is splinted by the neighbouring soft tissues and bones: neither reduction nor external splintage is required.

Closed manipulation has the great advantage that the skin remains intact so that there is no possibility of the fracture site becoming infected. Therefore if closed reduction is possible, it is, in general, the treatment to be preferred. The patient is either given a general anæsthetic or the fracture site is rendered analgesic by local infiltration or by i.v. local anæsthesia distal to a tourniquet. Anæsthesia

has the double effect of producing muscle relaxation so that the manipulation becomes easier, and of making the manipulation painless for the patient. The bone ends are then manipulated in an attempt to restore the normal anatomy. The specific manipulations which are required for the reduction of common fractures are described in the following chapters, but the same general principle underlies the closed manipulation of all fractures: the surgeon seeks to reverse the mechanical events which led to the production of the original fracture. Thus an understanding of the mechanism of the injury is essential if closed manipulation is to be used intelligently.

For the reduction of some fractures, e.g. fractures of the shaft of the humerus or the femur, a formal manipulation is unnecessary and traction (see p. 328) alone suffices.

Open operation (see p. 329).

Immobilisation.—The object of immobilising the fracture is (1) to maintain the alignment of the bone produced by reduction whilst healing occurs and (2) to promote union. Immobilisation may be provided in one of four ways:

(1) Externally by:	(*a*) splints	Conservative treatment
	or (*b*) traction	
or (2) Internally by:	(*a*) adjacent soft tissues	
	or (*b*) surgical implants (p. 332).	Operative treatment

Conservative Treatment

Splints.—The strength and rigidity required in the splint are proportional to the forces applied to the fracture. Thus immobilisation is usually achieved partly by the use of splintage and partly by deliberately reducing the loads on the fracture site, for example by resting an injured arm in a sling or by walking only on the uninjured leg and crutches.

The most commonly used material for external splintage is plaster-of-Paris applied by wrapping the limb in a wet plaster-impregnated bandage. The plaster is allowed to set so as to hold the fracture in the desired position. Because it is almost impossible to obtain sufficient 'grip' on a single bone to withstand the forces imposed on the bone by contraction of the muscles attached to it, a plaster splint must always extend proximally and distally to include the joints adjacent to the fracture site. This constitutes a significant disadvantage to the use of plaster-of-Paris since it often means that when the plaster is removed the adjacent joints are stiff, the muscles weak, and the blood flow diminished. Other disadvantages include the facts that wounds cannot easily be treated in plaster, that adjustments in the reduction may be difficult to achieve, that the material is relatively heavy and radio-opaque and that it is not always easy to maintain a reduction whilst the plaster bandage is being applied. Having said this, plaster remains overall the safest, cheapest and most convenient form of splintage available. It has however one serious hazard attached to its use.

The Hazard of plaster-of-Paris Splinting.—Plaster-of-Paris is inelastic. When a plaster is applied soon after an injury it is to be anticipated that swelling will occur at the fracture site. Such swelling cannot distend the plaster and it will, therefore, result in a gradual rise in pressure in the soft tissues at the fracture site. This rise in pressure may occlude the venous return from the limb producing venous engorgement distally and, shortly thereafter, an interruption in the arterial flow to the limb. If the arterial inflow to a limb is obstructed for an hour or more, the muscles and nerves become infarcted and subsequently replaced by fibrous tissue. This sequence of events represents a significant hazard to the use of plaster-of-Paris and if it is allowed to occur, it constitutes a disaster the consequences of which are very much more grave than any which could possibly follow total failure to treat the fracture. Thus if plaster-of-Paris is to be applied to a fresh fracture, it is essential that the plaster should not completely surround the limb. This may be achieved either by applying a slab of plaster to the limb leaving a wide gap on one side of the limb, or by splitting a completely encircling plaster (fig. 347). Any such plaster should be well padded with wool so that swelling may occur without compressing the soft tissues and the limb should be elevated after its application.

FIG. 347.—A split plaster-of-Paris cast.

The clinical features of an impaired blood flow are progressive in nature. The circulation in the exposed skin distal to the fracture should be examined carefully in the hours following the application of the plaster and any sign of an interruption of the blood supply (i.e. pallor or poor capillary filling in the limb) should be regarded as an indication that the blood supply is possibly impaired. In this event the whole plaster should be opened and all padding should be separated so that the skin is visible throughout the length of the split in the plaster. Should significant swelling occur, the patient will notice increasing discomfort and pain both at the fracture site and distal to it. These symptoms should also be regarded as an indication for easing a plaster encircling a limb. If the arterial inflow actually becomes interrupted so that the blood supply to the muscles is impaired, active movement of the muscles will become impossible (e.g. the fingers will be stiff) and attempts to stretch the involved muscles by passive movement will be painful. The pulse is weak or absent. *The detection of these signs is an urgent indication for the removal of plaster* and, if this does not improve the circulation, for exploration of the appropriate main artery.

If infarction is allowed to occur so that fibrosis of the muscles and nerves

FIG. 348.—Volkmann's ischæmic contracture following a supracondylar fracture of the humerus in childhood.

ensues, the resulting fibrous tissue contracts to produce deformity, stiffness, and weakness at the involved joints. This syndrome is known as *Volkmann's Ischæmic Contracture* (fig. 348).

External Skeletal Fixation.—As an alternative form of splintage to plaster-of-Paris, Steinmann or other pins may be passed through the bone proximal and distal to a fracture and the pins then connected to a special metal frame. This method of fixation is particularly useful if the fracture is compound so that access is required to a wound. It provides very rigid fixation, is easily adjustable and is light. The disadvantage is the necessity of using pins to transfix the bone: these expose the bone to the risk of infection and are difficult to pass in other than subcutaneous bones such as the tibia. In practice therefore the method is most useful for compound fractures of the tibia.

Traction.—Fractures may be immobilised by exerting traction on the involved limb. The role of traction in the production of immobilisation may be understood by likening the fracture and the adjacent joints to a bicycle chain. Each link of a bicycle chain is mobile and can be displaced on its neighbour if the chain is not under tension. If tension is applied in the long axis of the chain, the chain will straighten and movement of one link on another becomes difficult or impossible. Exactly the same principle applies to a fracture when traction is applied in the long axis of the limb.

Traction may be exerted on a limb by either (1) attaching an inelastic bandage (special materials are available) to the skin, and then a weight to the bandage (*skin traction*) or, (2) passing a metal wire or pin through the bone and attaching weights directly to the bony skeleton in this way (*skeletal traction*). The former technique has the advantage that there is no possibility of infecting the bone but it has the disadvantage that only a small weight (about 2·25 kg.) can safely be attached to the skin. The weight used must be sufficient to overcome the shortening and deforming force of the muscles acting across the fracture site and thus skin traction is almost only of use in infants and children where the strength of the muscles can be matched by a pull of 2·25 kg. In adults, skin traction is only used as a temporary measure and if a fracture is to be treated definitively by traction, skeletal traction is required.

Plaster-of-Paris or the weight of the limb itself may be used to provide traction in the upper limb. For example, a fracture of the shaft of the humerus is treated in a collar-and-cuff sling which simultaneously rests the limb and, by taking advantage of gravity acting on the elbow and forearm, exerts traction on the fracture site. The traction force may be increased by bandaging a slab of plaster-of-Paris to the arm. Such a slab not only pro-

Fritz Steinmann, 1872–1932. Professor of Surgery, Berlin.

vides more effective traction but also provides splintage at the fracture site.

The Adjacent Soft Tissues.—Certain bones, for example, a single metacarpal shaft (fig. 346), are satisfactorily splinted by adjacent soft tissues, provided the violence of the injury has not displaced the bones and in so doing torn their soft tissue attachments. No additional splintage is required for such fractures.

Operative Treatment

Indications.—Operation may be required for a fracture because:

(1) reduction is necessary but is impossible by closed means;

(2) having achieved reduction by closed means, it is impossible (or dangerous for the general health of the patient) to maintain it by external splintage; or

(3) the management of associated soft tissue injuries is difficult or impossible in the presence of external splintage and requires rigid immobilisation of the fractured bone.

Closed reduction may be impossible if soft tissues are interposed between the fracture fragments. The fracture must then be exposed at operation to allow the soft tissue to be extracted and the bone ends brought into apposition. Alternatively it may be impossible to reduce a fracture by closed means because the surgeon cannot obtain any purchase on one of the two fracture fragments. Thus in fractures through the anatomical neck of the humerus associated with anterior dislocation of the head of the humerus, closed manipulation is impossible since the head of the humerus is inaccessible save by operation. A third situation in which adequate reduction cannot be achieved by closed manipulation is that represented by fractures around joints in which there may be several small fracture fragments whose accurate replacement is essential if normal joint function is to be restored. Examples of such injuries are certain fracture-dislocations around the ankle and depressed fractures of the tibial condyles. Often the fragments cannot be manipulated at all, and certainly they cannot be manipulated accurately, through the skin.

The maintenance of reduction by external splintage may be impossible because no satisfactory form of splint is available to immobilise a small fragment or to overcome muscle pull. Small fragments requiring immobilisation are commonly adjacent to joints (as, for example, the head of the femur, fragments around the ankle, or the tibial condyles). Although it may be possible to immobilise such fragments by external splintage, this will involve immobilisation of the whole joint. Unfortunately a combination of severe injury and prolonged immobilisation may produce serious joint stiffness and, therefore, in skilled hands, better results may be obtained by internal fixation of the fracture so as to allow early mobilisation of the joint. The opportunity provided by the internal fixation of any fracture to mobilise muscles and joints early after injury, constitutes an argument for operating even when closed means of management are available, such as for example in the shafts

of the femur or tibia. This advantage has to be balanced carefully against the disadvantages, of which the most serious is the risk of sepsis. Unless the surgeon is experienced, closed means are preferable.

The inability of external splintage to overcome muscle pull is illustrated by transverse fractures of the patella, after which the quadriceps muscle may pull the proximal fragment of the patella upwards into the thigh. The two fragments can be pressed together through the skin under anæsthesia, but even if the knee is then splinted in full extension, the gap between the fracture fragments opens again as soon as the quadriceps muscle contracts. Thus the restoration of normal anatomy is impossible unless operation is undertaken to fix the two fragments of the patella together.

The maintenance of reduction may be possible by closed means but may be hazardous to the general health of the patient. Thus in fractures through the intertrochanteric region of the femur it is possible to immobilise the fracture either by applying a plaster-of-Paris spica or by the use of traction, and both of these techniques are employed in the young. In the elderly, the prolonged immobilisation in bed which either form of treatment requires is hazardous to the patient's general health since pressure sores, deep vein thrombosis, pulmonary embolism, and hypostatic pneumonia are all common complications of bed rest in this age group. Thus for this fracture in the elderly, operation is required to produce internal fixation of the fracture so as to allow the patient to be mobilised out of bed.

Fractures associated with damage to vital soft tissues may be best treated by internal fixation of the fracture so as, for example, to allow a ruptured artery to be repaired by primary suture.

Methods of Internal Fixation.—A variety of devices is available to splint fractures internally. The fracture fragments may be wired or screwed together (figs. 369 and 395) or united by one, or rarely two, onlay plates screwed to the bone (fig. 349), or by a nail passed down the medullary canal (fig. 401). Special devices are available for certain fractures, such as the pin and plate used for fractures of the proximal femur (fig. 405).

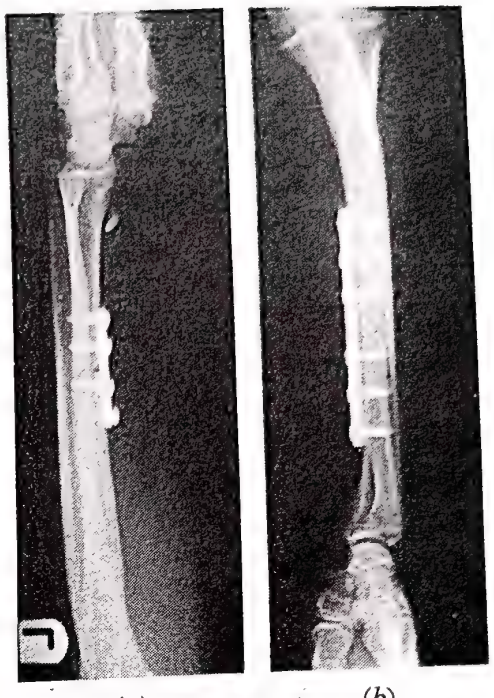
If it is felt that a fracture fragment cannot survive usefully—a decision which is sometimes made, for example, in connection with the head of the femur after fractures of the femoral neck—the bone may be removed and replaced with a prosthesis (fig. 403).

It has recently been argued that, if internal fixation is to be used at all, it should be as strong and as rigid as possible since: (1) this allows the joints of the limb to be mobilised early, free of external splints, and (2) there is evidence that union is promoted by rigid fixation of the fracture. Strong, rigid implants have been designed for this purpose and techniques have been developed for enhancing the quality of fixation by applying the implant in such a way as to compress the fracture site (fig. 349). In long bone shaft fractures this is done with an onlay plate, a technique known as ' compression plating '.

Internal fixation is technically difficult in comminuted fractures and in fractures through cancellous bone.

Local Management of Soft Tissues

Muscles may be injured at the time of the fracture or they may be affected indirectly by adhesion formation between themselves and the fracture site. Their function must be preserved as far as possible by encouraging the patient to contract all the muscles in the injured limb statically, and regularly to move through a full range all those joints which have not been immobilised. If the muscles are not exercised, they waste and adhere to the bone and other soft tissues, and the venous return from the limb is impaired. Muscular exercise is obviously much easier if the fracture has been controlled by internal fixation to leave the joints free.



(*a*) (*b*)

FIG. 349.—(*a*) Inadequate internal fixation: the onlay plate is too slender, the screws are too few, too near the fracture site and one is loose. (*b*) Adequate internal fixation: the onlay plate is more rigid and is firmly held to the bone by well-placed screws.

Immobilisation of *joints* produces gradual obliteration of the synovial space with fibrous tissue, and damages articular cartilage. This results in stiffness of the involved joint. Immobilisation of a joint may be an inevitable consequence of immobilising a fracture, but wherever possible it should be avoided. Thus plaster-of-Paris splints should not include joints if their immobilisation is not essential to the immobilisation of the fracture, and any joint which is not immobilised in plaster should be actively exercised.

If the *skin* is lacerated or dead, the fracture may be compound (p. 323). The treatment of such injuries presents special problems.

The Treatment of Compound Fractures.—A compound fracture is a surgical emergency: it must be treated urgently and with skill. Treatment aims at sterilising the fracture site, and consists of (1) wound toilet, (2) the reconstitution of skin cover, and (3) the use of antibiotics.

Wound Toilet.—It is imperative that this operation be carried out carefully, in optimal operating conditions, with a good light. If possible, a tourniquet should be applied to the limb following exsanguination so that the fracture site can be examined thoroughly. The wound in the skin is extended if necessary and the damaged soft tissues inspected. All dead tissue (which if left in the wound would provide a culture medium for bacteria) including the margins of the skin wound are then removed by sharp dissection. Dirt or foreign material is removed from the wound and the wound tissues are washed with sterile saline. At the end of this procedure all remaining bone and soft tissues should be surgically clean, and demonstrated to be viable by releasing the tourniquet to see that the tissues bleed.

Wound Closure.—Wound closure is safe only provided that the patient can be observed closely in the days following operation. If the wound is closed by suture without having been adequately sterilised, infection may develop deep to the suture line. Since the suture line is relatively inelastic, the tension deep to the wound then rises and further soft tissue damage results. The infection is finally very much more

severe than if the wound had not been sutured. Therefore, if it is impossible to arrange for close examination of the patient in the early post-operative period, it is safer to pack the wound with sterile dressings and leave it to granulate for 10 to 14 days following operation. At the end of this period the wound can be inspected and either closed by the application of a split skin graft or by secondary suture. If the patient and his wound can be observed post-operatively so that at the first sign of infection the sutures can be removed, the wound should be closed by simple suture provided this can be done without tension at the suture line. A substantial dead space may be produced by simple suture, and the deep soft tissues should then be closed with removable sutures passing through the skin, deep tissues and the dead space. If suture of the laceration is impossible without tension, the wound should be left open (or, in certain situations plastic procedures may be considered). A sutured wound of any size should be drained by closed suction.

Once the skin wound has healed satisfactorily without infection of the fracture site, the fracture itself may be treated as if it were simple. While the skin is healing the fracture should be reduced and splinted, but splintage should never (save in experienced hands or in the presence of severe associated soft tissue injuries) take the form of internal fixation since the foreign material which must necessarily be used to produce internal fixation hinders sterilisation of the fracture site by the local inflammatory response and by antibiotics. So far as possible, external splintage should allow for inspection of the wound.

Antibiotics and Prophylaxis against Tetanus are discussed on p. 16 and p. 26.
Gas Gangrene is discussed on p. 28.

The Treatment of Non-union (p. 321)

If an obvious cause of non-union such as infection is evident, the underlying pathology should be treated. Commonly there is no obvious cause of non-union, and in this event treatment relies upon two factors: (1) absolute fixation and (2) the use of a bone graft.

Absolute fixation cannot be produced by external splintage alone, but may be achieved by internal fixation either with an intramedullary nail or with sufficiently rigid onlay plates combined if necessary with external splintage. The periosteum adjacent to the fracture is elevated and a bone graft applied subperiosteally around the fracture site without disturbing the fibrous non-union itself. A bone graft, combined only with external splintage, is adequate if very little movement is permitted at the fracture site by the fibrous tissue crossing the fracture. The bone graft ideally should consist of the patient's own bone since the cells of the graft then contribute to new bone formation. Cortical bone is relatively ineffective in this context since per unit of mass it contains relatively few cells with osteogenic potential. Autogenous cancellous bone is, therefore, the material of choice and a convenient site for this is the patient's iliac crest. The matrix of the graft acts as a scaffold and may also induce new bone formation. Subperiosteal new bone formation is probably induced by the surgical elevation of the periosteum and the rawing of the subjacent cortical bone as well as by the graft itself.

FRACTURES IN CHILDHOOD

Fractures occurring in children differ from those in adults in 6 important respects: (1) the fractures unite more readily, (2) mal-union can to some extent be corrected by growth, (3) joint stiffness is rare after immobilisation, (4) the fractures may involve the epiphyseal plate and hence interfere with growth, (5) the bone may fracture incompletely, and (6) the patient is often

unable to protect himself and to give a history, a combination which gives rise to the Battered Baby Syndrome (see below). The first 3 differences make fractures in children much easier to treat than in adults, and make immobilisation by external splintage almost invariably the method of choice.

Union is almost invariable following all fractures in childhood: a fracture of the neck of the femur is an occasional exception. Not only is union invariable, but it occurs in about half the time required for an adult.

The correction of mal-union by growth seems to occur most readily when the residual angulation occurs about an axis parallel with that of the movement permitted at the adjacent joint. Thus, for example, in supracondylar fractures of the humerus backward angulation of the distal fragment (i.e. extension) can be corrected by growth but a varus deformity (i.e. adduction) cannot. Torsional deformities correct less well than angular.

Joint stiffness is rarely caused by immobilisation in a child. Following the removal of splintage, children quickly use the injured limb and usually regain a full range of movement rapidly and without physiotherapy.

Involvement of the epiphyseal plate in a fracture is not uncommon since the plate is weaker than the bone. Although epiphyseal injuries may lead to a disturbance of growth, they do so surprisingly rarely. The fracture, which often involves the metaphysis, should be accurately reduced but nothing can be done to prevent or to predict a disturbance of growth. Operative reduction should be avoided if at all possible.

FIG. 350.—A greenstick fracture of one cortex of the radius.

Incomplete fractures are called *greenstick fractures*: one cortex may fracture whilst the other bends (fig. 350). The resultant angulation may be hard to correct without completing the fracture.

The Battered Child.—The term ' battered child ' is used to describe a child who has received serious, deliberately inflicted injuries at the hands of his parents or some other adult. The true incidence of this type of injury is not known, but it is undoubtedly common. In one London hospital a case is diagnosed almost every month and for every case diagnosed there must be dozens which are unrecognised. The injuries occur because the child is unable to protect himself, and are unsuspected because he is unable to give a history.

The injured children are usually under the age of 2 years. They are taken to the general practitioner or to hospital, often after a suspicious delay, and the parents are either unable to explain the injuries or suggest some minor accident, such as falling off a sofa, which is quite inappropriate to the severity of the injuries. In more than half the cases there is a history or radiological evidence of previous injury. The commonest injuries are soft tissue bruises and abrasions, burns, fractures of the ribs and long bones, epiphyseal injuries, and sub-dural hæmatoma with or without a fractured skull.

Since this type of child-abuse is repetitive, it is vital, for the safety of the child, to make the diagnosis and take appropriate action as soon as possible. The doctor who first sees the child should be aware of the condition and ready to suspect it. Suspected cases must be admitted to hospital immediately in order to protect the child while the pædiatrician and the medical social worker undertake the investigations necessary to establish the diagnosis.

PATHOLOGICAL FRACTURES

The foregoing discussion has been concerned entirely with injuries to normal bones. Bone may be the seat of a number of pathological processes, for example neoplasm or osteoporosis, which significantly weaken it either generally or locally, and hence make it liable to fracture in the face of trivial forces. Such fractures are known as pathological fractures.

Pathological fractures due to secondary neoplasm should be treated by internal fixation, if the local state of the fracture and the general state of the patient allow, in order to make the patient more comfortable. Following internal fixation, radiotherapy may arrest the growth of the tumour and allow union to occur.

'STRESS' FRACTURES

High, oft-repeated loads applied to the skeleton may produce lesions known as 'stress' fractures (but for which a better term would be 'fatigue' fractures). Typical examples occur in the tibiae of runners training on town pavements, in the femoral necks of newly-inducted infantrymen carrying out fully-laden route marches (see Intra-Capsular Fractures of the Neck of the Femur, p. 388), and in the metatarsals (see march fractures, p. 363, and fig. 381). The bone in question becomes painful and is tender. Radiologically, the fracture, which is nearly always incomplete, is invisible at first but later is revealed by a zone of increased radiodensity due to callus formation. The only treatment necessary is rest.

INJURIES TO ARTICULAR CARTILAGE

Pathology.—Mitosis of human adult chondrocytes does not occur following injury and therefore true healing is impossible. In this sense the chondrocyte is similar to the neurone. Experimental defects involving only the cartilage do not heal: the corresponding lesion in man is only detected as an incidental finding during the exploration of a joint and its fate is presumed to be the same as that in experimental animals. An osseo-cartilaginous defect, produced by a fracture extending through the articular surface, results in bleeding from the bony surface into the joint. The defect fills with granulation tissue arising from the bone and this is eventually converted into fibro-cartilage.

Clinical Features.—There are no specific clinical features of a cartilage injury, but because an injury producing cartilage damage usually produces an effusion or bleeding into the involved joint (hæmarthrosis), swelling and fluctuation in the involved joint usually accompany cartilage damage. In the absence of treatment, some wasting always occurs in the muscles acting on the joint during the weeks after the injury. A loose fragment may fail to gain attachment to the synovial membrane and may then mechanically block movement in the joint, a symptom known as 'locking' of the joint.

Blood in a joint tends to remain liquid because of the presence of hæmolysins

in the synovial fluid, but it eventually clots and subsequently becomes organised into fibrous tissue. This organised hæmatoma adheres to the cartilage surfaces and to the synovial membrane, so that movement in the damaged joint is mechanically limited. Immobilisation—imposed either by pain or in the course of treatment—can be shown, experimentally, to damage cartilage and to lead to the proliferation of fibrous tissue in the synovial cavity. Immobilisation and injury also result in adhesion formation between peri-articular soft tissues such as tendons, ligaments and muscles. Thus articular injuries commonly lead to stiffness in the injured joint.

Because it is rare for defects in the articular surface to be perfectly reconstituted, irregularities persist after these injuries which may eventually result in osteoarthrosis.

INJURIES TO LIGAMENTS AND TENDONS

Pathology.—Ligament injuries may be either simple sprains or ruptures. In a simple sprain some of the collagen fibres of which the ligament is composed are torn but the ligament as a whole is mechanically intact. Blood vessels in the ligament are ruptured so that local swelling and bruising occur. Nerve fibres running in the ligament may suffer a traction injury. In a rupture, the same pathological events occur but to a greater extent, so that the ligament is broken into two and all the blood vessels, collagen fibres and nerve fibres in the involved ligament are divided. Following a rupture, the joint is mechanically unstable.

Tendons rarely rupture, save in pathological circumstances, for example if they become avascular or have been subject to persistent attrition over a roughened bony edge. Traction injuries to a healthy bone/tendon/muscle unit usually produce a rupture at the tendon muscle junction or an avulsion of the tendon from the bone. Tendons, especially those in the hand, may be involved in lacerations anywhere in their length.

Clinical Features.—Injuries to ligaments and tendons heal by the formation of a hæmatoma around the injured structure which subsequently becomes organised to form fibrous tissue. At this stage the divided ends of the ligament are connected by a scar in which the collagen fibres run at random and in which the ends of the original structure can be seen histologically. Such a scar gradually becomes replaced by well-orientated collagen fibres until eventually the histological appearances of the structure have been reconstituted. Whether or not the mechanical properties of the ligament return to normal, depends upon the length of the resulting scar, upon its strength, and upon the extent to which the scar adheres to the surrounding tissues. A tendon, when divided, usually retracts because of the contraction of its parent muscle. Such retraction may produce a gap so wide as to be unbridgeable and as a consequence healing does not occur. If the tendon does not retract, vessels invade the tendon from the surrounding tissues so that the scar tissue which eventually forms, involves both these tissues and the tendon itself. Thus the tendon becomes adherent, its excursion is limited and its function impaired.

Clinically, simple sprains result in two specific physical signs—localized tenderness (usually over the bone/ligament junction) and pain when the ligament is stressed. Ligament ruptures result in three physical signs—localised tenderness, pain when the ligament is stressed and in addition, mechanical instability. The demonstration of mechanical instability is diagnostic of a ligament rupture and in particular distinguishes a rupture from a simple sprain. These physical signs are well illustrated by ligament injuries at the ankle (p. 365) and knee (p. 374). Bruising, local swelling, an effusion into the joint and, with time, muscle wasting are usual, but non-specific, concomitants of these injuries.

Damage to the nerve fibres and mechanoreceptor endings in ligaments, and especially in joint capsules, breaks the postural reflex arcs of which these fibres form the afferent limb. As a consequence the muscles acting across the joint lose their normal postural co-ordination so that in the lower limb, the joint tends to be unstable: for example at the ankle the patient complains that the foot ' gives way '.

If a tendon has been divided, the active movement for which it is responsible is lost. Passive movement remains but may be painful. Loss of active movement may not be obvious clinically if other muscles are available to take over the function of the severed tendon, e.g. the profundus flexor tendons can flex the proximal interphalangeal joints and hence replace sublimis, and all the muscles passing behind the ankle can plantarflex the foot, so masking a rupture of the Achilles' tendon.

Disturbances of Normal Healing.—Failure to heal, the analogue of non-union in bone, may occur in tendons and ligaments if the ends of the divided structure are too widely separated. With lesser degrees of separation, an elongated scar may be produced allowing abnormal movement in the involved joint (in the case of a ligament) or a loss of part of the active range of movement (in the case of a tendon). The collagen fibres in the scar may fail to become well orientated so that the scar is persistently painful when stressed.

Failure to co-apt the ends of the ruptured structure will certainly result in imperfect healing. Absence of tension in the healing tissue may also play a part in poor collagen orientation since it has been shown in tissue culture that collagen fibres tend to array themselves parallel to lines of tension.

Treatment.—If tendons have been lacerated and their ends separated, they will not heal unless they are sutured together. Suture should be carried out as soon as possible provided the sterility of the wound can be ensured. Following suture, the tendon should be immobilised by external splintage of the joints across which it acts for 3 to 6 weeks. The detailed management of tendon injuries in the hand is discussed on p. 200.

Ruptured ligaments may be treated either by immobilisation of the involved joint or by suture. Immobilisation is satisfactory provided that the ends of the ruptured ligaments are lying in contact with each other. Unfortunately in a number of ligaments (for example the medial collateral and cruciate ligaments of the knee) the ends of the ligament may retract: it is then preferable to explore the ligament and suture the ends together.

The joint should be immobilised until it is felt that the site of the rupture will withstand the loads applied to it by protected movements—usually a period of 3 to 6 weeks. Ideally a sutured ligament should be sufficiently secure to allow such movement to occur immediately post-operatively, but in practice the sutures are usually not secure enough to permit this. In some ligaments, for example the lateral collateral ligament of the ankle, significant separation of the ends of the ligament rarely if ever occurs, and normal movements cause no significant separation of the two halves of the ligament. Such ruptures can be treated by early non-weight-bearing mobilisation without causing material elongation of the ligament as it heals.

Following a ligament injury, the muscles acting across the joint become weak and inco-ordinated and the joint stiff, sequels which are treated by appropriate active exercises.

CHAPTER 22

INJURIES TO THE UPPER LIMB

FRACTURES OF THE BONES OF THE HAND

Fracture of the Terminal Phalanx.—This bone is commonly fractured by crushing injuries. The skin and pulp are also crushed so that the skin is often lacerated and the fracture is compound. Perhaps because these injuries involve a small bone, they are often regarded as trivial. This is a mistake, for if the injury to the terminal phalanx and to the overlying soft tissues does not heal satisfactorily, the finger tip becomes permanently tender to touch and often painful in cold weather. Permanent tenderness of a finger tip is a severe disability: the patient tends to use the other fingers and to guard the affected finger so that it gradually becomes stiff. If the digit involved is the thumb, the situation is even more serious for loss of the thumb is functionally almost equivalent to loss of the arm.

Treatment, if the fracture is compound, consists of careful wound toilet and loose suturing of the skin followed by the application of a pressure dressing. The dressing should be changed at 48 hours and thereafter at regular intervals in order to inspect the skin. A broad spectrum antibiotic and tetanus toxoid are administered. If the skin dies or is lost, it may require replacement with full thickness skin on the pulp or split skin elsewhere on the digit (p. 201). If the fracture is simple, a pressure dressing should be applied until pain has subsided.

Fractures of the Middle and Proximal Phalanx

These fractures may be caused by a direct blow (when the bone is often comminuted) or by bending or twisting the finger (when the fracture is transverse or spiral). The fracture is usually unstable, and if it is, is angulated forwards. The tendons adjacent to the fracture may adhere to the fracture as it heals and hence limit movement in the finger.

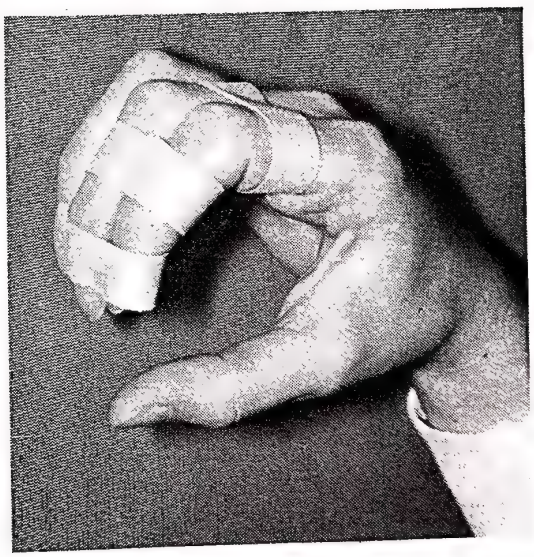


FIG. 351.—The fingers strapped together for undisplaced phalangeal fractures.

Treatment is difficult since it is not easy to maintain reduction and to immobilise the fracture without stiffening the joints of the finger. If the fracture appears to be stable and there is relatively little displacement, the fracture can be splinted satisfactorily whilst allowing movement at the joints of the finger by strapping the finger to its neighbour for 4 weeks (fig. 351). Care must be taken when this is done to ensure that there is no rotational de-

formity at the fracture site, for if there is, the finger will deviate so as to interfere with its neighbour as it flexes. If the fracture is displaced, it is reduced by traction followed by flexion of the finger over a curved aluminium splint applied to the flexor surface of the finger. The aluminium splint is incorporated into a Colles' plaster (fig. 352) and is maintained for at least 4 weeks. A Sheffield splint (fig. 353) may be used as an alternative to an

FIG. 352.—An aluminium splint for displaced phalangeal fractures.

FIG. 353.—A Sheffield splint for displaced phalangeal fractures or fractures of the metacarpals needing temporary splintage to relieve pain.

aluminium splint. If the fracture is not soundly united when the splint is removed after 4 weeks, the fracture may require a further period of splintage provided by strapping the finger to its neighbour. If accurate reduction cannot be obtained by manipulation and splintage, the fracture should be reduced at operation and the reduction held by crossed Kirschner wires.

In any finger injury it is important that *only* the injured finger should be immobilised. Neighbouring fingers should be actively mobilised throughout the period of treatment.

Mallet Finger.—This injury consists of a rupture, or avulsion-fracture, of the terminal slip of the extensor tendon to the distal phalanx. If the tendon is avulsed, the bony insertion of the tendon can be seen as a small fracture fragment on the dorsal aspect of the terminal interphalangeal joint (fig. 354). The injury is caused by forced flexion of the terminal phalanx whilst the extensors of the finger are contracting. It may occur, for example, during bed-making when the hand is thrust under the mattress to tuck in the sheets: the finger tip catches in the mattress and is forcibly flexed at a time when the patient is holding the interphalangeal joints actively extended.

The patient complains of localised pain and swelling and an inability actively to extend the terminal phalanx. Passive extension is possible but when the finger is released the terminal phalanx falls back into a position of 30° of flexion under the influence of the long flexor tendons (fig. 355).

Martin Kirschner, 1879–1942. Professor of Surgery, Heidelberg, Germany. Described the use of traction wires in 1909.

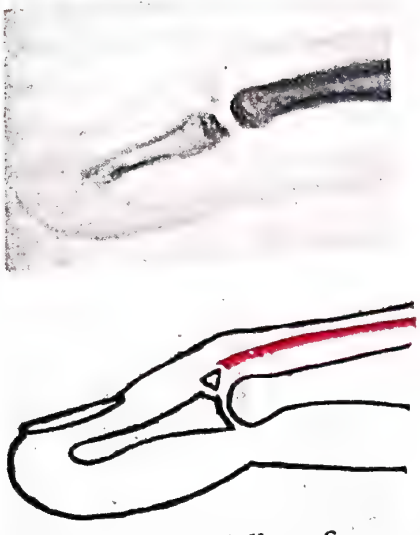

FIG. 354.—Mallet finger. Avulsion of a flake of bone to which the long extensor tendon is attached.

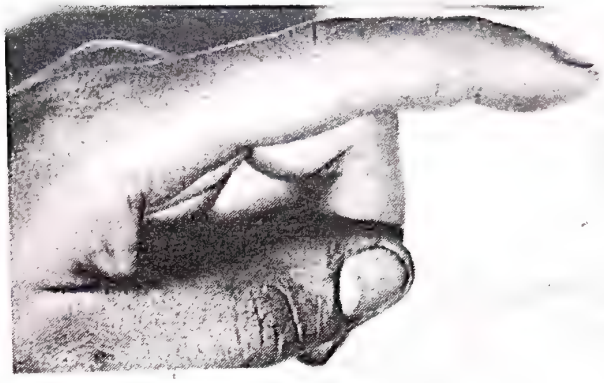

FIG. 355.—Mallet finger.

Treatment.—If a fracture fragment has been avulsed and can be seen radiologically to be rotated from its bed, the fragment should be sutured back into place. If no fragment has been avulsed, or if an avulsed fragment is not significantly displaced, the injury should be treated in a splint holding the terminal phalanx in full extension for 3 weeks (fig. 356). On this regime most tendons unite so that the patient regains active extension, but occasionally the deformity persists. The patient should be advised to accept this deformity since firstly, it often improves gradually over the year following the injury; secondly, the disability it causes is very slight, save in certain occupations such as playing the guitar; and thirdly, late treatment (by suture of the tendon) tends to stiffen the distal interphalangeal joint.

Dislocation of the Interphalangeal and Metacarpo-phalangeal Joints.—These are uncommon. They can usually be reduced easily by traction on the finger followed by flexion of the joint over the fulcrum provided by the surgeon's finger on its flexor aspect. Occasionally the head of the proximal bone 'button holes' through the capsule or, in the case of the thumb, through the two slips of the flexor pollicis brevis tendon (alternatively the long flexor tendon may become interposed in the joint). Closed reduction is then impossible and the injury should be treated by operation.

Ruptures of the Collateral Ligaments.—Forced adduction or abduction at the interphalangeal or metacarpo-phalangeal joints may rupture the collateral ligament on the tension side of the joint. The joint momentarily subluxates but reduces spontaneously unless the ruptured collateral ligament becomes interposed between the joint surfaces.

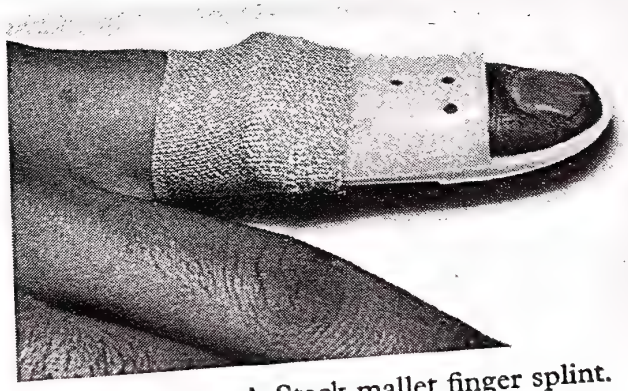

FIG. 356.—A Stack mallet finger splint.

Clinically, the joint is tender on the side of the ruptured ligament and mechanical instability can be appreciated. Instability can be confirmed by a stress X-ray. There is no abnormality in ordinary radiographs unless the bony attachment of the involved ligament has been avulsed and is radiologically visible, or the ligament is interposed in the joint space in which case persistent malalignment of the finger will be noticed.

Treatment.—The finger should be immobilised on an aluminium splint (fig. 352). If the collateral ligament is interposed in the joint surface or an avulsed bony fragment is displaced, the joint should be opened and the collateral ligament or fracture fragment sutured in its anatomical position.

Fractures of the Metacarpals.—Fractures of the shaft or neck of one or more of the medial four metacarpals are produced by the knuckles striking

Hugh Graham Stack, Contemporary. Orthopædic Surgeon, Harold Wood Hospital, Essex, England.

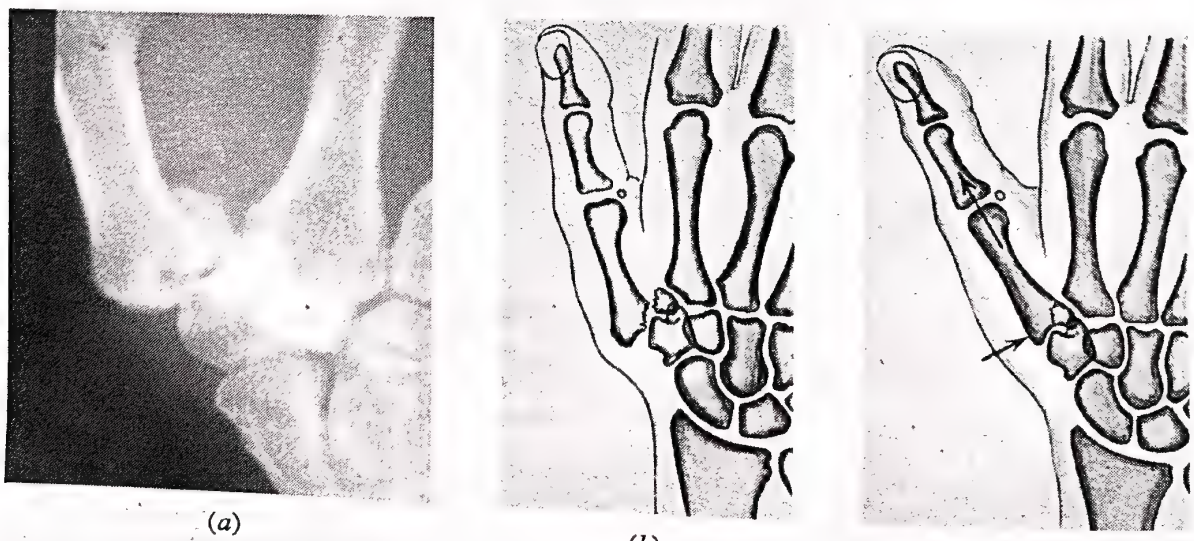
objects (i.e. by punching), or by blows on the dorsum of the hand. Fractures of a single shaft are splinted by the adjacent metacarpals and suffer little displacement. Fractures through the neck are usually associated with some forward angulation of the head of the bone but this deformity, even if gross, results only in recession of the knuckle and a minimal apparent loss of extension at the metacarpo-phalangeal joint. This is of no significance if full movement at other joints and a good grip is achieved by early mobilisation. Transverse fractures of the metacarpals are sometimes slow to unite, but all other fractures unite well.

Treatment.—If pain demands temporary splintage, the hand should be rested on a Sheffield splint with the immobilised finger in a position of function, i.e. flexion not extension (fig. 353). When pain has settled, the earlier mobilisation is started the better.

It should be explained to patients with angulated fractures of the neck of the metacarpal that, if no specific treatment other than early mobilisation is undertaken, their hand will return to normal save for a 'dropped knuckle' and perhaps a small extensor lag. If they prefer not to accept this disability, an attempt should be made to reduce the fracture by flexing the metacarpo-phalangeal joint to 90° and then pressing the proximal phalanx, and with it the distal fragment, dorsally in relation to the shaft of the metacarpal. The reduction is held by a strip of plaster wrapped round the extensor surface of the finger and incorporated proximally in a Colles' plaster (fig. 364). The plaster is allowed to set as the reduction is held by the surgeon. The disadvantages of this form of treatment are (1) that the method of holding the reduction, although the best available, is inadequate and the fracture usually slips in plaster and (2) that the finger is stiff for a longer total time than after early mobilisation.

Fractures of 3 or more metacarpal shafts require reduction and splintage since the metacarpus as a whole is unstable.

Fracture-Dislocation of the Base of the First Metacarpal (Bennett's Fracture).—This injury is caused by a blow to the point of the thumb. An oblique fracture of the base of the metacarpal occurs extending proximally to involve the articular surface. The shaft of the bone is drawn proximally by



(*a*) (*b*) (*c*)

FIG. 357.—(*a*) Bennett's fracture dislocation, (*b*) the nature of the initial displacement and (*c*) the principles of reduction.

Edward Hallaran Bennett, 1837–1907. Professor of Surgery, Trinity College, Dublin. Described this fracture in 1828.

the pull of the long muscles of the thumb, so that it subluxates from the carpo-metacarpal joint (fig. 357).

Treatment.—The fracture-dislocation is easily reduced by traction, extension of the thumb, and pressure over the dorsal aspect of the base of the first metacarpal. The difficulty is to maintain reduction. This can be done if the 1st metacarpal is immobilised in plaster in almost full extension at the carpo-metacarpal joint whilst direct pressure is applied over the dorsum of the base of the bone as the plaster sets, so as to press the shaft medially against the palmar fragment. Unfortunately a reduction held in this way often slips. Therefore some surgeons apply continuous traction to the thumb by means of a plaster cast applied to the forearm, in which is incorporated a loop of thick wire to take adhesive traction applied to the end of the thumb. Alternatively the fracture may be fixed internally with a screw.

Lacerations of the Hand. (These are discussed on p. 198.)

INJURIES TO THE CARPUS

Any of the bones of the carpus may be fractured but by far the commonest injury is fracture of the scaphoid.

Fractures of the Waist of the Scaphoid

The injury occurs following a fall on to the outstretched hand, typically in young adults. It is uncertain precisely how this causes fracture of the scaphoid, but it seems possible that the bone is 'bent' at its waist over the radial styloid.

The patient presents with a complaint of pain in the wrist, but function of the wrist may not be grossly impaired. On examination there is tenderness over the scaphoid in the anatomical snuff-box, a little swelling and no bruising. These physical signs often appear trivial and suggest a 'sprained wrist' rather than a fracture. Radiological examination (which should include not only an antero-posterior and lateral view of the wrist, but also two oblique views) may not display the fracture immediately after injury since no displacement occurs at the fracture site.

Treatment.—Because this fracture does not produce substantial clinical and radiological signs it is often missed and wrongly diagnosed as a 'sprained wrist'. The wrist is then treated with strapping and as a consequence the fracture may not unite. Therefore any 'sprained wrist' in which a fracture of the waist of the scaphoid cannot be excluded should be treated for 2 weeks in a scaphoid plaster (fig. 358). Two weeks after the injury, the plaster should be removed and the wrist re-X-rayed. By this time bone resorption will have occurred at the site of a scaphoid fracture so that the injury will be radiologically obvious (fig. 359). If the fracture is diagnosed at the time of the injury or at re-X-ray 2 weeks later, a scaphoid plaster

FIG. 358.— A scaphoid plaster.

FIG. 359.—Fracture through the waist of the scaphoid.

should be applied for 8 weeks.

Non-union is not infrequent even after immobilisation for 8 weeks, because the blood supply to the proximal part of the bone often enters entirely through the distal pole. Thus when the waist of the scaphoid is fractured the proximal pole is infarcted. The fracture then fails to unite and avascular changes, similar to those seen in the femoral head (p. 388), may develop in the proximal half of the bone. These changes may lead to osteoarthrosis of the wrist (fig. 360). Non-union used to be treated by further immobilisation for periods of as long as a year but although immobilisation may eventually result in union of the fracture, it may also result in a stiff wrist. It is therefore preferable to offer the patient with an un-united fracture at 8 weeks two alternatives: to accept the un-united fracture (which will not always give rise to significant disability) or to treat the non-union by a bone graft and internal fixation with a small screw followed by a further 8 weeks immobilisation in plaster.

Fracture of the tubercle of the scaphoid occurs occasionally and is an insignificant injury. It is functionally immaterial whether the fracture unites or not, and the wrist need only be treated by such immobilisation as is necessary to relieve pain. The essential difference between this injury and fractures of the waist of the scaphoid is that in this injury no articular surface is involved, whereas after fractures through the waist of the scaphoid the mechanism of the wrist may be prejudiced by an unsound fibrous non-union.

FIG. 360.—Non-union of a fracture of the waist of the scaphoid with secondary osteoarthrosis of the wrist.

Lunate and Perilunate Dislocation of the Wrist

A fall on the palm of the outstretched, dorsiflexed hand may dislocate the whole of the carpus backwards in relation to the radius and lunate. This is a perilunate dislocation of the wrist. The dislocation may persist, spontaneously reduce, or reduce but in so doing displace the lunate forwards. This third possibility produces a dislocation of the lunate. These dislocations may be complicated by a fracture of the waist

of the scaphoid. If they are, the proximal pole of the scaphoid remains with the lunate, and the distal pole with the rest of the carpus.

Surprisingly, it is not uncommon for these injuries to be missed clinically and radiologically. Clinically the wrist and fingers are stiff and the wrist swollen and tender. If the lunate has dislocated, it may compress the median nerve to cause median nerve signs. A well-centred lateral X-ray clearly reveals the dislocated lunate in front of the carpus or the posterior displacement of the carpus, but a poor, slightly rotated lateral view may conceal the dislocation. The antero-posterior view at first sight may be passed as normal, but close inspection will show that the bones of the proximal row of the carpus (scaphoid, lunate and triquetral) are not disposed round the head of the capitate with the intervention of a regular joint space as in the normal wrist, and, if the lunate has dislocated, the lunate appears tri-angular rather than quadrangular in outline because it is rotated as it is dislocated forwards.

Avascular Necrosis of the Lunate (Kienböck's Disease)

This may follow serious injury, for example dislocation, in which all the soft tissue attachments of the bone are ruptured so that the bone is infarcted. It may also follow trivial injuries, sometimes after an interval of years. Sometimes there is no history of trauma at all.

The wrist becomes painful and stiff. Radiologically the lunate is dense and deformed (fig. 361). Long-standing cases are complicated by osteo-arthrosis.

Treatment.—The patient should be advised to adjust his occupation so as to limit the demands on his wrist. If this is impossible, the lunate or the proximal row of the carpus is excised, or the wrist is arthrodesed.

FIG. 361.—Kienböck's Disease.

FRACTURES OF THE DISTAL RADIUS AND ULNA

Colles' Fracture

This is a fracture of the distal end of the radius produced by a fall on to the palm of the outstretched hand. The injury is uncommon below the age of 50. After this age, it becomes increasingly common so that overall it is one of the commonest fractures. It is particularly common in women, as are fractures of the proximal femur, and, like fractures of the proximal femur, its increasing frequency with age has been attributed to the development of osteoporosis in post-menopausal women. The association of the fracture with increasing age is probably also due to the fact that the elderly are more liable to fall than are the young.

Morbid Anatomy.—The fracture line lies approximately 2 cm. proximal to the distal articular surface of the radius. The bone is not infrequently comminuted, especially on the dorsal surface. The distal fragment is: (1) displaced dorsally, (2) angulated dorsally, (3) driven proximally into the

Robert Kienböck, 1871–1953. Professor of Radiology, Vienna. Described this condition in 1910.
Abraham Colles, 1773–1843. Professor of Surgery, Royal College of Surgeons in Ireland (1804–1836) and Surgeon Dr. Steven's Hospital, Dublin. Described this fracture in 1814.

shaft, (4) angulated laterally and (5) supinated. There is always an associated injury to the inferior radio-ulnar joint: the articulating surfaces of these bones are displaced relative to each other and their connecting ligaments (including the triangular cartilage) are torn or the ulnar styloid is avulsed. It is uncertain whether the latter injury is due to avulsion of the ulnar styloid by the triangular cartilage or by the ulnar-collateral ligament of the wrist.

Clinical Features.—The appearance of the wrist is typical and is described as a 'dinner-fork' deformity (fig. 362). Viewed from the side the dorsal aspect of the wrist is unduly prominent; viewed from the dorsum the lateral aspect of the wrist is slightly prominent and the hand is radially deviated. The fracture site is tender. The radial styloid is no longer distal to the ulnar

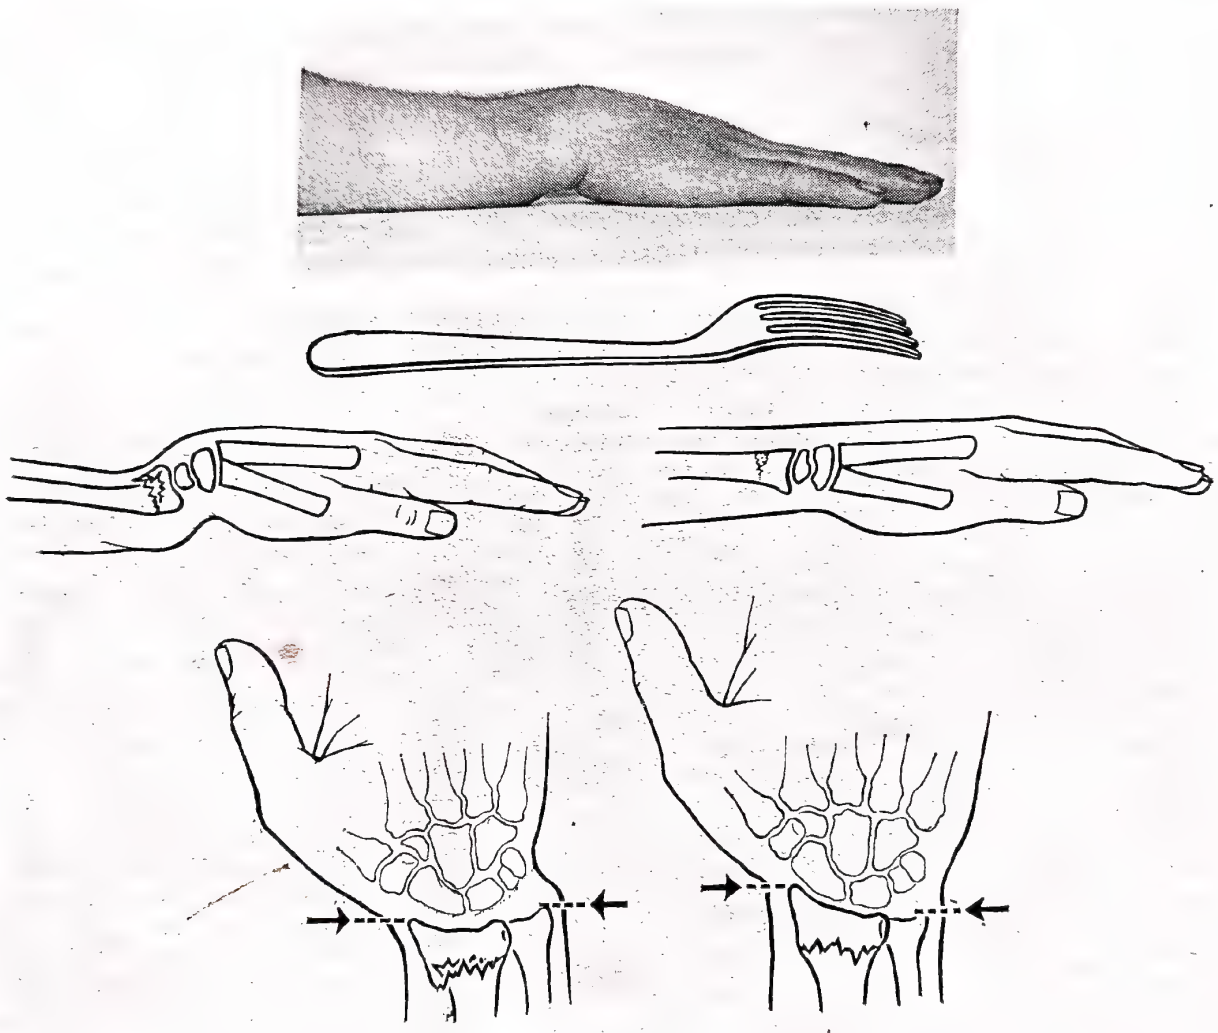


FIG. 362.—Dinner-fork deformity of Colles' fracture. Note the levels of the radial and ulnar styloid processes before and after reduction.

styloid; instead the two styloid processes are approximately at the same level, a reflection of shortening in the radius (fig. 362). Radiologically the fracture, the extent of the displacement, and the degree of comminution will be obvious (fig. 363).

Treatment.—The fracture is reduced by manipulation and immobilised with a plaster back-slab which is completed to form a Colles' plaster (fig. 364) 24 hours after the injury.

Manipulation of a Colles' Fracture.—The patient is given a general anæsthetic or a regional block using either intravenous anæsthesia distal to a tourniquet or a brachial plexus block. An assistant grasps the upper arm whilst the surgeon grasps the injured hand as if he were 'shaking hands'. He then exerts firm traction in the long axis of the limb in order to disimpact the fragments of the radius. When this has been accomplished, he presses the distal fragment into palmar-flexion and ulnar-deviation using the thumb of his other hand. At the same time, he draws the patient's hand into pronation, ulnar-deviation and palmar-flexion. A plaster slab is then applied to the lateral, dorsal and medial aspects of the forearm, wrist and hand from the elbow to the metacarpal heads holding the wrist in palmar-flexion and ulnar-deviation (fig. 364(*a*)). Satisfactory reduction is confirmed by X-ray. The slab is converted to an encircling Colles' plaster if the circulation to the fingers is satisfactory 24 hours later.

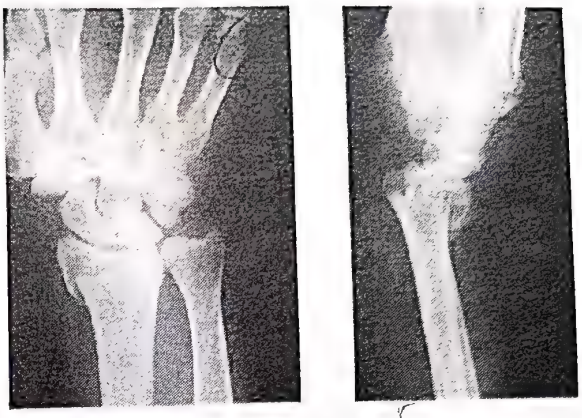

FIG. 363.—Colles' fracture.

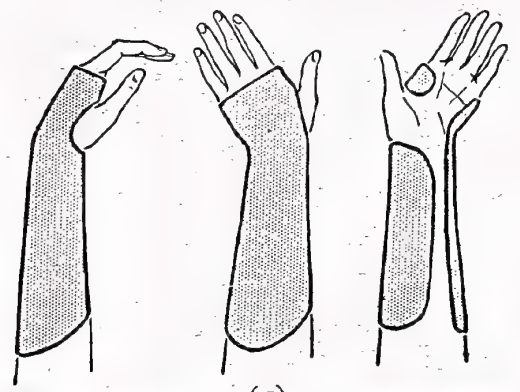
The plaster is maintained for 6 weeks. If extreme palmar-flexion and ulnar-deviation is required to maintain the reduction, this position should be maintained only for 3 weeks, at the end of which time the plaster is removed and re-applied with the wrist more nearly neutral. It should be noted that although pronation is required to correct the supination element of the deformity, a plaster is applied which does not control the movements of pronation and supination. In this sense a Colles' plaster is inadequate for this injury: it is used only because, in the age group involved (the elderly), the injury to the inferior radio-ulnar joint results in a greater limitation of pronation and supination if these movements are restricted than if they are permitted and loss of forearm rotation is a more serious disability than is that attributable to malunion. The fingers should be actively mobilised immediately after the injury since otherwise they may become stiff.



(*a*)

(*b*)

FIG. 364.—Colles' plaster. (*a*) Plaster slab in ulnar deviation and slight palmar-flexion applied immediately after the reduction of a Colles' fracture. (*b*) The completed plaster.

Union is almost invariable, but there is often some residual deformity because (1) even if the initial reduction is perfect, recurrent backward angulation of the distal fragment is common if the dorsal cortex of the radius is comminuted and, (2) a Colles' plaster does not control the supination element of the deformity. When the plaster is removed, the wrist is often stiff and may require re-

mobilisation in a physiotherapy department. The inferior radio-ulnar joint is also commonly stiff and may be very difficult to remobilise. Occasionally persistent limitation of pronation and supination combined with significant displacement of the distal radius relative to the distal ulna may, in younger patients, require excision of the distal ulna (a procedure which can be regarded as an excision arthroplasty of the inferior radio-ulnar joint).

Fracture of the Radial Styloid

This injury occurs following a direct blow on the wrist (the injury used to be called 'chauffeur's fracture', when cars were started with a starting handle, since if this kicked back it often struck the wrist on its lateral aspect) or occasionally following a fall on the wrist. The fracture line runs proximally and laterally through the radial styloid roughly from a point opposite the articulation between the scaphoid and the lunate. Displacement is uncommon and the only treatment required is the application of a Colles' plaster for 6 weeks.

Displacement of the Distal Radial Epiphysis

This is an injury confined to children. The displacement is similar to the Colles' displacement and the fracture line runs partly through the epiphyseal plate itself and partly through the metaphysis. The injury may be surprisingly difficult to reduce. Reduction should be carried out under general anæsthesia and a Colles' or above-elbow plaster applied for 6 weeks. Fortunately, a disturbance of growth is rare.

Fracture through the Distal End of the Radius in Children

These may occur at any level proximal to the epiphyseal plate. They may be greenstick or complete. The former are often almost undisplaced and only require support in a Colles' plaster for 3 to 4 weeks. The fracture may however be complete, with marked angulation (concave dorsally) at the fracture site. This is a deceptive injury for it is often regarded by the inexperienced as the equivalent of a Colles' fracture and treated in the same way. If it is, so that pronation and supination are not controlled by the plaster which is applied, significant re-angulation commonly occurs at the fracture site leading to mal-union and marked limitation of pronation and supination. Following reduction, the fracture should be held by a well-moulded plaster which extends above the elbow with the hand palmar-flexed, ulnar-deviated and fully supinated, the elbow itself being at right angles so that pronation and supination are controlled. Both undisplaced and displaced fractures should be X-rayed one week after reduction to ensure that angulation of the fracture has not occurred in plaster. If it has, re-manipulation is required.

Smith's Fracture

This is the reverse of Colles' fracture, the distal fragment being palmar-flexed rather than dorsiflexed. It is uncommon. The injury is conventionally attributed to a backward fall on the outstretched hand but it seems more likely that it is in fact due to a fall on the dorsum of the palmar-flexed wrist, not to a fall on the palm of the outstretched hand at all. Reduction is by reversal of the original mechanism and immobilisation in an above-elbow plaster for 6 weeks or, better, by internal fixation using an Ellis plate.

FRACTURES OF THE SHAFT OF THE RADIUS AND ULNA

Fractures of One Forearm Bone without Angulation.—A fracture of the radius or ulna, without angulation, may occur as a consequence of a blow applied directly to the forearm. The fracture requires immobilisation in an above-elbow plaster for 6 weeks in an adult, 3 weeks in a child. (See also: Fracture-Dislocation of the Forearm, p. 347).

Robert William Smith, 1807–1873. Professor of Surgery, Trinity College, Dublin. Described the reverse Colles' fracture of the lower ends of the radius in 1847.
James Stokes Ellis, Contemporary. Professor of Orthopædic Surgery, University of Southampton, England.

Fractures of Both Forearm Bones

These fractures usually occur at approximately the same level and are caused by a direct blow, which in effect bends the bones at the point where the blow is received. Occasionally the bones may be fractured by torsion of the forearm: in this case the fractures are oblique and are disposed at different levels in the two bones.

Treatment.—In the adult it is imperative that an absolutely perfect reduction be achieved since otherwise a loss, often substantial, of pronation and supination will occur. In the child residual angulation of about 5° can be accepted as it will be corrected by remodelling. Residual rotation (pronation or supination) at the fracture site cannot be corrected by remodelling.

Perfect reduction is usually impossible by closed manipulation. Therefore in the adult only one attempt should be made to reduce the fractures conservatively. If this fails, the injury is best treated by operative reduction of both fractures followed by internal fixation using either intramedullary Rush nails or, better, strong plates applied with the fracture sites in compression. Following mechanically adequate internal fixation no plaster is required provided the patient undertakes only gentle activities with his arm. If plates have been applied which maintain reduction but which are not mechanically sound, they will need the support of an above-elbow plaster for at least 6 weeks. In a child, an acceptable reduction can usually be obtained conservatively but if it cannot the fractures should be treated by internal fixation using onlay plates, never Rush nails.

The Technique of Closed Manipulation.—The elbow is flexed to 90° and the surgeon applies traction to the hand against counter-traction applied by an assistant grasping the upper arm. Traction corrects angulation and disimpacts the fractures so that the bones in the distal part of the forearm can be pronated or supinated to align them with those in the proximal part. If the radial fracture is distal to the insertion of pronator teres, the proximal radius will lie in mid pronation, but if the fracture is proximal to the insertion of pronator teres, the proximal radius lies in full supination and this is therefore the position in which the surgeon places the hand. When the fracture has been reduced, an assistant applies an above-elbow plaster whilst the surgeon maintains traction. The fracture is X-rayed immediately the plaster has been applied, at 48 hours and then weekly for 3 weeks. The plaster is maintained for 6 weeks. If at any time the position of the bones is seen to be unsatisfactory, the fracture is treated by open reduction.

Fracture-dislocation of the Forearm

Monteggia fracture-dislocation consists of a fracture of the ulna and dislocation of the superior radio-ulnar joint.

The Galeazzi fracture-dislocation consists of a fracture of the radius and dislocation of the inferior radio-ulnar joint.

The presence of a fracture of one forearm bone should always raise the suspicion that the inferior or superior radio-ulnar joint has been dislocated as well. This suspicion is confirmed if angulation occurs at the fracture site, for this is only possible in a fracture of a single forearm bone if the ligaments connecting the angulated bone to its opposite number have been torn. Thus

Leslie V. Rush, Contemporary. Surgeon, Rush Memorial Hospital, Meridian, Mississippi, U.S.A.
Giovanni Battista Monteggia, 1762–1815. Professor of Surgery, Milan. Described this fracture in 1814.
Riccardo Galeazzi, 1866–1952. Director of the Orthopædic Clinic, University of Milan. Described this fracture in 1934.

the general rule that a fracture somewhere in the shaft of a long bone demands an X-ray, not only of the bone itself but of the proximal and distal joint, is particularly well exemplified by this fracture.

Treatment is by open reduction of the fracture and if necessary of the dislocation, followed by internal fixation of the fracture and immobilisation of the arm in an above-elbow plaster.

INJURIES TO THE ELBOW

The elbow is very liable to become stiff following an injury, regardless of its exact nature. It is uncertain why this is so: commonly no specific explanation for the stiffness can be found and it is presumed that adhesions have formed within and around the capsule of the joint. It seems likely that too vigorous an attempt to move the joint in the first few weeks after an injury may promote stiffness of this kind and therefore in general it is wise to rest the elbow for a short period following injury (immobilisation may, of course, be inevitable as a consequence of the nature of the injury). The joint is then mobilised under close supervision in a physiotherapy department, making repeated measurements of the precise range of flexion and extension that has been obtained.

Myositis Ossificans.—This is a condition, misleadingly named, which may occur following musculo-skeletal injury anywhere in the body but which is particularly common following injuries at the elbow. Why it should be common at the elbow is unknown.

Pathologically, the condition consists of ossification in a hæmatoma. This may occur following a fracture, or may follow a purely soft tissue injury in which periosteum has been avulsed. It is believed that the periosteal cells proliferate within the hæmatoma and ossify it. Since the new bone replaces the hæmatoma, the bone tends to lie between the muscles rather than to involve the muscles themselves. Thus myositis ossificans is not, as its name implies, an ossifying inflammatory disease of muscle.

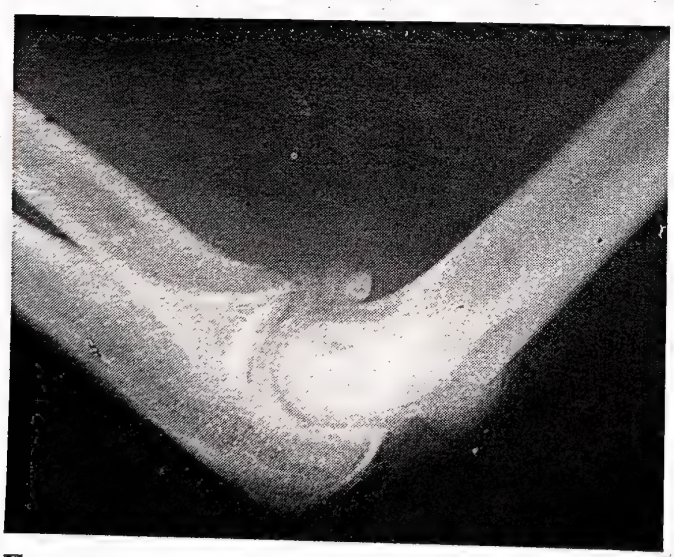


FIG. 365.—Myositis ossificans anterior to the elbow: mature bone.

Clinically, at the elbow the development of the condition may first be suggested by a failure of the range of movement gradually to increase following gentle mobilisation. If exercises are then pressed strenuously, the range of movement actually decreases rather than increases and pain in the elbow becomes worse. At this stage (about 3 or 4 weeks after injury) there are no abnormal radiological signs. By 4 to 6 weeks after injury a faint cloud of new bone for-

mation with indistinct edges can be seen in the area destined to become ossified. The new bone gradually becomes more dense and more organised until finally it takes on the radiological appearance of mature bone (fig. 365).

Treatment is difficult. When the condition is first suspected the elbow should be rested absolutely in a plaster cylinder until pain and tenderness have settled. Remobilisation should then be started extremely gently taking care to measure the range of movement at least twice a week in order to detect the earliest sign of any reduced mobility. Attempts have been made to remove the new bone surgically. This should never be attempted until the bone has a radiologically mature appearance, since if it is, the hæmatoma produced by the operation is liable to ossify in its turn. The removal of a block of mature new bone is often surgically difficult and may give a disappointing increase in the range of movement since by the time that the operation is possible, fibrous adhesions have formed between all the soft tissues around the elbow. However the condition is treated, some permanent limitation of movement is the usual outcome.

Dislocation of the Elbow

This usually occurs in a posterior direction, following a fall on the outstretched hand with the elbow slightly flexed. The coronoid process of the ulna passes posteriorly below the distal end of the humerus. Spasm of the triceps muscle then locks the elbow in a position of posterior dislocation (fig. 366).

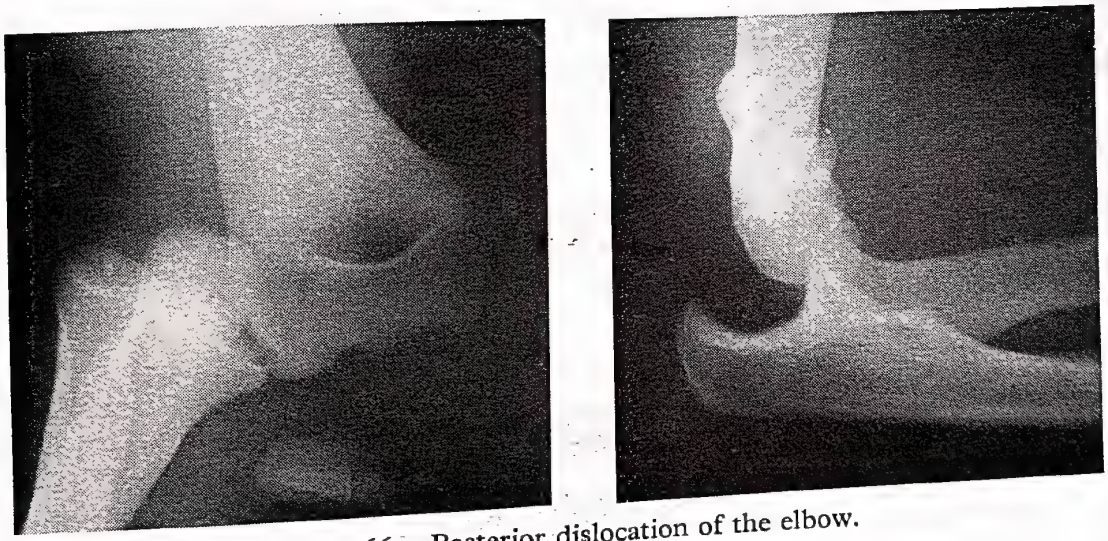

FIG. 366.—Posterior dislocation of the elbow.

Clinical Features.—The patient is unable to move the elbow from a position of slight flexion. The point of the olecranon can be felt to be abnormally posterior to the humeral epicondyles: a clinical feature which distinguishes this injury from supracondylar fracture of the humerus (fig. 367). Radiological examination reveals the dislocation and may show associated fractures either of the coronoid process, of the head of the radius, or of the distal articular surface of the humerus. The fractures are often best, or only, seen in a post-reduction radiograph, an investigation which should never be omitted.

Treatment consists of giving the patient a general anæsthetic to produce muscle relaxation. It is then easy to reduce the dislocation by applying traction in the long axis of the (slightly flexed) ulna. The sensation of reduction is usually obvious and once achieved the elbow can be put through a full range of movement. The reduction is stable because of the bony con-

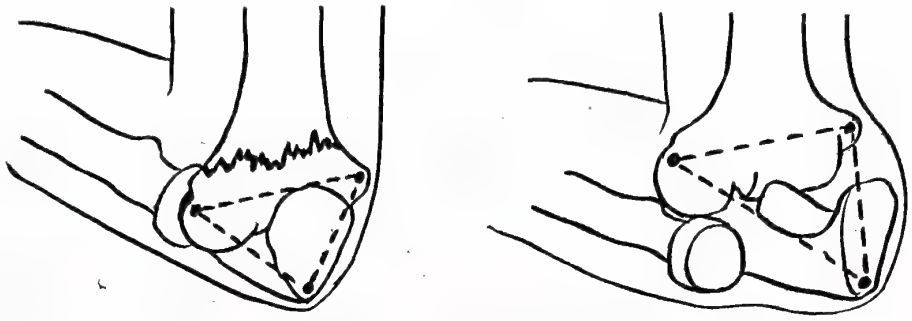

FIG. 367.—Bony points in the elbow. 1. In the normal elbow and in the elbow after a supracondylar fracture, the triangle formed by the tip of the olecranon and the two epicondyles is roughly equilateral. 2. When the elbow is dislocated the tip of the olecranon is displaced and the triangle is no longer equilateral.

figuration of the elbow, but it must be remembered that this injury can only occur if the capsule and ligaments of the elbow have been ruptured. The elbow should therefore be immobilised in a plaster back slab and a sling for 3 weeks and thereafter gently mobilised.

Rupture of the Collateral Ligaments of the Elbow

Forced abduction of the forearm bones on the humerus may rupture the medial collateral ligament or avulse its bony attachment to the medial epicondyle. Adduction may produce a similar injury to the lateral collateral ligament.

Clinical Signs.—There is marked tenderness, bruising, and swelling in the region of the injured ligament. Mechanical instability of the joint may be suspected clinically, and can be proven by examining the elbow under an anæsthetic, if necessary taking a stress radiograph.

In the absence of a fracture, the arm is treated in the same way as following the reduction of a dislocation of the elbow. The treatment of an associated fracture of the medial epicondyle (an injury equivalent to a rupture of the medial collateral ligament) is discussed on p. 355.

Fractures of the Proximal Ulna

Two fractures of the proximal ulna may involve the elbow: fracture of the olecranon and fracture of the coronoid process.

Fracture of the olecranon is usually caused by a fall on to the point of the elbow, the olecranon being broken by the distal end of the humerus. The fracture line is transverse and runs through the narrowest point of the olecranon. The pathological and clinical features of the injury and its treatment are closely paralleled by transverse fractures of the patella.

Clinical Features.—It is essential to decide clinically whether or not the triceps expansion is intact over the fracture site. If it is, there will be local bruising, swelling and tenderness, but active extension of the elbow against gravity will be possible, there will be no clinically detectable gap at the fracture site, and radiologically there will be no separation of the fracture fragments. If the triceps expansion is ruptured, active extension against gravity is

impossible and the proximal fragment is drawn up into the arm by the triceps muscle creating a palpable gap at the fracture site and an obvious separation of the fragments radiologically (fig. 368).

FIG. 368.—Fracture of the olecranon with separation.

Treatment.—If there is no significant separation of the fracture fragments and active extension is possible, the elbow may be treated by 6 weeks' immobilisation in a padded plaster cylinder followed by gentle mobilisation or by internal fixation. If the fracture fragments are separated, the fracture must be reduced and immobilised by internal fixation since the fracture cannot be completely reduced even by full extension of the elbow, and immobilisation of the fully extended elbow may result in disastrous stiffness of the joint. The fracture should therefore be fixed internally, for example, by a screw placed through the tip of the olecranon (fig. 369). Following operation, the elbow should be immobilised for 3 weeks in a plaster back slab. Thereafter screw fixation is usually sufficiently secure to allow progressive mobilisation of the elbow.

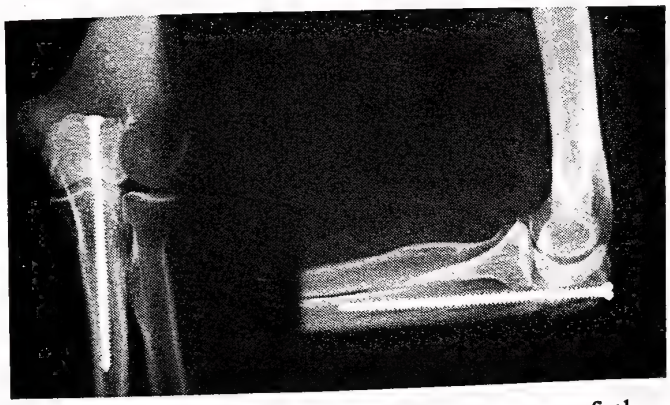

FIG. 369.—Internal fixation of a fracture of the olecranon with a screw.

Fracture of the coronoid process is uncommon and usually accompanies dislocation of the elbow. The coronoid process is usually approximated to the ulna by reducing the dislocation. If it is not, open reduction is required.

Fractures of the Proximal Radius

These fractures occur as a consequence of a fall on the outstretched hand. If the thrust goes directly up the long axis of the radius, the neck of the bone may be fractured and is often impacted: a mechanism similar to that which produces fractures of the neck of the humerus. More commonly the fracture line runs vertically to split off a fragment of the head (fig. 370). The two fractures may be combined to produce a comminuted fracture of the head of the radius.

The clinical signs are often trivial and do not suggest that a fracture has occurred. There is commonly very little bruising and minimal swelling. The only significant physical signs are painful limitation of movement combined with tenderness over the head of the radius. The injury is revealed radiologically.

Treatment.—If the fracture involves the articular surface and significant

displacement has occurred, the head of the radius must be excised. If it is not, the resulting deformation of the head of the radius limits movement, the fracture fragment may not unite so that it forms a loose body, and late osteo-arthrosis is almost inevitable. If the fracture line runs through the neck of the radius or runs through the head but with very little displacement, the elbow should be immobilised for 3 weeks in a plaster back slab and then gently mobilised in a physiotherapy department. If the final outcome is significant limitation of pronation and supination combined with deformation of the head of the radius, the head of the radius should be removed some months after injury.

FIG. 370.—Vertical fracture of the head of the radius.

Under no circumstances should the head of the radius be removed in a child since this results in loss of growth at the proximal end of the radius and hence in progressive derangement of the elbow and radio-ulnar joints.

Supracondylar Fracture of the Humerus in Children

This injury is one of the most serious fractures in childhood and poses considerable therapeutic problems.

Mechanism and Morbid Anatomy.—The injury is caused by a fall, with the elbow slightly flexed, on to the outstretched hand which is pronated by the injury. The fracture line runs transversely through the epiphysis and distal metaphysis of the humerus (fig. 371).

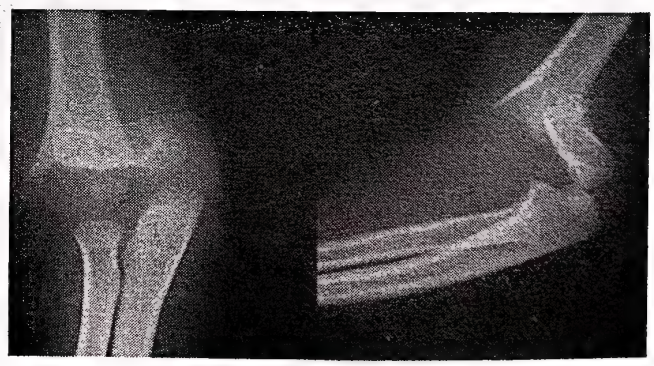

FIG. 371.—Supracondylar fracture of the humerus; there is danger to the neuro-vascular structures between the fragments in this very displaced fracture. (See fig. 348.)

The displacement of the distal fragment may be minimal, but more commonly there is substantial, complex displacement. Such displacement consists of the following elements: 1. backward displacement of the distal fragment, 2. backward angulation of the distal fragment, and 3. pronation of the distal fragment (because the hand is usually pronated at the time of the injury). Pronation produces internal rotation of the distal fragment (the two movements are really the same). As a consequence, the medial cortex of the distal fragment moves posteriorly relative to the medial cortex of the shaft of

the humerus, whilst on the lateral side of the fracture the fragments often remain ' hitched ' to each other. The pull of the arm muscles then draws the medial side of the distal fragment proximally, posterior to the shaft of the humerus, whilst leaving the lateral side roughly in its original anatomical position. The effect of this displacement is to adduct the distal fragment relative to the shaft of the humerus. Thus pronation results in internal rotation and adduction of the distal fragment.

Clinical Features.—The elbow swells rapidly following this injury so that gross swelling may obscure the other physical signs within 3 or 4 hours. During this time bruising is not obvious. The child is unable to move the elbow. If significant swelling has not occurred, the posterior prominence of the point of the elbow is obvious and it is possible to palpate the medial and lateral epicondyles and the point of the olecranon so as to establish that they are normally related to each other (fig. 367). This finding distinguishes the injury clinically from a posterior dislocation of the elbow.

The possibility of an interruption of the blood supply to the forearm following this injury must be paramount in the mind of the surgeon from the moment that he first sees the child. This complication may occur at the time of the injury if the brachial artery is contused or lacerated by the anterior aspect of the proximal fragment of the humerus. In this event the radial pulse will not be palpable. More commonly the radial pulse is present at the time of the injury but is obliterated by swelling and flexion of the elbow following reduction. It is therefore imperative to examine carefully the blood supply to the hand on the injured side at repeated intervals over the first 2 or 3 days following injury.

The details of the injury may be difficult to make out radiologically, since ossification of the distal end of the humerus is complex and presents a confusing radiological picture. Further difficulty is created by the fact that the elbow cannot be extended to take an X-ray. These difficulties can to some extent be overcome by X-raying the other elbow in the same position of flexion for comparison.

Treatment.—Reduction of this fracture is difficult and if the surgeon has not already had the opportunity of reducing the fracture himself he should always call in an experienced surgeon urgently so that the latter has the opportunity of assisting the manipulation before gross swelling has made palpation of the normal anatomy impossible.

Technique of Manipulation of a Supracondylar Fracture

The assistant grasps the upper arm whilst the surgeon holds the injured hand as if he were ' shaking hands '. The surgeon then exerts firm steady traction for a period of 2 minutes or more in the *long axis of the forearm*: that is to say he does not attempt to extend the elbow until traction has drawn the distal fragment beyond the proximal fragment. This reduces the chance of damaging the brachial artery with the distal end of the humerus when the elbow is extended in the next stage of the manipulation, or of entrapping it in the fracture site when the elbow is subsequently flexed. Following traction in the flexed position, the surgeon extends the elbow, feeling the radial pulse as he does so. When full extension has been obtained, the forearm is fully supinated to correct the pronation described above. The fact that the hand and distal fragment are fully supinated is confirmed by fully supinating the uninjured hand and externally rotating the shoulder: the two hands should now have assumed the same attitude. Next, the carrying angle at the elbow is corrected by eye. The

surgeon then grasps the upper arm with his second hand placing his fingers over the biceps muscle so that his thumb rests on the olecranon. He then changes the position of the hand exerting traction, placing it so that he grasps the distal forearm with his index on the radial pulse. He then slowly flexes the elbow using the hand with which he is exerting traction to produce a combination of flexion and continuous traction in the long axis of the forearm. The thumb over the olecranon presses the olecranon (and with it the distal fragment) forwards into flexion; the fingers of this hand exert counter-traction against the hand pulling in the long axis of the forearm. Flexion is continued until a point just beyond 90° is reached. Throughout this manœuvre the radial pulse is felt and if it is obliterated by flexion (which may be due either to impingement of the brachial artery on the distal end of the proximal fragment of the humerus or to compression of the brachial artery as the swollen forearm 'folds' into it) the elbow is extended until the pulse returns. When the maximum degree of flexion has been obtained compatible with the presence of a radial pulse, a light back slab is applied over padding to hold this position and the reduction is checked radiologically.

FIG. 372.—The upper radiograph shows an incompletely reduced supracondylar fracture which remodelled to the appearance seen in the lower illustration over the course of two years with full return of function.

Following reduction of the fracture, *the child is admitted to hospital* and the arm is elevated. Throughout the following 36 hours the state of the circulation in the hand is examined regularly and any suggestion that the circulation is impaired is treated instantly by removal of the plaster and increased extension of the elbow. If extension of the elbow does not return the circulation to normal, the brachial artery must be explored to ensure its patency.

The triceps muscle wrapped around the back of the fracture holds the fragments in a position of reduction provided adequate flexion has been obtained. X-rays are taken at 48 hours and again 1 week after injury to check that reduction has been maintained, but it is difficult to obtain a view in which the fracture fragment can be adequately displayed. The best view is one taken 'shooting through the elbow' at right angles to the distal end of the humerus.

The fracture unites in 3 or 4 weeks. The sling is then removed and the child's arm gently mobilised. Some stiffness and malunion, resulting especially in a loss of the carrying angle, are not infrequent sequels to this injury. Deformities due to incomplete reduction (other than loss of the carrying angle) are gradually reduced by bone remodelling over the years following injury (fig. 372).

Supracondylar Fracture of the Humerus in Adults

This injury, like a fracture of the olecranon, is caused by a fall on to the point of the elbow, but in this case the olecranon breaks the humerus rather than the humerus

breaking the olecranon. Which of these two fractures occurs appears to depend upon the degree of flexion at the elbow at the moment of impact. The fracture line runs vertically upwards from the centre of the distal articular surface of the humerus and then diverges to reach the medial and lateral cortices, forming a 'Y' shaped fracture. There may be further comminution of the fragments.

The diagnosis is made upon the clinical evidence of injury to the elbow combined with the obvious X-ray appearances.

Treatment.—In young adults attempts should be made to reduce this fracture accurately but this is difficult. The best method of achieving accurate reduction is by open operation and internal fixation. Unfortunately, elbow stiffness is common following this procedure even if reduction has been accurately achieved. In the elderly the fracture should be ignored, the elbow rested in a plaster cylinder for 2 weeks, and then gradually mobilised regardless of displacement at the fracture site. A surprisingly good range of movement is often obtained in this way.

Fracture of the Medial Epicondyle

This is an avulsion injury of either the humeral attachment of the wrist and finger flexors, or of the medial collateral ligament of the elbow. If the fragment is only slightly displaced, the elbow should be rested for 3 weeks and then gently mobilised. Even if fibrous union occurs it is of no consequence. If the fragment is displaced and rotated, closed reduction is impossible. It is imperative to replace the fragment accurately, especially if it is displaced into the elbow joint, since, if this is not done, permanent instability of the joint may result. The fracture site should be exposed surgically and the fragment re-attached either by periosteal sutures or by a small screw.

Fracture of the Shaft of the Humerus

Mechanism.—These injuries are due either to a twisting injury to the arm or to a direct blow over the shaft of the humerus. The former injury produces a spiral fracture which may include a 'butterfly' fragment, the latter produces a transverse fracture which may also have a 'butterfly' fragment, but usually a smaller one.

Clinical Features.—The physical signs of tenderness, swelling, deformity and abnormal movement usually make the presence of a fracture obvious and this is confirmed radiologically.

Treatment.—Reduction of these fractures is not necessary since gravity acting on the arm exerts steady traction which tends to correct any angulation that may occur. Because the shoulder is a multi-axial joint, any angulation which may persist at the fracture site does not interfere materially with function and, surprisingly, up to 20° of angulation at the united fracture produces no clinically obvious deformity (Klenerman). It is necessary only to rest the arm in a collar-and-cuff (not a sling since a sling supports the weight of the arm and hence removes the traction force on the fracture site) and, for pain relief, to bandage to the arm a slab of plaster running from the top of the acromion, down the lateral side of the arm, under the elbow and up the medial side of the arm for 5 cm. For further security the arm, splinted by the U-slab, may be bandaged to the chest wall. Immobilisation should be maintained for 3 weeks during which the hand and, as far as possible, the elbow are kept mobile. From 3 to 6 weeks the arm is removed daily from the collar-and-cuff to mobilise the shoulder. Non-union is rare, but does occur occasionally. If it does, it should be treated by a bone graft and internal fixation, using an onlay plate.

Leslie Klenerman, Contemporary. Orthopædic Surgeon, Northwick Park Hospital, Harrow, Middlesex, England.

An occasional complication of fractures of the humerus at the level of the spiral groove is damage to the radial nerve. The nerve is rarely transected, so that if there is a radial nerve palsy immediately after injury, fixed flexion of the wrist and fingers should be prevented by a combination of splintage and passive mobilisation whilst recovery is awaited. Only if there is no recovery after 2 months should the fracture site be explored and the radial nerve dissected free and (if necessary) sutured.

INJURIES TO THE SHOULDER

Fractures of the Proximal Humerus

The proximal end of the humerus may fracture through the surgical neck following a fall on to the outstretched hand which drives the humerus upwards against the acromion and glenoid, or through the anatomical neck following a fall on to the point of the shoulder which drives the humerus directly against the glenoid.

Fractures through the surgical neck are common in the elderly. The fracture is often comminuted: the main fracture line runs through the surgical neck, but in addition one or both of the tuberosities may be separated to give a total of 4 fragments (the head, the 2 tuberosities, and the shaft) (fig. 373). This fracture has been divided on radiological grounds into an adduction and an abduction variety. This distinction has no therapeutic importance and in any event is probably based upon a radiological illusion. The greater tuberosity may be avulsed totally from the rest of the humerus and is then occasionally drawn proximally by the short rotators. More commonly the fracture fragments are held to each other by the soft tissues enclosing the proximal end of the humerus and are impacted into each other. All the fragments have a good blood supply so that non-union is rare.

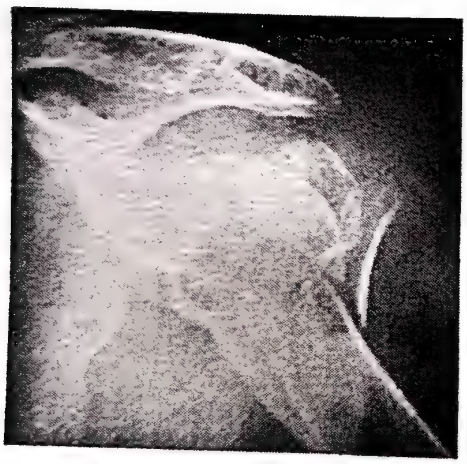

FIG. 373.—Comminuted fracture through the surgical neck of the humerus in an elderly subject.

Fractures through the anatomical neck may be combined with anterior dislocation of the head of the humerus from the shoulder joint. The head of the humerus then comes to lie as an isolated fragment anterior to the glenoid.

Clinical Features.—The patient complains of pain in the shoulder and usually cannot move the joint. Occasionally, however, in minor impacted fractures through the surgical neck, limited movement is possible. The diagnosis is made radiologically.

Treatment of fractures of the surgical neck is simple. The arm is rested in a sling until pain has subsided sufficiently to allow active mobilisation of the shoulder to be commenced. Fractures of the anatomical neck without dislocation of the shoulder should be treated in the same way. Shoulder stiffness following these injuries is usual: it commonly improves over a period of about 9 months but may be permanent.

The treatment of fractures through the anatomical neck of the humerus combined with anterior dislocation of the shoulder is difficult. The dislocated head cannot be reduced by conservative means. It is advisable to remove the head of the humerus, since it is totally avascular, and to replace it if possible with a Neer prosthesis.

If the greater tuberosity is fractured and has retracted substantially from the rest of the humerus under the pull of the short rotators, the fragments must be displayed surgically and the tuberosity attached to the rest of the humerus by suture. Post-operatively the patient's arm should be rested in a sling and active abduction deferred for at least 3 weeks.

Fracture of the Outer End of the Acromium.—This injury is uncommon and occurs following direct violence to the acromium. Treatment is symptomatic.

Fracture of the Glenoid.—This fracture is uncommon. Treatment is by early mobilisation of the shoulder joint.

Dislocation of the Shoulder

This is a not uncommon injury. The head of the humerus usually dislocates forwards from the shoulder joint so as to lie beneath the coracoid process, to produce a sub-coracoid anterior dislocation of the shoulder (fig. 374).

The injury is produced by forced extension and external rotation of the abducted arm. The head of the humerus is forced against the anterior capsule of the shoulder and either ruptures the capsule or avulses the labrum from the glenoid. The latter injury, since the glenoidal labrum is avascular, rarely heals. Having torn the anterior soft tissues of the shoulder, the humerus passes over the anterior margin of the glenoid and in so doing the posterior part of the articular surface of the head may suffer a compression fracture. Once dislocated from the shoulder joint so as to lie beneath the coracoid, the humerus is locked in this position by muscle spasm.

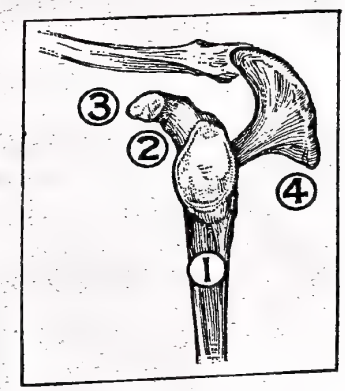

FIG. 374. — The positions taken up by the head of the humerus following a dislocation of the shoulder. 1. Sub-glenoid. 2. Sub-coracoid. 3. Subclavicular. 4. Posterior or dorsal.

Rarely the humerus may dislocate posteriorly from the shoulder joint and very occasionally, particularly in women with poor musculature, may subluxate vertically downwards (fig. 374). Rarely the shoulder dislocates downwards with the arm in full abduction (Luxatio in Erecta).

The clinical features of anterior sub-coracoid dislocation are classical. The outer aspect of the shoulder is flattened and the arm appears to take origin from a point under the junction of the middle and outer thirds of the clavicle. The shoulder cannot be moved and the arm is held in a position of slight abduction (fig. 375).

Posterior dislocation of the shoulder may be difficult to diagnose clinically, since the appearance of the shoulder is essentially normal.

Charles Sumner Neer, Contemporary. (*See footnote p. 237.*)

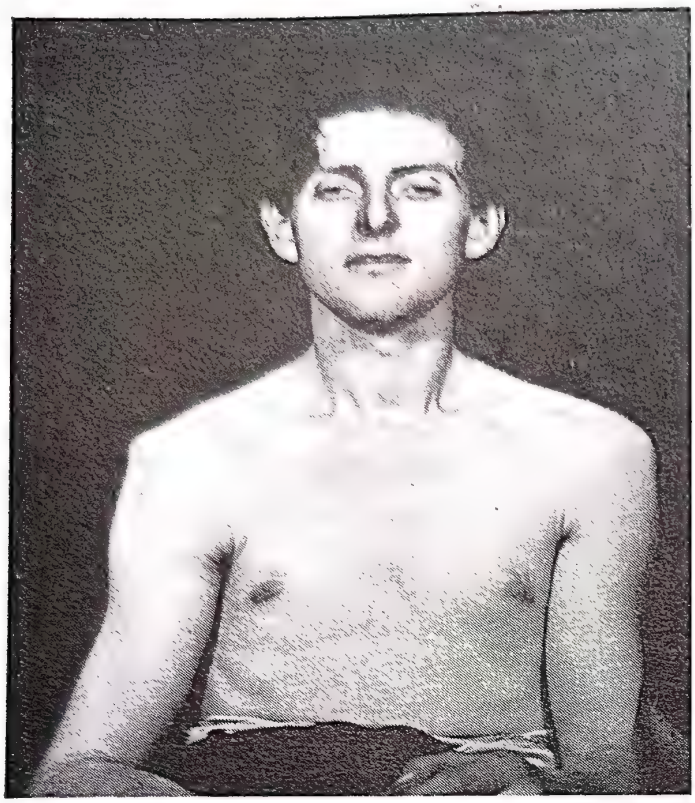

FIG. 375.—Sub-coracoid dislocation of the right shoulder.

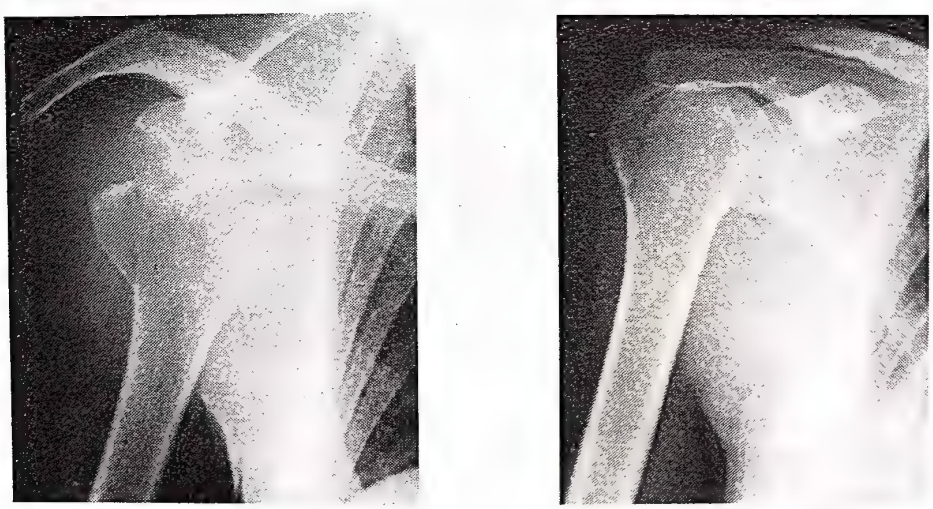
X-ray.—Radiologically an anterior dislocation of the shoulder may be diagnosed on an antero-posterior view because the head of the humerus can be seen to be lying beneath the coracoid (fig. 376). A posterior dislocation is less easily diagnosed since the head of the humerus does not move appreciably in a medial direction. Thus in an antero-posterior projection the appearances of the shoulder are not grossly abnormal. An axillary view, however, will display the head of the humerus lying either anterior or posterior to the glenoid.

Treatment.—Reduction of a dislocated shoulder is easy if the patient is given a general anæsthetic producing muscle relaxation. If the surgeon is skilled, it is perfectly possible to reduce a dislocated shoulder without anæsthesia and even without analgesia, but if the surgeon is unskilled this will simply frighten and hurt the patient and possibly damage the shoulder joint. Thus in general it is desirable to anæsthetise the patient with muscle relaxation. When this is done reduction of a dislocated shoulder can be accomplished simply by pressure in an appropriate direction over the head of the humerus. There are however two classical methods by which an anterior dislocation can be reduced and it is occasion-



(*a*) (*b*)

FIG. 376.—(*a*) Sub-coracoid dislocation of the shoulder with fracture of the greater tuberosity of the humerus. (*b*) Satisfactory reduction.

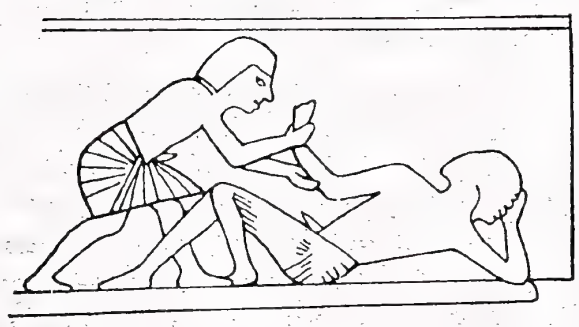
ally necessary to resort to one of these manœuvres even in a patient whose muscles are relaxed. The more satisfactory of the two is the method described by Kocher.

Technique of Reduction of an Anterior Dislocation of the Shoulder (Kocher's Method)

The patient lies on his back. If the left arm is injured, the surgeon stands on the patient's left side and grasps the injured elbow with his left hand. Traction is exerted in the long axis of the humerus for approximately 2 minutes and then, using his right hand, the surgeon gradually externally rotates the patient's humerus by flexing the elbow and using the forearm as a lever. When full external rotation has been obtained, traction is maintained and the elbow is brought across the patient's body so as fully to adduct the shoulder. The patient's hand is then brought across to his opposite shoulder so as fully to rotate the shoulder internally (fig. 377). At some point during this manœuvre an obvious reduction is felt and the contour of the shoulder returns to normal. Reduction is confirmed by putting the shoulder through a full range of movement under anæsthesia.

(*a*)

FIG. 377 (*a*).—Kocher's method for the reduction of a dislocated shoulder.



(*b*)

FIG. 377 (*b*).—Kocher's method is 3,000 years old. Detail sketch from wall painting in the Metropolitan Museum, New York, from Ramesside Tomb. (*M. K. Hussein, F.R.C.S., Cairo from Jnl. of Bone & Joint Surgery. By permission of E. & S. Livingstone.*)

The arm is then immobilised in a sling and bandaged to the side so as to maintain full adduction and internal rotation of the shoulder for a period of 3 weeks. At the end of 3 weeks the sling is removed and progressive mobilisation of the shoulder commenced, avoiding only external rotation in abduction. (The position in which the shoulder dislocates.)

Recurrent Dislocation of the Shoulder

If correctly treated, the majority of dislocations of the shoulder heal to give no further disability. Occasionally the shoulder becomes unstable and recurrently dislocates after trivial violence. Finally the patient may acquire the knack of actively dislocating and reducing the shoulder for himself. If the patient cannot reduce the dislocation for himself, and indeed even if he can, this instability may cause significant disability and require treatment.

Treatment.—Recurrent dislocation of the shoulder is treated by operation.

Emil Theodor Kocher, 1841–1917. Professor of Surgery, Berne. Described this method of reducing a dislocated shoulder in 1870.

An anterior approach is made to the shoulder. The original lesion in the capsule or glenoidal labrum is displayed and repaired. The subscapularis muscle is then overlapped in front of the joint so as to reinforce the anterior aspect of the joint and thereafter to limit external rotation. Alternatively the coracoid process, with the coraco-brachialis and biceps muscles attached to it, is transposed to the anterior lip of the glenoid so as to form a bone block which prevents further anterior dislocation of the shoulder.

Recurrent posterior and downward dislocation of the shoulder occurs occasionally, and is treated (but with difficulty) by operation.

INJURIES TO THE PECTORAL GIRDLE

Acromio-Clavicular Dislocation

This injury is due to traction on the arm or to a violent downward blow on the point of the shoulder. Dislocation of the acromio-clavicular joint can only occur if not only the capsular ligament of the acromio-clavicular joint, but also the coraco-clavicular ligament, ruptures. If both these structures are torn, the scapula falls under the weight of the arm whilst the clavicle is drawn upwards by the pull of the sternomastoid muscle.

Clinical Features.—An obvious prominence is present at the outer end of the clavicle where this bone is displaced upwards relative to the acromion. The acromio-clavicular joint is tender.

An antero-posterior X-ray should be taken of both acromio-clavicular joints so as to compare one with the other. The presence of a step is diagnostic of an acromio-clavicular dislocation (fig. 378).

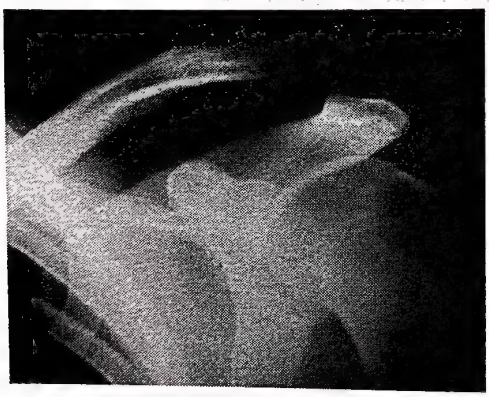


FIG. 378.—Dislocation of the acromio-clavicular joint.

Treatment.—Primary treatment of the dislocation is difficult. Strapping can be applied so as to lift the point of the elbow relative to the clavicle, but this is very uncomfortable, hard to maintain, and if effective may cause pressure sores. It is probably preferable to reduce the dislocation by passing a screw through the clavicle to engage in the coracoid and thus draw the coracoid up to the clavicle. The screw should be removed about 3 months following the injury since it will inevitably work loose as the scapula moves on the clavicle.

Since (i) the disability from this injury even if untreated is slight (although in women the prominence of the clavicle may be thought to be unsightly), (2) conservative treatment is usually ineffective and (3) operative treatment leaves a scar, many surgeons prefer only to rest the arm in a sling and then mobilise the shoulder when pain has settled. Osteo-arthrosis in the acromio-clavicular joint is an occasional late sequel which can be treated by excision of the outer end of the clavicle.

Fracture of the Clavicle

If this occurs lateral to the attachment of the coraco-clavicular ligament, displacement is rare since the two fragments of the clavicle are both fixed to the scapula. In the absence of displacement no specific treatment is required. If displacement occurs, a rupture of the coraco-clavicular ligament must accompany the fracture, and the injury should then be treated in an exactly similar way to an acromio-clavicular dislocation.

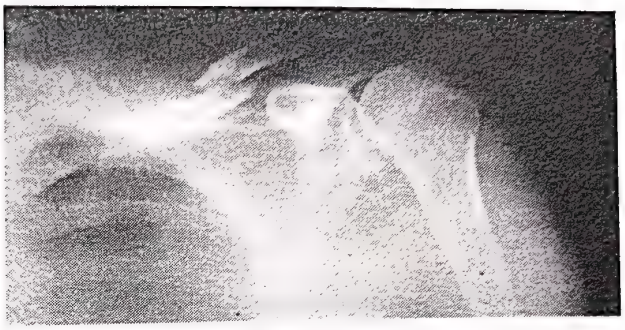

FIG. 379.—Fracture of the shaft of the clavicle with moderate angulation

Fractures of the shaft of the clavicle medial to the point of attachment of the coraco-clavicular ligament are common, especially in children and young adults. The injury is caused by direct violence and in children the fracture is often of the greenstick variety. In adults there is usually more angulation and displacement than in children. Significant displacement so that the bone ends are not in contact is rare, because the soft tissues attached to the clavicle tend to hold the bone ends together.

On clinical examination there is tenderness and often obvious angulation of the clavicle at the fracture site. The diagnosis is usually obvious radiologically (fig. 379).

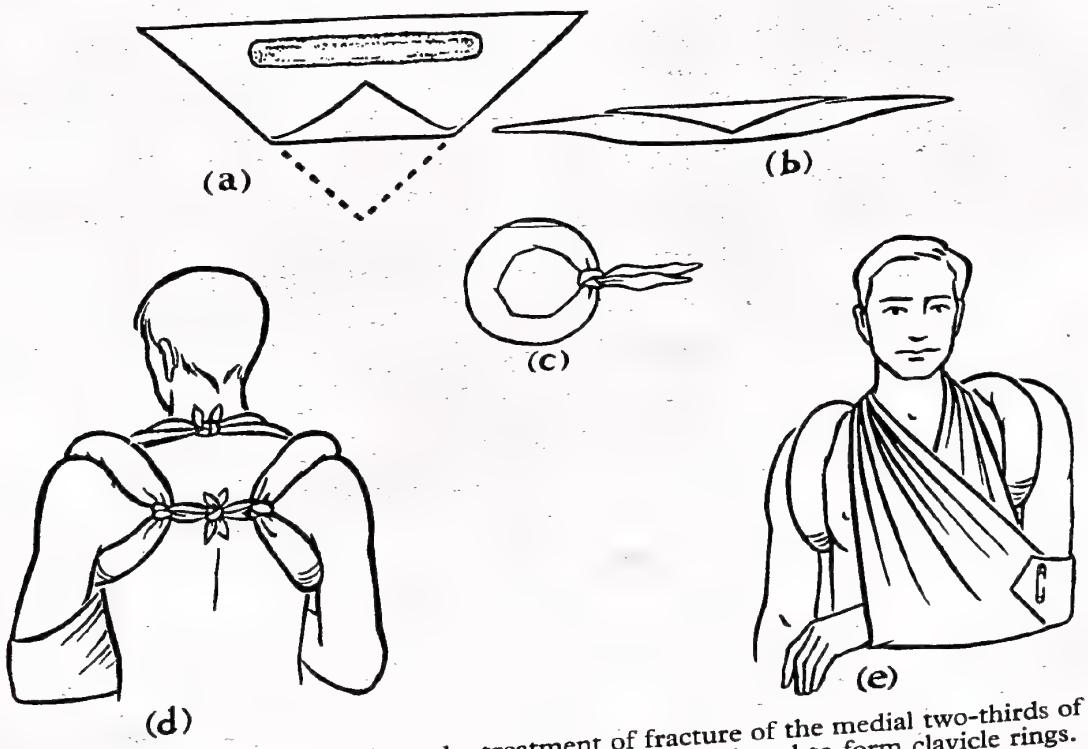

FIG. 380.—The 3 slings method for the treatment of fracture of the medial two-thirds of the shaft of the clavicle. Two of the slings have been fashioned to form clavicle rings.

Treatment.—No attempt should be made to reduce the fracture, since it is impossible to hold the reduction even if it is achieved. The time-honoured method of immobilising this bone is to apply clavicle rings or a figure-of-eight bandage to the two shoulders and a sling for the injured limb (fig. 380). Clavicle rings or a figure-of-eight bandage are invariably uncomfortable and probably do not contribute materially to immobilisation of the fracture. Many surgeons therefore rely only on a sling for the injured limb, combined with analgesics.

The fracture almost always unites, but non-union may occur when there is substantial displacement at the fracture site. In these fractures a case can be made for immediate internal fixation of the fracture using a Kirschner wire introduced into the bone from its lateral end.

Established non-union can be treated by bone grafting if the non-union gives rise to pain. Fortunately, most ununited fractures of the clavicle are painless. Since it is difficult to achieve union even with a bone graft, non-union should not be treated unless it gives rise to symptoms.

Dislocation of the Sterno-clavicular Joint.—This is a rare injury in which the clavicle is displaced backwards relative to the manubrium. The clavicle may occasionally obstruct the trachea, making reduction urgent.

Fracture of the Body of the Scapula. Comminuted, stellate fractures occur in the body of the scapula following direct violence. They should be treated symptomatically by resting the arm in a sling until the pain has diminished enough to allow mobilisation of the shoulder.

CHAPTER 23

INJURIES TO THE LOWER LIMB

INJURIES TO THE FOOT

Fractures of the Metatarsals

Fractures of the shafts of the metatarsals are caused by crushing injuries, for example by weights falling on the feet or the wheels of vehicles running over them. When these fractures accompany severe crushing of the foot, the broken bone may be the least significant part of the injury: the soft tissues are also crushed so that a not-infrequent end result is a thickened, stiff and painful foot, in which the fractures have united satisfactorily.

Reduction after fracture of one or two metatarsals is not required unless some part of the shaft, in a grossly displaced fracture, is projecting into the sole of the foot. Splintage is also unnecessary and early mobilisation with non-weight-bearing exercises is to be encouraged. Return to activity is achieved by taking weight on the heel as soon as the patient feels he can, which may be in 2 to 3 weeks. Full function is possible in 8 to 12 weeks.

If more than two bones are broken, the fractures are usually unstable and the foot must be immobilised in a plaster boot for 4 to 6 weeks. Active mobilisation of the foot is required thereafter.

Avulsion of the styloid process of the fifth metatarsal is a common, minor injury which causes unnecessary inconvenience if treated in a walking plaster. The styloid process is avulsed by the pull of the peroneus brevis contracting during forced inversion of the foot.[1] The fragment is frequently detached by 2 mm or more, but even if bony union does not occur, a fibrous non-union is always symptomless. The foot should not be immobilised and it is unnecessary to apply anything more than adhesive strapping to support the foot and control swelling.

Fracture of the neck of the second or third metatarsal may occur not as a result of a single violent episode, but as a result of fatigue (*march fracture*). The fracture usually follows excessive walking—hence the term march fracture. It is predisposed to by a short first metatarsal which causes undue stress to fall on the necks of the second and third metatarsals during the toe-off phase of gait. Sudden pain, localised over the dorsal aspect of the bone, is characteristic. An immediate X-ray will often fail to reveal the crack, but if repeated in 3 weeks callus will be obvious (fig. 381). The only treatment needed is strapping and restricted activity. Many patients are probably treated as ' foot strain ', and more or less ignored with good results.

[1] When sustained by ballroom dancers = ' dance ' fracture.

Fracture of the Talus

Fractures of the talus are uncommon but may occur as a result of a fall from a height. The neck of the bone is shorn through by the sharp anterior articular surface of the tibia, and the body of the talus may then be extruded from the ankle joint to be palpable under the skin. As in the case of the os calcis, considerable swelling rapidly develops and obscures the diagnosis, which is often established only after radiography. Infarction of the body of the talus is not uncommon and leads to non-union and osteo-arthrosis of the ankle (compare Fractures of the Neck of the Femur (p. 387) and of the Scaphoid (p. 341).

Treatment.—If the body of the talus is displaced, closed reduction, using skeletal traction through the os calcis, is sometimes successful, but usually operative reduction is necessary. Following reduction, the ankle is immobilised for 6 weeks in a plaster boot. Weight-bearing is avoided for 3 months in the hope of preventing deformation of the dome if it is avascular.

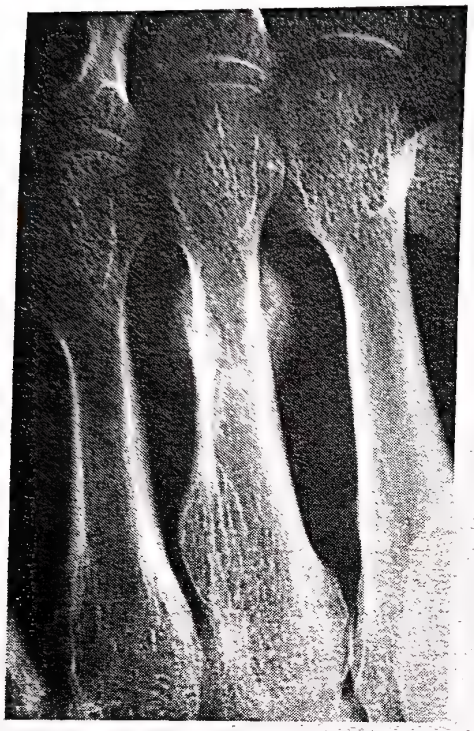

FIG. 381.—March fracture of the third metatarsal.

Fracture of the Os Calcis

Fractures of the os calcis are caused by falls from a height. The bone is shattered like an eggshell and the fracture usually involves the sub-talar joint (fig. 382).

The degree of displacement varies according to the violence. In some cases there is little or no displacement; in others the whole os calcis is flattened and widened. The Achilles' tendon tends to pull the posterior part of the bone upwards and the heel is always everted.

This injury, especially if it involves the sub-talar joint, is likely to leave the foot stiff regardless of treatment. As a consequence, walking on sloping of uneven surfaces is difficult and often painful. Though the foot is often painful for months, pain nearly always subsides eventually. Stiffness on the other hand is usually permanent, but tolerable to the patient.

Treatment.—Elaborate mechanical methods used to be employed in an attempt to restore the normal anatomy, but even when anatomically successful, such treatment does not improve the function of the foot. The best results are achieved by accepting the deformity and concentrating on early

FIG. 382.—Fracture of the os calcis involving the sub-talar joint.

Achilles (*see footnote p. 316*).

non-weight-bearing mobilisation combined with compression by wool and crepe to control swelling. Weight-bearing is started in 8 to 12 weeks.

INJURIES TO THE ANKLE

Mechanism and Morbid Anatomy.—The ankle is usually injured by indirect violence: the foot being inverted, everted, externally rotated or internally rotated on the tibia. Rarely the ankle may be injured by a force which shears the talus transversely relative to the tibia, or which drives it vertically up into the tibia. Each of these mechanisms of injury produces a characteristic fracture pattern, so that these injuries can be classified, although with some over-simplification, on the basis of the mechanism.

Although the mechanism is described as if the foot moved (e.g. into inversion) on a fixed tibia, in practice these injuries nearly always occur with the foot fixed, for example by a hole in the ground or in a ski, whilst the tibia continues to move, driven by the momentum of the body weight. The foot is inherently more stable in eversion than in inversion and hence injuries due to inversion are more common than those due to eversion. Because during normal walking the feet are placed in a little external rotation relative to the line of travel, a sudden arrest of the weight-bearing foot whilst the tibia continues to move forward has the effect of externally rotating the foot on the tibia. (The student can demonstrate this for himself by walking, stopping his foot dead as it is placed on the ground, and noting the direction in which his tibia moves as he tends to fall forward.) Thus inversion and external rotation are the two most common mechanisms of injury.

The important factor in ankle injuries is the stability of the tibio-fibular mortice. If the mortice is stable, that is to say if no abnormal motion is possible between the tibia and the talus, the injury is relatively trivial. If abnormal motion is possible, the injury is potentially serious since persistent instability at an anatomically abnormal mortice causes pain and ultimately osteo-arthrosis of the ankle. Thus if the mortice is stable, the aim of treatment is to protect the ankle until healing has occurred; but if the mortice has been disrupted it must be reconstructed (reduced) and held (immobilised) until bone and soft tissue healing is complete.

External Rotation.—External rotation of the talus damages the ankle progressively, causing 1st, 2nd and 3rd degree external rotation or Pott's fractures.

1st Degree External Rotation Injury.—External rotation of the talus applies a twisting force to the lateral malleolus which suffers a spiral fracture starting distally at the level of the inferior tibio-fibular joint (fig. 383). The fracture fragment, which includes the malleolus, has a spike which lies posterior to a second spike projecting from the fibular shaft. The malleolar spike is attached to the tibia by the posterior inferior tibio-fibular ligament. Thus the lateral malleolus is attached to the tibia and the mortice is stable.

2nd Degree External Rotation Injury.—Further force either ruptures the posterior inferior tibio-fibular ligament or avulses its tibial attachment to produce the so-called 'third malleolus'. The talus is now free to turn in the mortice and as it does so the deltoid ligament avulses the tip of the medial malleolus to produce a low transverse medial malleolar fracture (rarely the ligament itself ruptures) (fig. 383). The mortice is now unstable.

Percivall Pott, 1714–1788. Surgeon, St. Bartholomew's Hospital, London. Described this fracture-dislocation of the ankle in 1765.

3rd Degree External Rotation Injury.—As the body-weight continues to move the tibia forward on the fixed foot, the talus, once the mortice has been broken, is free to slide beneath the posterior margin of the tibia. As it does so it may fracture the

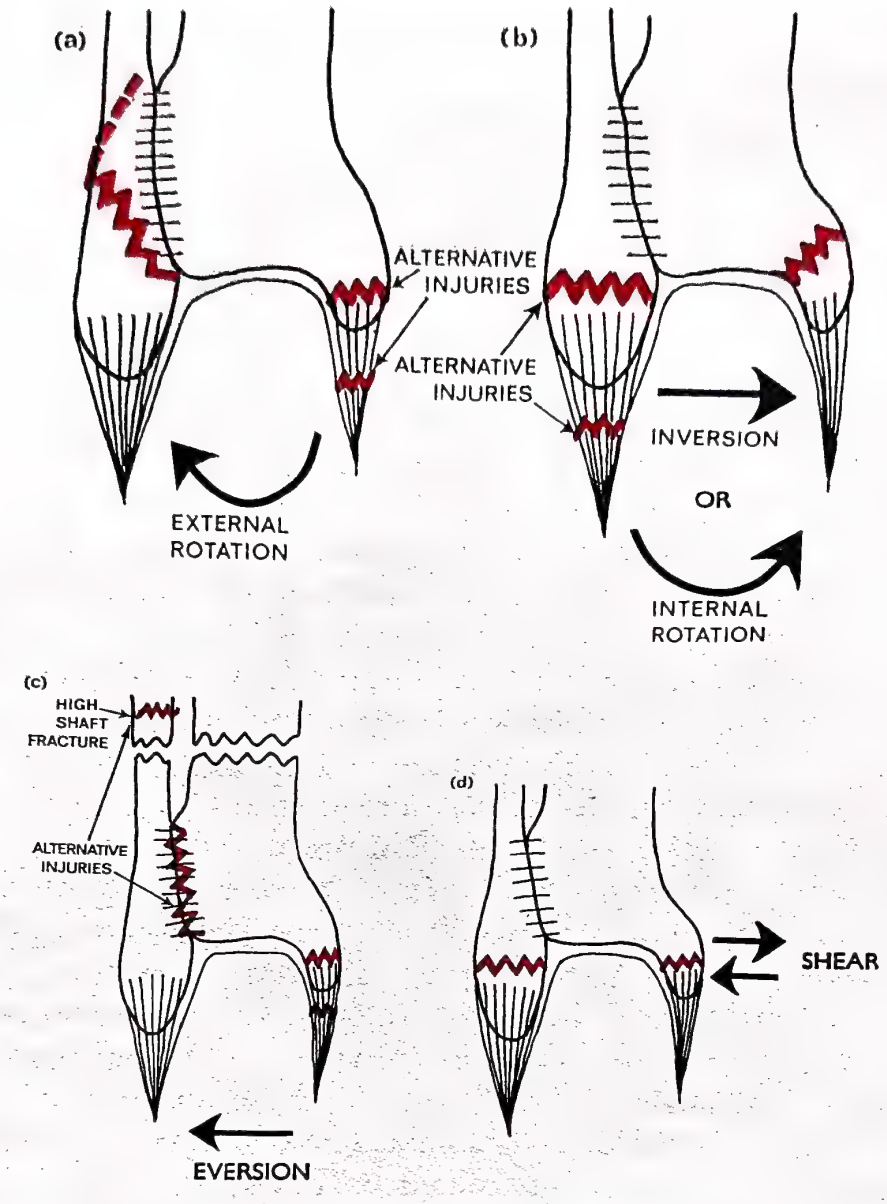

FIG. 383.—Varieties of ankle fracture.

margin producing a second variety of ' third malleolus '. Once the dome of the talus has passed posterior to the tibia, contraction of the calf muscles pulls the talus proximally and locks it in this position. Not only is the mortice now unstable but the ankle is dislocated as well (fig. 384).

Inversion (Adduction) Injuries.—In the plantar-flexed ankle, the talus is held in the mortice by the ligaments of the ankle. Thus if the ankle is forcibly inverted when plantar-flexed the lateral ligament may be sprained or ruptured (fig. 383). A rupture starts at the anterior fasciculus and extends backwards through the lateral ligament and medially through the anterior capsule, allowing the talus to tilt more and more in the mortice as it does so. Sprains and ruptures of the lateral ligament are the commonest ankle injuries and are usually loosely diagnosed as a ' sprained ankle '.

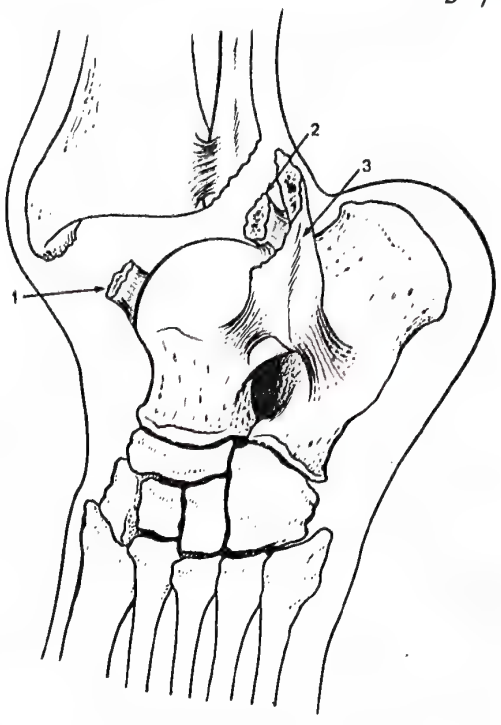

FIG. 384.—The morbid anatomy of a third degree external rotation injury of the ankle. Note that the medial malleolus (1), the third malleolus (2) and the lateral malleolus (3) are all attached directly or indirectly by ligaments to the talus or os calcis and hence that they move with the foot. (For clarity, the talus is shown in this figure as lying distal to the tibia. In fact, it lies behind the lower end of the tibia.)

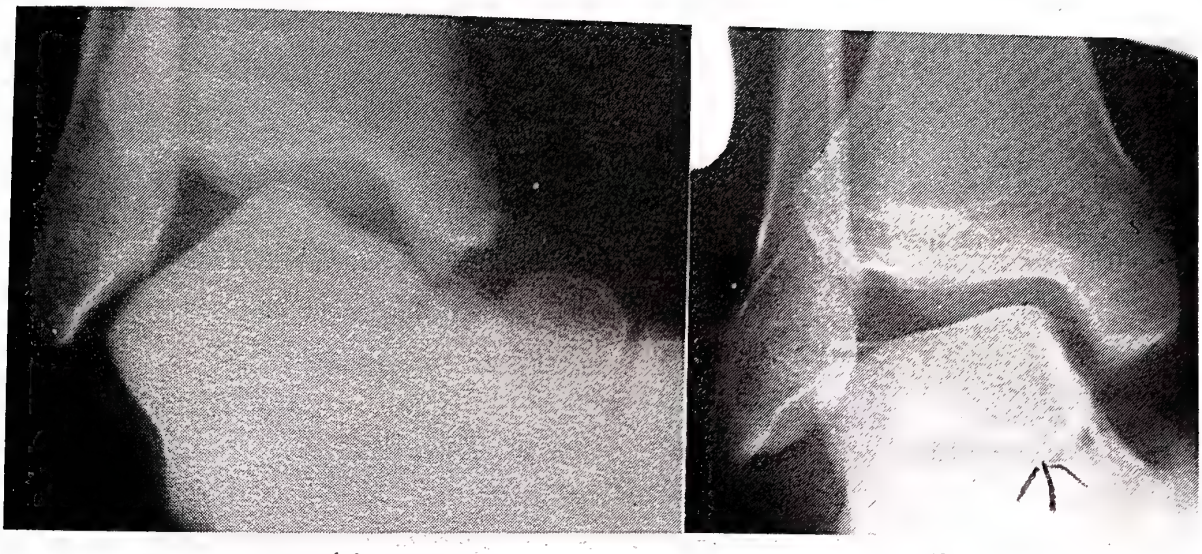
Ruptures cannot be differentiated from sprains clinically but the distinction can be made by stress radiography (fig. 385).



(*a*) (*b*)

FIG. 385.—Inversion stress X-rays of two ankles with ruptures of the lateral ligament. (*a*) An AP view showing gross talar tilt indicating a complete rupture of the lateral ligament. (*b*) Less marked talar tilt, but note the transchondral fracture of the dome of the talus where the talus strikes the fibula. A routine AP X-ray of both these ankles revealed no abnormality.

The neutral or dorsiflexed talus is a tight fit in the bony mortice because the dome of the talus is broader anteriorly than posteriorly. Inversion of the foot and hence of the talus in this position therefore stresses the bones of the mortice as well as the ligaments. The medial malleolus may be sheared from the tibia—producing a fracture line running upwards from the root of the malleolus—and the lateral malleolus may then suffer a low transverse avulsion fracture at the level of the attachment of the lateral ligament (fig. 383).

The talus is now unstable in the mortice and further force may cause it to dislocate posteriorly as in third degree external rotation injuries.

Eversion (Abduction) Injuries.—Eversion of the talus levers the fibular malleolus outwards. If the inferior tibio-fibular ligament holds, the fibula may fracture high up in the calf since the shaft of the fibula is forced inwards as the long arm of a lever whose fulcrum is at the ankle. If the ligament ruptures, the mortice springs open as the fibula moves away from the tibia (fig. 383). This condition is described as a *diastasis of the inferior tibio-fibular joint.* The diagnosis may be suspected if the talus seems on an antero-posterior X-ray to be abnormally far from the medial malleolus, and is confirmed by stress radiography. If the ligament has ruptured, the mortice is unstable.

Continued eversion force may cause an avulsion fracture of the medial malleolus or rarely a rupture of the deltoid ligament as in external rotation injuries.

Internal Rotation.—This mechanism is rare and produces injuries similar to those produced by inversion.

Transverse Shear Injuries.—These are rare. They produce transverse fractures of the lateral and medial malleoli at the level of the top of the dome of the talus. Obviously the mortice is completely unstable.

Vertical Compression Injuries.—These are also rare but are occasionally caused by falls from a height. The talus is driven up into the distal tibia which suffers a comminuted fracture.

To deduce the mechanism of an ankle injury, the key is the radiological appearance of the fibular fracture (fig. 383). To summarise, this is as follows:

External rotation	—spiral at the level of the inferior tibio-fibular joint.
Inversion	—low transverse.
Internal rotation (rare)	—low transverse.
Eversion	—high in the shaft.
Transverse shear (rare)	—high transverse.

Treatment

Ligament Injuries.—1. *The Lateral Ligament.*—Sprains of the lateral ligament should be treated by compression bandaging, early mobilisation within the limits of pain and swelling, and co-ordination exercises. Ruptures (which in everyday clinical practice are as common as simple sprains but are often not diagnosed as such since the diagnosis requires stress radiography) should be treated by the same regime save that for the first 3 weeks the patient should not bear weight on the injured foot.

2. *The Inferior Tibio-Fibular Ligaments (Inferior Tibio-Fibular Diastasis).*—Rupture of these ligaments is best treated by internal fixation using a screw passed through the fibula into the tibia. Plaster-of-Paris is applied for 6 weeks post-operatively.

Fractures.—If the fracture or fractures are undisplaced, the possibility arises that the mortice is stable. If there is only one fracture on X-ray and no tenderness over a ligament clinically (for example an ankle with an isolated spiral fracture of the lateral malleolus and no tenderness over the deltoid ligament), the ankle can be regarded as stable and treated by compression bandaging and limited weight-bearing or by weight-bearing in plaster for 6 weeks.

If the injury is one which may be associated with instability, e.g. a fracture of both the lateral and medial malleoli, it is wise to examine the ankle using stress radiography or image intensification. If the talus can be made to move abnormally in the mortice by displacing the fractures, the mortice is unstable and should be treated as such. If not, the ankle is immobilized in plaster for 6 weeks during which time weight-bearing is limited.

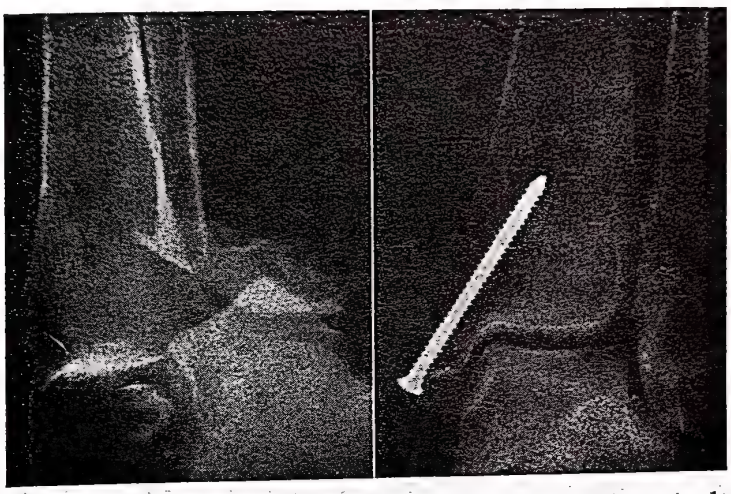


FIG. 386.—Third degree external rotation injury treated by internal fixation of the medial malleolus with a screw.

If the mortice is obviously unstable (fig. 386) or can be demonstrated to be so, most surgeons reduce the fracture and employ internal fixation. If a perfect reduction is achieved by manipulation, an above-knee plaster with the knee flexed to 30° (to control rotation) may be applied for 6 weeks as an alternative to internal fixation. During this time the patient does not bear weight on the foot and maintenance of the reduction is checked by weekly X-rays for 3 weeks. For a second 6 weeks weight-bearing is increased with or without a below-knee plaster. The danger of the first form of management (internal fixation) is that the fracture may be infected, of the second that the fracture may displace in plaster.

After a fracture-dislocation, most patients return to light work in 12 weeks and to heavy work in 6 to 9 months.

The Technique of Closed Reduction of a Fracture-Dislocation of the Ankle

As judged from the pre-reduction X-rays of a severely displaced fracture, it may appear unlikely that a satisfactory reduction could ever be obtained without operation. This impression is often misleading, reduction being possible because all the fragments are attached to the bones of the foot (fig. 384). The essential feature of the

reduction is to concentrate on restoring the alignment of the foot to the tibia, rather than on reducing the separate fragments by local manipulation of the individual fractures.

Third Degree External Rotation Injury.—The manipulation consists of reversing the direction of the forces which caused the original injury (a general principle in the reduction of all fractures) and since the injury is caused by external rotation of the foot followed by backward and then proximal displacement of the talus, reduction is produced by traction in the long axis of the limb so as to draw the talus clear of the distal end of the tibia, followed by forward displacement of the talus on the tibia, and then internal rotation and medial displacement of the foot. The talus cannot be 'over-reduced' anteriorly because the tissues posterior to the ankle will not permit it, or into excessive internal rotation because the fibular 'spikes' interlock, nor medially because the dome of the talus strikes the root of the medial malleolus.

The anæsthetised patient lies supine with the knees flexed over the end of the operating table. The surgeon sits at the foot of the table and grasps the injured heel with his left hand (if the right ankle is injured) placing his thenar eminence behind the lateral malleolus (fig. 387). Steadying the tibia with the right hand, the surgeon then exerts traction on the injured foot and draws it forwards so as to bring the talus beneath the articular surface of the tibia. He then internally rotates the foot and displaces it medially until firm resistance is encountered. Having appreciated the sensation of reduction, a well-padded below-knee plaster is applied whilst an approximate reduction is maintained. The surgeon then grasps the foot and tibia as before, but now through the plaster, and repeats the manœuvre leading to reduction, taking care to hold the foot plantigrade as the plaster sets. If the ankle is very unstable, external rotation should be controlled by extending the plaster to the thigh with the knee flexed to 90° for 3 weeks. The plaster should be split and the patient admitted to hospital for 24 hours so that the circulation to the toes can be observed.

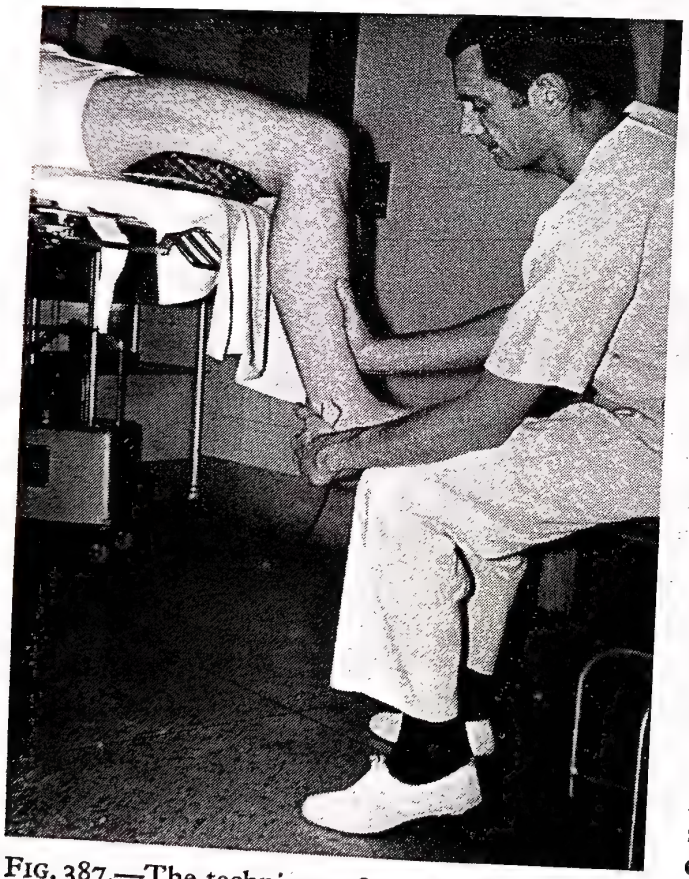

FIG. 387.—The technique of reduction of a third degree external rotation injury.

The Technique of Internal Fixation of Fractures of the Ankle.—A number of implants are available for the treatment of these fractures the details of which are beyond the scope of this text. The essentials, however, are: (1) to operate either before swelling has developed or after it has subsided, i.e. after 10 days of elevation and immobilization; (2) to employ a scrupulously aseptic technique; (3) to obtain secure fixation and accurate reduction of the medial malleolus (fig. 386) since the medial side is the key to the long term health of the ankle; and (4) to reduce the 'third malleolus' (see 3rd degree external rotation injuries, p. 366), if this is displaced and constitutes more than one-third of the articular surface of the tibia as seen in a lateral X-ray. After internal fixation the ankle may or may not require external splintage in plaster but weight-bearing should certainly be avoided for 6 weeks.

Rupture of the Achilles' Tendon

The Achilles' tendon is the commonest tendon to rupture, and since the injury is frequently diagnosed incorrectly, special note should be made of its

clinical features. It is an injury most common in middle-aged men and, though it can occur during games and severe exertion, it often happens as a result of a trivial stumble, the sensation of rupture being mistaken for a blow on the back of the leg. Such ruptures apparently occur because the tendon is ischæmic and weaker than normal. The rupture usually takes place about 3 cm. above the insertion of the tendon into the os calcis. A gap is easily palpable, and sometimes visible, at the site of the rupture (fig. 388). The foot can be dorsiflexed to a greater extent than the normal foot. The power of plantar-flexion is reduced so that the patient cannot stand on tiptoe on the injured foot, but it is to be noted that it is never completely absent. This is a most important point, because the surgeon can be led to imagine that the tear must be incomplete by the fact that some power of plantar-flexion exists. This power is, of course, exerted by the long flexors of the toes, the tibialis posterior, and the peronei. Very few cases of suspected 'partial' rupture of the Achilles' tendon are in fact incomplete and it is dangerous to make this diagnosis because suture of the tendon is much more difficult if the operation is delayed.

FIG. 388.—Palpable gap in the diagnosis of a rupture of the Achilles' tendon.

The diagnosis of 'rupture of the plantaris tendon' is occasionally made in patients younger than those typically sustaining the classical Achilles' tendon rupture. It is probable that 'plantaris rupture' is an imaginary condition, and that the clinical picture is that of a partial tear of the calf muscle fibres at a much higher level than the true Achilles' rupture.

Treatment.—Early suture of the Achilles' tendon followed by immobilisation of the ankle in a plaster cast for 6 weeks gives excellent results, but late suture is usually disappointing because the proximal end has retracted and lost its elasticity, so that the gap sometimes cannot be closed even by plantar-flexion of the foot and flexion of the knee (in which position the gastrocnemius and soleus muscles are relaxed).

FRACTURES OF THE SHAFT OF THE TIBIA AND FIBULA

Fracture of the Shaft of the Tibia Alone

This fracture is usually due to torsion causing a spiral fracture which may appear to be oblique on X-ray. Diagnosis is easy, as the bone is subcutaneous and irregularity or localised tenderness are readily detected.

Treatment.—When the fibula remains intact, the displacement of a fractured tibia is relatively slight, and as angulation is rarely more than 5°, it is usually sufficient to apply an above-knee plaster cast without any attempt at reduction. Though it might appear that fractures of the tibia when the fibula is intact would be unlikely to give rise to difficulty in treatment, in fact delayed union is not uncommon. It is probable that the intact fibula acts as a 'strut' to prevent the fragments of the tibia coming into close contact.

Fracture of the Shaft of the Fibula Alone

This fracture is usually due to direct violence or to eversion injuries at the ankle (p. 368). The procedure of ' springing ' the fibula assists diagnosis, and consists in compressing the fibula against the tibia, local pain being referred to the site of a fracture. A radiograph confirms the diagnosis, and treatment, if any is required, need be nothing more rigorous than the application of an adhesive elastic strapping.

Fractures of the Tibia and Fibula

These fractures occur either as a result of direct or of indirect violence. Road traffic accidents are the commonest cause of fractures due to direct violence: the bumper of a motor car strikes the leg and fractures the tibia and fibula by a mixture of impact and bending. The fractures occur at about the same level in the two bones, are transverse, oblique or (commonly) comminuted, and are frequently compound from without—the impact tearing the skin as well as breaking the bone.

Indirect violence may be applied to the tibia and fibula either in the form of torsion (the body turning during a fall on the fixed foot), or by bending (the foot and lower tibia being fixed while the body falls sidewards, bending the tibia as it does so). The former injury is common in ski-ing, the latter in football. Both injuries may be compound, often trivially so, from within.

Fractures of the tibia are more commonly compound than those of any other bone and skin closure is particularly difficult because the bone is subcutaneous. When the skin has healed, the fracture may be treated as if it had been simple in the first place. The treatment of compound fractures is discussed on p. 331.

Treatment.—Fractures of the bones of the leg can be treated in 3 ways:

(1) By plaster after manipulative reduction. This form of treatment is used for fractures in patients under the age of 16, and for fractures in older patients, in whom a stable reduction can be obtained. It is the most widely used and the safest form of treatment.

(2) By skeletal traction through the lower end of the tibia or the os calcis with the leg in a special frame or a plaster cast. Traction may render formal manipulation unnecessary. This form of treatment is used if a stable reduction cannot be maintained by plaster alone. A variant of this method, in which pins are passed through the tibia both above and below the fracture and are then fixed to an external metal frame, can be used to immobilize the fracture rather than to apply traction. It is particularly useful in the treatment of compound fractures.

(3) By internal fixation with plates and screws or an intramedullary nail. This form of treatment should only be used in expert hands. It is particularly indicated in multiple fractures and the elderly. It is contraindicated in compound fractures (p. 331). It has the advantage that the joints can be mobilised early, but the disadvantage that the fracture may be infected at operation.

The Technique of Closed Reduction of a Fractured Tibia and Fibula

Several methods are available, of which the following is the simplest if the surgeon is single-handed. The patient is anæsthetised to produce muscle relaxation and is placed supine with his knees flexed over the end of the operating table. The surgeon is seated facing the injured leg and the height of the table is adjusted until the foot just clears the surgeon's knee. An inelastic bandage is tied over plaster wool as a 'halter' round the ankle and looped under the surgeon's foot (fig. 389). The surgeon can thus exert traction on the fracture with his foot whilst leaving both his hands free to 'hitch' the bone ends. When this has been accomplished a well padded plaster is applied from below the knee to above the ankle and an X-ray is taken to check reduction—the bone ends should overlap by at least half their diameter and longitudinal alignment should be correct to within 10°; rotatory alignment is checked by inspection of the leg. If reduction is satisfactory, the bandage round the ankle is removed and the foot of the plaster is completed with the foot plantigrade. The knee is then placed in 5° of flexion and the plaster is applied up to the mid-thigh. Finally the plaster is split and the patient is admitted to hospital for elevation of the limb and observation of the circulation. Up to 10° of angulation at the fracture site can be corrected at any time in the next few days by cutting the plaster circumferentially at the level of the fracture, wedging it open on the concave side of the angulation, and then completing the plaster.

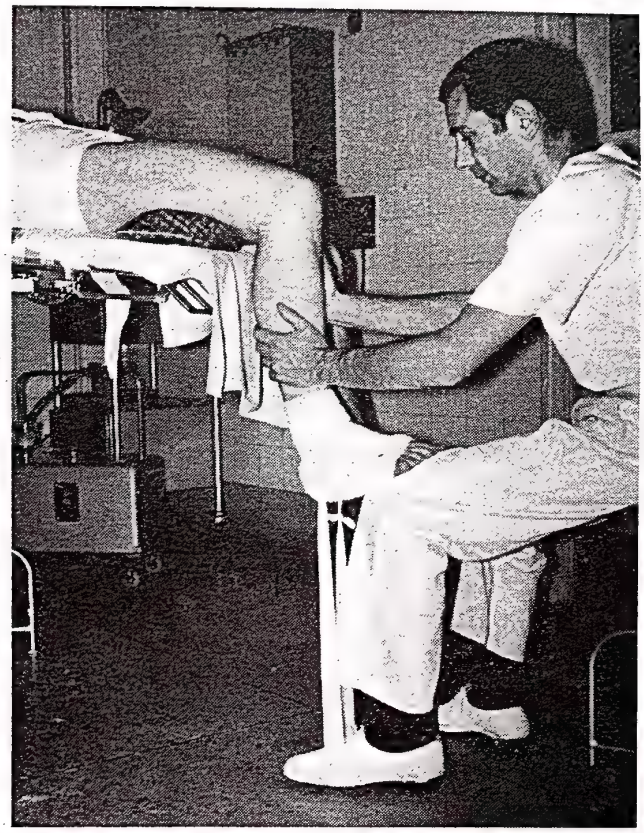

FIG. 389.—The technique of closed reduction of a fractured tibia and fibula.

The tibia usually takes about 12 weeks to unite. It is rarely fit to take weight without support under 16 weeks but if the fracture is stable, weight bearing may be allowed shortly after injury in a plaster cast, with the aid of internal fixation, or in an appliance (a 'cast-brace') composed of a cast around the shin to which is attached a brace which transmits some weight from the shoe directly to the proximal fragment.

Should the fracture be ununited at 3 months, further immobilisation in an above-knee plaster cast, preferably with weight-bearing, is required. If union has still not occurred after a further 6 weeks, immobilisation can be continued, but many surgeons prefer to reduce the duration of treatment by bone-grafting the tibia, with or without the addition of internal fixation (p. 330).

INJURIES TO THE KNEE

No joint sustains so wide a range of injuries as does the knee. This is because it is a commonly injured, major weight-bearing joint whose stability depends almost entirely upon soft tissues (ligaments and muscles). Its ligaments are both extra- and intra-articular and alone amongst the major

joints it contains menisci. Injuries to the knee may be divided into those which affect the ligaments, the menisci, the extensor apparatus, and the tibial and femoral condyles.

The Ligaments

The Mechanism.—A blow on the lateral side of the knee when the patient is bearing weight on the leg has the effect of abducting the tibia on the femur and stresses the medial collateral ligament. If the violence is relatively minor, some of the fibres of the ligament give way, but the ligament as a whole remains intact. Such an injury is a simple sprain. Should the violence be more severe, the ligament may be ruptured, usually at its femoral attachment. Because the medial meniscus is attached to the medial collateral ligament, peripheral detachment of the medial meniscus is commonly associated with this injury. Further forced abduction of the tibia stresses the cruciate ligaments, one or both of which may be sprained or ruptured. If the medial collateral and cruciate ligaments are ruptured, the tibia becomes grossly unstable on the femur in abduction so that the knee can be subluxated.

The reverse mechanism (i.e. adduction of the tibia on the femur) is far less common (because the knee is more commonly struck on its lateral than on its medial aspect) and results in an injury first to the lateral collateral and then to the cruciate ligaments.

The posterior cruciate ligament may be injured if the anterior aspect of the tibia is struck when the knee is flexed, an injury which not uncommonly occurs to the front-seat passenger in a motor car if he is thrown violently forward against the dashboard.

Isolated anterior cruciate ruptures may occur if the knee is forcibly hyperextended.

Clinical Features.—It is important to obtain an exact description of the injury and of the ensuing events, since this often helps to distinguish one soft tissue lesion from another. A description of the injury itself will suggest the mechanism and hence, as indicated above, the pathology. If bleeding has occurred into the joint (a hæmarthrosis), the knee swells within 1 or 2 hours and this suggests the presence of serious intra-articular damage. Should the knee swell, but only over the course of 12 or 24 hours, the swelling is likely to be due to an effusion. This implies the existence of a less severe injury. As fluid collects in the joint, the knee becomes increasingly painful and movement becomes more difficult. When a moderately large effusion has developed, only a few degrees of movement are possible and the knee is held in about 10° of flexion (a situation which must be distinguished clinically from locking of the knee (p. 376)).

Physical Signs.—Soon after the injury an effusion or hæmarthrosis can be demonstrated. Localised tenderness can be elicited over the collateral ligaments if these are injured. No clearly localised tenderness is demonstrable if a cruciate ligament is injured. It is vital that the student should have an accurate understanding of the surface anatomy of the knee, since the diagnosis

of soft tissue injuries and the distinction of meniscus injuries from ligament injuries depends upon the accurate localisation of tenderness in relation to the underlying structures (fig. 390).

If a ligament has been sprained rather than ruptured, stressing the ligament will not demonstrate abnormal movement but will provoke pain in the injured ligament. Thus, for example, if the tibia is abducted on the femur, pain will be elicited from a simple sprain of the medial collateral ligament. If the ligament has ruptured, the knee as a whole may be too painful to allow the ligament to be stressed. The knee should then be examined under anæsthesia: the tibia in nearly full extension is abducted and then adducted on the femur and any abnormal movement which occurs is compared with that in the uninjured knee. Excessive movement suggests the presence of a rupture of the appropriate collateral ligament and may be recorded by taking a stress X-ray of the knee. If the tibia is flexed to 90° on the femur, the anterior cruciate ligament resists forward glide of the tibia on the femur: excessive forward glide therefore indicates a rupture of the anterior cruciate ligament. Excessive posterior glide indicates a rupture of the posterior cruciate ligament.

If a ligament injury, especially a rupture, is missed soon after injury and hence goes untreated, the pain will settle, but the knee will not become sign- and symptom-free. If the joint is examined some months after injury, mechanical instability and often an effusion may be demonstrated and marked quadriceps wasting will be seen.

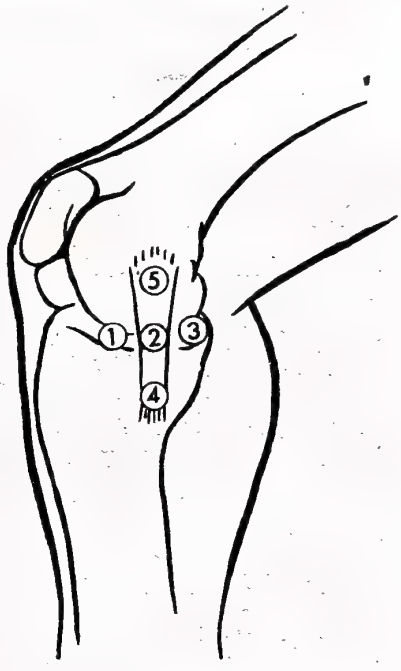

FIG. 390.—Sites of localised tenderness in knee injuries: 1, 2 and 3 on the joint line suggest tears of the medial meniscus; 4 and 5 suggest sprains or ruptures of the tibial or femoral attachments of the medial collateral ligament.

Radiological Appearances.—At the time of injury, there are usually no abnormal radiological features. The cruciate ligaments, when stressed, may sometimes avulse their tibial attachment rather than rupture in their length and the lateral collateral ligament may avulse its fibular attachment: the resultant fractures can be seen radiologically, especially if the bone fragment is significantly displaced. Rarely, there may be slight persistent separation of the medial femoral and tibial condyles if the medial collateral ligament has ruptured and become interposed in the joint space. Some weeks following injury, new bone formation may be seen at the femoral attachment of a collateral ligament if the periostium has been avulsed at the time of injury (a condition known as Pellegrini-Stieda's disease).

Treatment of ruptures of these ligaments is controversial.

The cruciate ligaments when ruptured never lie with their ends in apposition. The collateral ligaments also commonly recoil. Therefore if simple immobilisation is employed, the ligaments may not heal because their ends are not apposed. For this reason many surgeons explore a rupture of any ligament of the knee so that the ends of the ligaments can be sutured together. This operation is technically difficult in the case of the cruciate ligaments, but

Augusto Pellegrini, Contemporary. Surgeon, Ospedale Mellini, Chiari, Italy.
Alfred Stieda, 1869–1945. Professor of Surgery, Konigsberg, which was in Germany until 1945 but is now Kaliningrad in the U.S.S.R. Pellegrini described traumatic calcification of the collateral tibial ligament in 1905; Stieda published his account of the condition in 1908.

relatively simple for the collateral ligaments. Following operation the knee is immobilised in a few degrees of flexion in a plaster cast extending from the groin to the ankle for 3 to 6 weeks. Alternatively the knee may be immobilised, without operation, in the hope that the ruptured ligaments will then unite spontaneously. Whilst in plaster, quadriceps exercises are begun and as soon as the plaster is removed the knee is actively mobilised and the thigh muscles exercised. Weight-bearing should be deferred for 3 weeks from the time of injury.

Simple sprains of the collateral ligaments require only limitation of normal activities combined with mobilisation and quadriceps exercises for 3 to 6 weeks.

The Menisci[1] (The Cartilages)

Mechanism.—The menisci are commonly torn in sports or when rising from a kneeling position. Tears of degenerate menisci also occur in the osteoarthrosic knee. The mechanism is rotation of the tibia on the femur in the flexed, weight-bearing knee. This sequence of events comes about, for example, if a games player stands on one leg with the knee slightly bent and then twists his body. The medial meniscus tends to be damaged if the femur is internally rotated on the tibia, the lateral meniscus if the femur is externally rotated. Medial meniscus injuries are more common than lateral meniscus injuries in a ratio of about 20 to 1 and both are rare in women.

Morbid Anatomy.—Tears may occur in the anterior horn, the posterior horn or as bucket-handle tears in the body of the meniscus (fig. 391). Following an initial tear, progressive damage to the meniscus is common, so that eventually the original anatomy of the tear may not be discernible. The menisci are avascular and once torn do not heal.

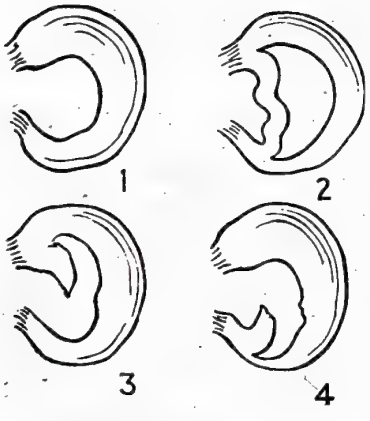

FIG. 391.—Tears of the meniscus. 1. Normal. 2. Bucket-handle. 3. Posterior Horn Tear. 4. Anterior Horn Tear.

The lateral, and commonly the medial, meniscus may occasionally be congenitally discoid in shape rather than semi-lunar. Discoid menisci are more prone to tear than the normal meniscus and, even if untorn, occasionally give rise to very loud 'clunks' in the knee.

Clinical Features.—Patients suffering meniscus injuries may not necessarily attend a doctor at the time of the original injury. Physical examination of the knee is often not diagnostic and the diagnosis rests largely upon the history. In the history the important features are an accurate description of the original injury, a complaint of locking and unlocking, and the lateralisation of any pain or clicks.

The mechanism of the injury has already been described. Following injury the knee swells overnight as an effusion collects, and usually comes to

[1] Meniscus (Greek) = a crescent.

be held in about 10° of flexion, from which position movement is painful. As the effusion settles, the range of movement gradually increases until after about 6 weeks it is nearly full. However, at the time of the injury the torn portion of the meniscus may become interposed between the femoral and tibial condyles so as mechanically to prevent either full extension or (much more rarely) full flexion of the knee. (Such a mechanical block to flexion or extension is known as 'locking'.) The patient may notice this at the time of the injury but more commonly it is masked by the more obvious events of pain, swelling and the consequent limitation of movement. The displaced meniscus sometimes returns to its original position (so as to unlock the joint) as the effusion settles and thus the original episode of locking may never be noticed by the patient. Usually, however, it becomes obvious that the knee is locked as the effusion subsides.

Following a return to apparent normality, the knee may still be prone to two sequelæ: recurrent episodes of locking and 'giving way'. These events are attributable to displacement of the torn segment of the meniscus between the articulating femoral and tibial condyles. Such displacements may suddenly prevent either full extension or full flexion of the knee ('locking'). This sudden inability to move the joint is always obvious to the patient and is accompanied by pain in the appropriate compartment of the joint. Sometimes the knee unlocks spontaneously or it may have to be manipulated by a physician or by the patient himself in order to regain a full range of movement. The history of sudden unlocking with a click located in one or other joint compartment is diagnostic of a torn meniscus (or, less commonly, the presence of a loose body in the knee). 'Giving way' denotes a condition in which the knee suddenly flexes under the patient so that he falls to the ground, or, more commonly, the knee may feel as if it is about to give way (i.e. may feel unstable) without actually collapsing. This symptom may be caused by a torn meniscus or may be due to damage to the mechano-receptors in the capsule of the knee upon whose normal activity the co-ordination of the thigh muscles depends. Quadriceps weakness may produce the same symptom. (Since the stability of the knee is dependent upon the accurate, co-ordinated contraction of the thigh muscles, any injury producing muscular weakness and inco-ordination may cause a feeling of instability in the joint.)

Physical Signs.—Soon after injury the meniscus is tender. As with ligament injuries, the demonstration of such tenderness depends upon an accurate knowledge of the surface anatomy of the knee. Tenderness over the anterior or posterior horns of either meniscus cannot easily be confused with tenderness over any other structure, but tenderness over the centre part of the meniscus cannot be distinguished from tenderness over a collateral ligament (fig. 390). Wasting of the thigh is invariable within 2 weeks of injury. If the knee is locked, a full range of movement cannot be obtained and gentle attempts to force a full range will produce a sensation of elastic resistance and pain localised to the appropriate compartment of the joint. If a meniscus is torn, there will always be an effusion (albeit sometimes a small one) in the knee. Thus, the absence of an effusion excludes a meniscus injury. On the

other hand effusions occur in other conditions so that their presence is not diagnostic of a meniscus injury. McMurray's sign (the demonstration of a painful click if the flexed tibia is rotated upon the femur) is sometimes positive. The distinction between a medial and a lateral meniscus injury depends entirely upon the localisation of tenderness and lateralising features in the history.

There are no abnormal radiological features in routine X-rays but meniscal tears can be demonstrated by arthrography. Recently arthroscopy has been increasingly used in the diagnosis.

Treatment.—If a definite diagnosis of a torn meniscus is made, the meniscus should be excised since it will not heal spontaneously. Commonly, the diagnosis cannot be made with certainty and surgery should then be deferred. The patient is treated with quadriceps exercises so as to build up his thigh muscles and the knee is watched. Should symptoms suggestive of a meniscus injury persist, it may be inferred that the meniscus is torn, and the knee is explored.

If the knee is locked at the time when it is first examined, the patient may rapidly be made more comfortable by manipulation of the knee. No special manœuvre is needed: the patient is given a general anæsthetic producing muscle relaxation. The knee usually then falls straight and can be put through a full range of movement. Occasionally a click is encountered as the knee is put through a full range when the cartilage is displaced from between the condyles.

Menisectomy

The leg is exsanguinated using an Esmarch's bandage and an inflatable tourniquet. The cartilage is exposed by an oblique incision running from the appropriate femoral condyle downwards towards the tibial tubercle. The torn cartilage is steadied by a blunt hook and its anterior attachment to the tibia is divided. The cartilage is then grasped by forceps and pulled forwards, dividing its attachment to the coronary ligament. When the cartilage has been freed as far posteriorly as it can be displayed, it is dislocated into the inter-condylar notch and the posterior horn divided. The synovial membrane and capsule are sutured with plain catgut and the skin sutured with interrupted nylon sutures. A Robert Jones bandage is applied before the tourniquet is removed so as to limit bleeding into the joint. Post-operatively quadriceps exercises are started immediately.

FIG. 392.—Cyst of the right lateral meniscus.

Cysts of the Menisci.—A cyst of a meniscus is due to myxomatous degeneration occurring in the substance of the cartilage itself. The lateral cartilage is affected perhaps 20 times more commonly than the medial.

Clinically a tense swelling, often more obvious when the knee is flexed, appears over the joint line (fig. 392). The cyst sometimes appears suddenly owing to its extrusion from the joint. Pain follows exertion but may occur at rest. It is commonly described as being like toothache.

Thomas Porter McMurray, 1887–1949. Professor of Orthopædic Surgery, Liverpool, England.
Johann Friedrich August von Esmarch, 1823–1908. Professor of Surgery, Kiel, Germany. Introduced this bandage in 1869 for use on the battlefield.
Sir Robert Jones, 1858–1933. Orthopædic Surgeon, Royal Southern Hospital, Liverpool, England. He was the nephew of Hugh Owen Thomas (see footnote p. 385) and did much to spread the knowledge of his uncle's work.

Treatment.—The cartilage together with the cyst should be removed if symptoms are persistent, but like a ganglion in any other site it can be ignored and often disappears spontaneously after a number of years. Local removal is unsatisfactory as recurrence is inevitable.

The Extensor Apparatus

The extensor apparatus of the knee comprises the quadriceps muscle, the tendinous insertion of the quadriceps muscle into the patella, the patella retinaculæ, the patella itself, the ligamentum patellæ and the insertion of the ligamentum patellæ into the tibial tubercle. This apparatus constitutes a single functional unit and provides the active extension of the knee which is vital to normal gait. The apparatus may be injured anywhere in its length either by direct or by indirect violence (i.e. by a direct blow or by forced flexion of the knee when the quadriceps muscle is contracting).

Contusion of the quadriceps muscle results from direct violence. Localised pain follows attempts at contraction of the muscle and an extravasation of blood occurs within the muscle sheath. The extravasated blood may appear subcutaneously some distance from the site of the contusion, for example near the patella. Rest and pressure dressings are required for the first few days and thereafter the knee is progressively mobilised.

Contusion of the deep fibres of the quadriceps muscle may be associated with avulsion of the periosteum from the femur. The resulting hæmatoma may ossify to produce a radiologically demonstrable and occasionally palpable bony swelling on the anterior aspect of the femur (fig. 393). (This pathological process is sometimes referred to, wrongly, as myositis ossificans (p. 348).)

FIG. 393.—An ossifying hæmatoma overlying the femur.

Rupture of the muscle belly of the rectus femoris occurs at about mid-thigh level in young athletes as a consequence of very forceful, but resisted active extension of the knee. Extension of the knee is still possible after the pain of the rupture has subsided. When all local œdema has disappeared, the proximal end of the muscle will become prominent and will stand out as a visible lump when the patient contracts the thigh. Distal to this lump there is a palpable gap in the muscle. No surgical treatment is possible (since the muscle will not hold sutures), nor is surgical treatment necessary because the injury causes no permanent disability.

Rupture of the tendinous insertion of the quadriceps muscle into the patella is an uncommon injury which usually occurs in middle-aged and elderly patients, often after a trivial indirect injury such as stumbling. It may, however, occur

in athletes. It is probable that the underlying pathology in the middle-aged is similar to that in ruptures of the Achilles' tendon, namely ischæmic necrosis of the tendon. The gap is easily visible and palpable a few weeks after injury (fig. 394) but is less obvious immediately after injury when the space is filled with hæmatoma, the tissues are swollen and the quadriceps inhibited. Soon after the episode the diagnosis may therefore be missed. The tendon should be repaired with mattress sutures.

Fractures of the patella may be due to indirect violence, i.e. to forced flexion of the knee when the quadriceps are contracting (in which case the fracture runs transversely across the patella) or to direct violence, for example a blow on the anterior aspect of the flexed knee (in which case the fracture is usually comminuted, although sometimes only one or two fragments are broken from the main body of the bone). The latter fractures are described as 'stellate' and are sometimes compound.

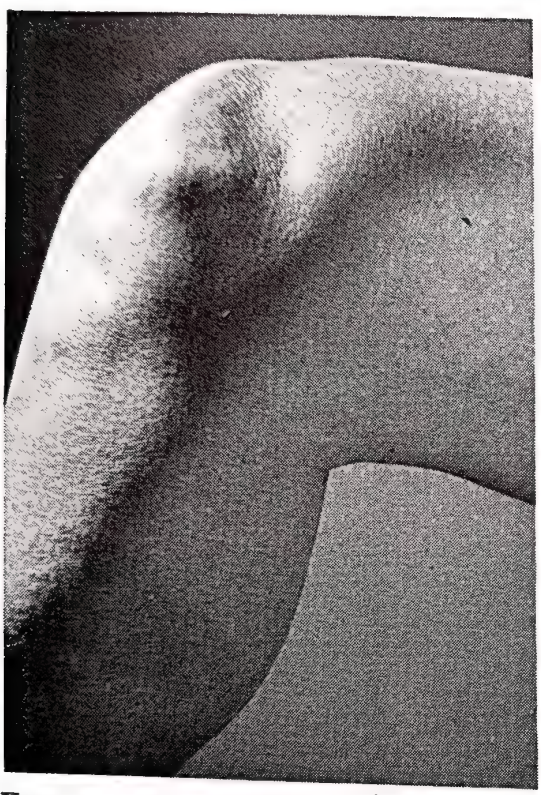

FIG. 394.—Rupture of the insertion of the quadriceps muscle into the patella.

Transverse fractures of the patella may be isolated injuries: the two fragments of the patella do not then become displaced since they are held in their normal position by the pre-patella expansion of the quadriceps tendon and the patella retinaculæ. Should force continue to be exerted on the extensor apparatus after the patella has fractured, the fracture may extend as a tear into these soft tissues. The quadriceps muscle then draws the proximal fragment of the patella proximally so that a substantial gap opens at the fracture site (compare Fractured Olecranon, p. 350).

Undisplaced transverse fractures may be suspected by the demonstration of local tenderness and with care can be visualised radiologically (their demonstration is not easy since in an antero-posterior view the shadow of the patella is obscured by that of the distal end of the femur). Active extension of the knee is possible (but painful) without an extensor lag. Treatment is by immobilisation of the knee in a plaster cylinder for 6 weeks combined with quadriceps exercises and followed by mobilisation in a physiotherapy department.

Fractures with separation are obvious clinically because the gap is palpable. They are also obvious radiologically. Active extension of the knee is impossible. Treatment is by open reduction and internal fixation using a screw or wire (fig. 395). Should the fracture line traverse the patella so as to produce one large and one very small fragment it is often best to excise the small fragment rather than to attempt reconstruction.

Comminuted fractures of the patella cannot be accurately reduced and they therefore invariably result in significant irregularity of the posterior, articular surface of the bone. Such irregularity predisposes to osteo-arthrosis of the patello-femoral joint. These fractures should therefore be treated by removal of all the fragments of the patella (i.e. by patellectomy) followed by reconstruction of the soft tissue components of the extensor apparatus. Following this operation, full, powerful, active extension of the knee is possible but there may be some loss of flexion. Surprisingly, the appearance of the knee is nearly normal. Vertical fractures separating one or two small fragments from the lateral or medial border of the patella can be treated symptomatically if the extensor mechanism is intact.

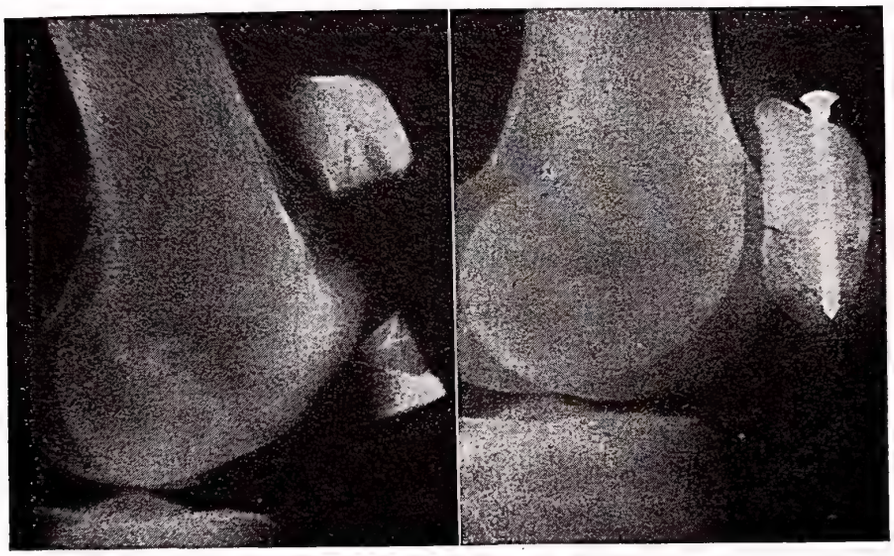

FIG. 395.—Transverse fracture of the patella fixed internally with a screw.

Ruptures of the ligamentum patellæ occur, although rarely, in young athletes following extreme violence. The diagnosis is obvious, since the patella is drawn upwards to create a considerable, palpable gap. The knee is bruised, swollen and tender. Active extension is impossible. Treatment is by suture of the ruptured ligament followed by immobilisation of the leg in a plaster cylinder for 6 weeks.

Avulsion of the tibial tubercle occurs very rarely in adults. Minor avulsion injuries are not uncommon in adolescents, a condition known as Osgood-Schlatter's Disease (see p. 282 and fig. 307). A similar condition occurs, more rarely, at the distal pole of the patella and is known as Sinding-Larsen's disease (p. 282).

Dislocation of the patella over the lateral femoral condyle may occur following a direct blow on the medial side of the patella or without significant violence if some predisposing anatomical abnormality exists in the knee. Following direct violence, the medial patella retinaculum is ruptured and the patella passes over the lateral femoral condyle to lie on its lateral aspect. Once in this position, the patella remains there unless replaced by the patient himself or by a physician, and thus the knee is locked. The anatomical abnormalities which predispose to this condition are a small patella, a high patella, an unusually low lateral femoral condyle, marked knocked knee (so

that the extensor mechanism tends to bowstring across the lateral aspect of the knee), or marked internal rotation of the legs (producing 'kissing patellæ'). Minor degrees of misalignment in which the patella does not actually dislocate may be responsible for some cases of Chondromalacia Patellæ (p. 234).

Once the patella has dislocated it is prone to do so repeatedly, and spontaneously. This condition is known as '*Recurrent Dislocation of the Patella*' and results in repeated locking or giving way of the knee. It is attributable to chronic elongation or rupture of the medial patella retinaculum so that the transverse, distal fibres of the vastus medialis muscle no longer stabilise the patella in a medial direction when the quadriceps muscle contracts. The clinical features of the initial dislocation are obvious. Recurrent dislocation is also usually obvious, but occasionally if the dislocations reduce spontaneously the patient is not aware that the patella is dislocating and merely complains that his knee repeatedly locks or gives way.

The treatment of an initial dislocation is reduction of the patella, followed by immobilisation of the knee in a plaster-of-Paris cylinder for 3 weeks to give the medial patella retinaculum a chance to heal. Following removal of the plaster the knee is mobilised and particular attention is given to developing the quadriceps muscle.

Recurrent dislocation of the patella requires operative treatment. Numerous procedures have been described, but the most commonly employed is medial transposition of the tibial tubercle combined with release of the lateral patellar retinaculum and 'double-breasting' of the medial retinaculum.

Fractures of the Tibial and Femoral Condyles

These injuries may be due to indirect violence (by a mechanism similar to that which produces ruptures of the collateral ligaments) or to direct violence:

FIG. 396.—Fracture of the lateral tibial condyle with severe displacement. The neck of the fibula is also fractured.

1. If the tibia is abducted or adducted on the femur, either the appropriate collateral ligament ruptures in tension or the femoral or tibial condyle on the opposite side of the knee collapses in compression. The result is a *depressed fracture of the tibial* (*or rarely femoral*) *condyle* (fig. 396). An associated tear of the meniscus is not infrequent.

2. Fractures due to direct violence are commonly produced by motor cars running into pedestrians. The bumper strikes the leg in the region of the knee and produces a *comminuted fracture* at the site of impact. The articular surfaces are frequently disrupted to produce a grossly irregular surface.

3. A direct blow applied to the anterior aspect of the flexed knee (i.e. to the patella) may drive the patella backwards into the femur, splitting the two femoral condyles from the femoral shaft

so as to produce a '*Y*' *shaped fracture of the femoral condyles.* This fracture may also be produced by falls from a height on to the heels.

4. Finally a transverse *supracondylar fracture of the femur* may occur without involvement of the knee joint.

The diagnosis is suspected clinically by obvious deformity, bruising and swelling of the knee. The details of the injury are made out radiologically.

The treatment of fractures of the condyles is difficult. In young adults an attempt should be made to reconstruct the joint surfaces, but if comminution is extreme, this is often impossible. If reconstruction seems possible, it should be attempted by open operation with internal fixation of the fracture fragments. In more elderly patients or in young adults with minimally depressed fractures good results can be obtained conservatively either by treating the knee with early mobilisation on skeletal traction, or alternatively by immobilising the knee for 3 to 6 weeks in a plaster cylinder followed by active mobilisation in a physiotherapy department. Whatever form of treatment is employed, weight-bearing should be avoided for 3 months. Osteo-arthrosis is a common late complication.

Supracondylar fractures of the femur present a special problem, since the gastrocnemius muscle tends to flex the distal fragment, producing posterior angulation at the fracture site. This is very difficult to control conservatively, although it is possible to do so, using two Steinmann pins, one through the tibial tubercle to provide traction in the long axis of the femur and one through the distal fracture fragment to provide forward traction at right angles to the long axis of the femur. Alternatively the fracture can be treated by internal fixation of the fragments using a blade-plate.

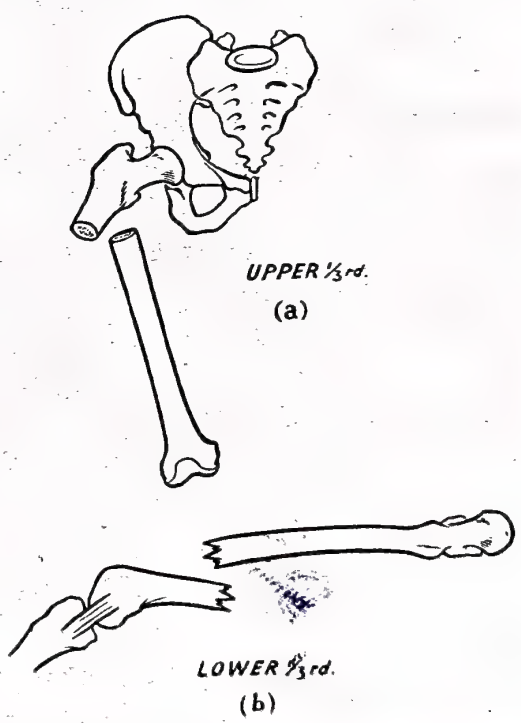

FIG. 397.—Characteristic deformities following fractures in the upper and lower thirds of the shaft of the femur.

FRACTURES OF THE SHAFT OF THE FEMUR

Fractures of the shaft of the femur occur in infants and young adults. In the latter the injury is usually due to severe violence so that associated injuries are common.

Displacement depends upon the direction of violence, muscular contraction and gravity. In the upper third of the shaft, the proximal fragment is flexed by the iliopsoas muscle, abducted by the gluteal muscles, and everted by the external rotators. The lower fragment is adducted by the adductor muscles, drawn proximally by the hamstrings and quadriceps, and everted by the weight of the limb. In middle-

Fritz Steinmann, 1872–1932. Surgeon, Berne, Switzerland. Described a pin for skeletal traction in 1907.

third and lower-third fractures, the deformity is one of backward angulation of the distal fragment and shortening (fig. 397).

The diagnosis is usually obvious clinically and is confirmed radiologically.

There is no obvious bleeding in a simple fracture of the shaft of the femur but bleeding into the thigh—often in excess of a litre—is invariable in adults and such blood loss must be replaced.

Treatment.—As in any other fracture, the aims of treatment are: (1) reduction (i.e. restoration of alignment and of length), (2) immobilisation of the fracture and (3) the prevention of knee stiffness.

1. *Restoration of alignment* is essential in the femur because mal-alignment throws an abnormal strain upon the knee joint, so that osteo-arthrosis is prone to develop in later life. Residual posterior angulation results in an extensor lag and hence in instability of the knee.

2. *Restoration of adequate length* is essential unless the patient is to wear an ugly raised shoe. Shortening tends to occur at the fracture site because (1) it is often produced by the initial injury, (2) the powerful thigh muscles pull the distal fragment proximally and (3) substantial bleeding at the fracture site is invariable and tends to ' balloon ' the thigh to produce an increase in girth and decrease in length. Full restoration of length is not necessary: up to 2 cm of shortening is acceptable as this amount is easily concealed by pelvic tilt.

3. *Immobilisation of the fracture site* can be achieved by traction and counter-traction, by internal fixation, or by plaster-of-Paris fixation (but in the adult this involves a very heavy, extensive plaster and is ineffective in overcoming muscle pull).

4. *Severe knee stiffness* is a common complication of fractures of the shaft of the femur, especially in the distal half, as a result of scarring in the thigh muscles and adhesion formation in the joint. Delayed union is especially prone to result in permanent knee stiffness. Distraction seems to cause non-union and it is preferable to have a femur which is a little short but united with a fully mobile knee, than a femur which is of full length but in which union is delayed and knee movement is limited.

Conservative Treatment (Traction and Counter-traction).—Because of the muscular contraction by the powerful muscles of the thigh, an untreated fracture of the femur may easily develop 10 cm of shortening (' over-riding '). The maintenance of length against this constant tendency to shorten is the special problem presented in this fracture. It is, therefore, essential to have a clear understanding of the principles of traction and counter-traction.

In most fractures, other than in those of the shaft of the femur, it is common practice to overcome shortening by a manipulation under anæsthesia and, if the bone ends can be successfully ' hitched ' against each other, to maintain this length merely by encasing the limb in plaster. This is quite impossible in the femur because, even if the fragments could be ' hitched ', the soft bulk of the thigh would allow them to slip again soon after the plaster was applied. If the fracture is oblique or comminuted it is impossible

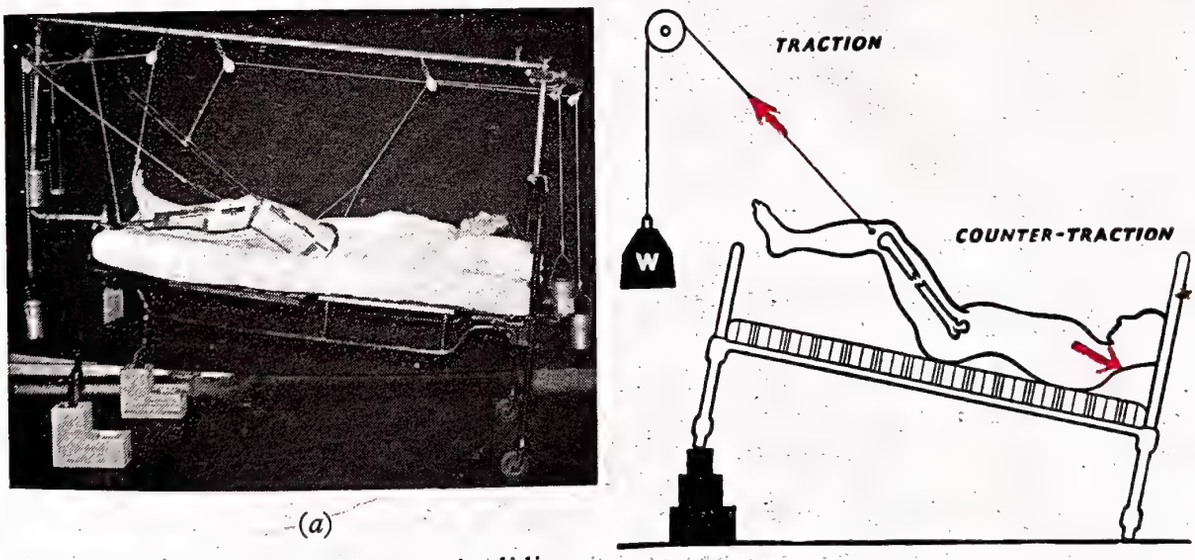
to obtain stable end-to-end contact in the first place because the thigh muscles are so powerful. Thus the reduction has to be maintained by the continuous application of traction.

In applying traction to the distal fragment so as to hold the thigh to an acceptable length, it is always necessary to use counter-traction to the proximal fragment to prevent the trunk and pelvis following the traction force and again allowing the thigh to shorten.

There are two entirely different methods of applying traction and counter-traction: (1) Sliding traction and (2) Fixed traction. The latter is now rarely used.

1. **Sliding Traction** (*syn.* Weight Traction, Balanced Traction).—There are many modifications of detail in applying sliding traction, but the essential principles are:

(*a*) Traction is applied to the distal fragment by weights and pulleys attached to the limb either by skin strapping or by skeletal traction. Skeletal traction is to be preferred in the adult as it is more comfortable and can be more powerful. It is secured by driving a 4 mm. stainless steel Steinmann pin through the upper end of the tibia. Skin traction is perfectly adequate in children.



(*a*) (*b*)

FIG. 398.—The principal elements in sliding traction: traction and counter-traction.

(*b*) Counter-traction is provided by using the weight of the body. This is brought into action by elevating the foot of the bed so that the patient's trunk and pelvis tend to slide away from the source of traction. With a traction force of 9 kg. the foot of the bed is raised about 22 cm (fig. 398).

(*c*) The normal forward bowing of the shaft of the femur is maintained by support for the back of the thigh. Because of the tendency for the thigh to sag under the influence of gravity, the original deformity of backward angulation tends to persist, and must be controlled by slings or supports under the thigh.

Further apparatus permits knee movement, holds the foot in dorsiflexion (to prevent equinus deformity), and counterpoises the whole apparatus so that it 'floats' with the patient as he moves in bed.

Sliding traction is attractive because it is comfortable, and does not expose the patient to the risk of an infected fracture. The main danger of the method is that bone contact may be lost ('dis-traction') through excessive traction.

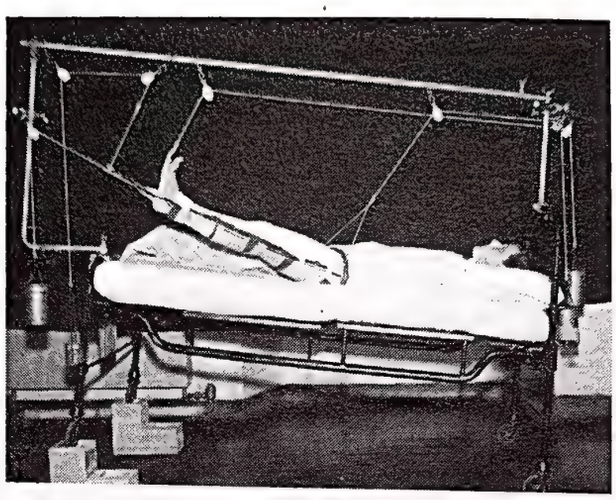
2. **Fixed traction** depends entirely on the use of the Thomas splint. Its modern application hardly differs from the original method used by H. O. Thomas nearly 100 years ago.

Hugh Owen Thomas, 1834–1891. Surgeon, Liverpool, England. Though he never held a hospital appointment, preferring to attend patients in their homes, he is regarded as the founder of orthopædic surgery. He introduced his splint in 1875.

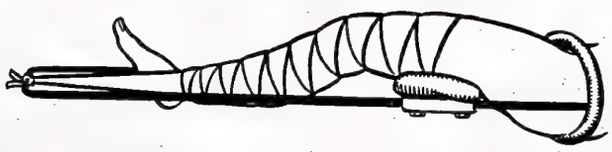
In this method of traction, cords are attached to the distal fragment, either by skin extensions or by a skeletal pin, and after passing the Thomas splint over the limb so that the padded leather ring takes a purchase against the ischial tuberosity, traction is applied by tying the cords to the foot of the splint. Counter-traction is thus exerted by pressure of the ring against the soft tissues and the ischial tuberosity (fig. 399).

Backward angulation of the shaft of the femur is controlled by slings passed between the side-bars of the splint behind the thigh. Fixation of the fracture is obtained by enclosing the limb and the splint in a bandage.

It is evident that this method can exert only a relatively slight traction force, because the skin of the perineum would not be able to withstand a counter-traction force as great as that used in sliding traction. The great art of the method is therefore



(*a*)



(*b*)

FIG. 399.—Fixed traction applied with a Thomas splint and adhesive strapping to the skin.

to hold the fracture with minimum force. To do this, the fracture must be capable of reduction under anæsthesia and the Thomas splint with fixed traction is then used merely to retain a reduction already achieved. This method has been modified by Bonnin, who adds skeletal sliding traction to fixed traction in order, not so much to treat the fracture (which is controlled by the fixed traction), but to draw the ring of the Thomas splint away from the groin.

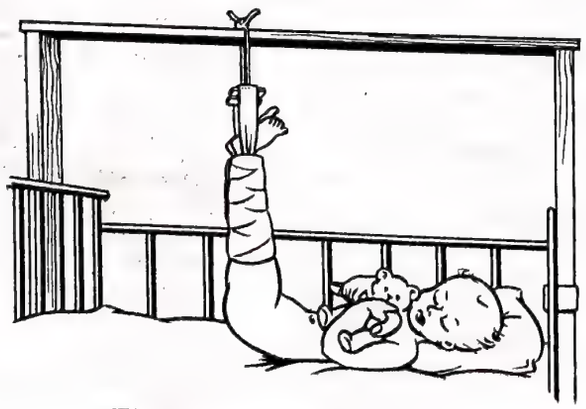


Fig. 400.—A 'gallows' splint.

Fixed traction provides more effective immobilisation of the fracture than does sliding traction and hence is said to result in a higher incidence of union. On the other hand, early knee stiffness is more marked after treatment by this method, although at the end of one year there is little difference in the range of knee movement obtained by either method.

Union.—A transverse or comminuted fracture takes about 12 weeks to unite if treated by traction.

Josiah Grant Bonnin, Contemporary. Formerly Orthopædic Surgeon, Central Middlesex Hospital, London.

During this time the muscles of the leg must be exercised, at first statically but latterly with knee movement. Lateral mobility of the patella must be maintained manually from the moment of injury.

When the fracture is judged to be united, the traction is removed and the patient allowed to mobilise the leg in bed. If the fracture site remains comfortable, the patient is allowed up on crutches and gradually returns to full weight bearing.

A gallows splint (fig. 400) *is useful for children* below the age of 5 years. Traction is applied by means of strapping, and the legs are slung up to the crosspiece, so that the pelvis is just lifted from the mattress (a position which is very convenient for nursing purposes). The child's weight acts as counter-traction. Alternatively, children of this age can be treated in a plaster spica.

Operative Treatment: Internal Fixation.—Conservative treatment has the following disadvantages: (1) it involves prolonged treatment in hospital, (2) knee stiffness is common, (3) reduction may be impossible if muscle is interposed between the fracture fragments and (4) it requires constant intelligent attention to detail in order to ensure that the reduction is not lost and that pressure sores, e.g. over the Achilles' tendon do not develop. These disadvantages can be circumvented by internal fixation using a nail and plate in the subtrochanteric region of the shaft or an intramedullary (Küntscher) nail in the second and third quarters of the shaft (fig. 401). The nail can be inserted either by exposing the fracture site, or 'blindly' using X-ray control.

Provided the fracture is not too comminuted, no external splintage is required post-operatively and the patient can get up on crutches, progress to weight-bearing and start knee flexion within a few days of operation. These advantages have to be set against the occasional disaster of a surgically induced infection.

On balance, there is little to choose between conservative and operative treatment unless reduction cannot be achieved conservatively in a mid-shaft fracture, or the fracture is in the proximal shaft of an adult, for then the abduction and flexion of the proximal fragment is sometimes impossible to control conservatively. Operative treatment is never necessary in children.

FIG. 401.—Küntscher intramedullary nail in the femur.

INJURIES TO THE HIP

Fractures of the Proximal Femur

Since the days of Sir Astley Cooper these fractures have been divided into *intra-capsular* and *extra-capsular*. Intracapsular fractures occur in that portion of the neck of the femur which lies within the capsule of the hip. Extracapsular fractures occur in the remainder of the neck and through the trochanteric mass.

Gerhard B. G. Küntscher, Contemporary. Director, Harbour Hospital, Hamburg, Germany.
Sir Astley Paston Cooper, 1768–1841. Surgeon. Guy's Hospital, London.

Intra-capsular Fractures of the Neck of the Femur

Pathology.—These fractures are anatomically sub-divided into subcapital and, more distally, transcervical but it is possible that they all consist of a fracture starting superiorly at the junction of the head and neck (i.e. to be 'subcapital'), which propagates downwards through the head–neck junction until it encounters the calcar femorale, and which may then be deflected distally by the calcar so that it emerges inferiorly somewhere in the neck (i.e. to be 'transcervical'). Two features of this fracture make treatment difficult: (1) the blood supply to the proximal fragment is often impaired and (2) the proximal fragment can be neither manipulated nor immobilised by conservative means.

The head of the femur receives its *blood supply* via the femoral neck from vessels which reach the neck in synovial folds reflected from the capsule to the bone. These vessels may be ruptured when the intra-capsular portion of the femoral neck fractures. Since vessels enter the femoral neck throughout its length, the more proximal the fracture the greater is the chance of serious vascular damage. Similarly the greater the displacement which occurs at the fracture, the greater will be the vascular damage. A small, inconstant blood supply reaches the head through the ligamentum teres. This vessel may not be patent in the arteriosclerotic elderly and in such patients the vessels in the neck are more fragile. Thus the danger of an impaired blood supply in the proximal fragment increases:

(1) the more proximal is the fracture;
(2) the more displaced is the fracture;
(3) the more elderly is the patient.

A poor blood supply may result in (1) non-union and (2) avascular necrosis of the femoral head (see ' Complications ', p. 390).

These fractures are very much more common in elderly women in whom they are associated with seemingly trivial domestic stumbles. The fact that these fractures seem to be produced by very slight violence is perhaps due to the fact that osteoporosis has weakened the femoral neck. There is now however evidence that the fracture is due to fatigue in these patients, not to a fall; i.e. that the patient falls because the bone fractures, not that the bone fractures because the patient falls.

Rarely *fatigue fractures* may occur in the femoral neck of young adults exposed to unusual physical activites such as route marches with a full military pack.

In young adults the fracture may occur following severe violence applied in the long axis of the femur so as to shear the femoral neck. Such fractures may be associated with dislocation of the hip.

Displacement is usual at the fracture site and takes the form of external rotation and adduction of the distal on the proximal fragment. Occasionally subcapital fractures are impacted: no rotation then occurs and the fracture appears to be abducted, rather than adducted.

Clinical Features.—In unimpacted fractures the leg is short and lies in external rotation; there is tenderness over the fracture site in the groin;

attempted movement of the hip is painful; and the patient is unable to lift the leg off the examination couch. In impacted subcapital fractures there is tenderness over the fracture site but otherwise there may be no abnormal physical signs. These fractures are therefore easily missed clinically.

An exact diagnosis requires X-ray examination. Even on X-ray, impacted fractures with minimal displacement may be missed.

Treatment is invariably operative because the proximal fragment cannot be controlled conservatively. In patients under 65 years of age, and in impacted fractures in older patients, the fracture is fixed internally using three pins, a tri-flanged nail such as those designed by Smith-Petersen or Watson Jones or, in the practice of some surgeons, a blade-plate (see Extra-capsular Fractures, p. 391).

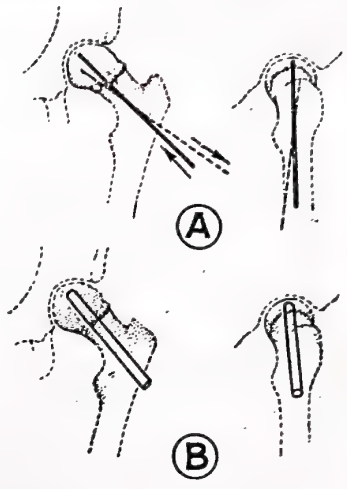

FIG. 402.—(*a*) Insertion of guide wire. The wire in the satisfactory position is retained. (*b*) The nail is inserted and the wire withdrawn. (*A.P. and lateral views.*)

The Technique of Internal Fixation.—A tri-flanged nail (with or without a plate) is inserted under X-ray control (fig. 402).

The patient is placed on a special operating table incorporating traction to the feet and counter-traction via a post in the perineum. The fracture can usually be reduced simply by placing the leg in abduction and internal rotation combined with traction. If the reduction is satisfactory (as checked by X-rays of the neck of the femur in two planes), a lateral incision is made over the great trochanter and a guide wire 2 mm. in diameter is inserted into the femoral neck. X-rays are taken, and if the direction of the wire is unsatisfactory, it is repositioned. The nail is provided with a central cannula which enables it to be slid over the guide wire and hammered into the head. A plate may then be bolted to the nail and screwed to the proximal shaft. The wound is closed and the patient is returned to bed without external splintage.

FIG. 403.—Replacement of the femoral head and neck with a Thompson prosthesis.

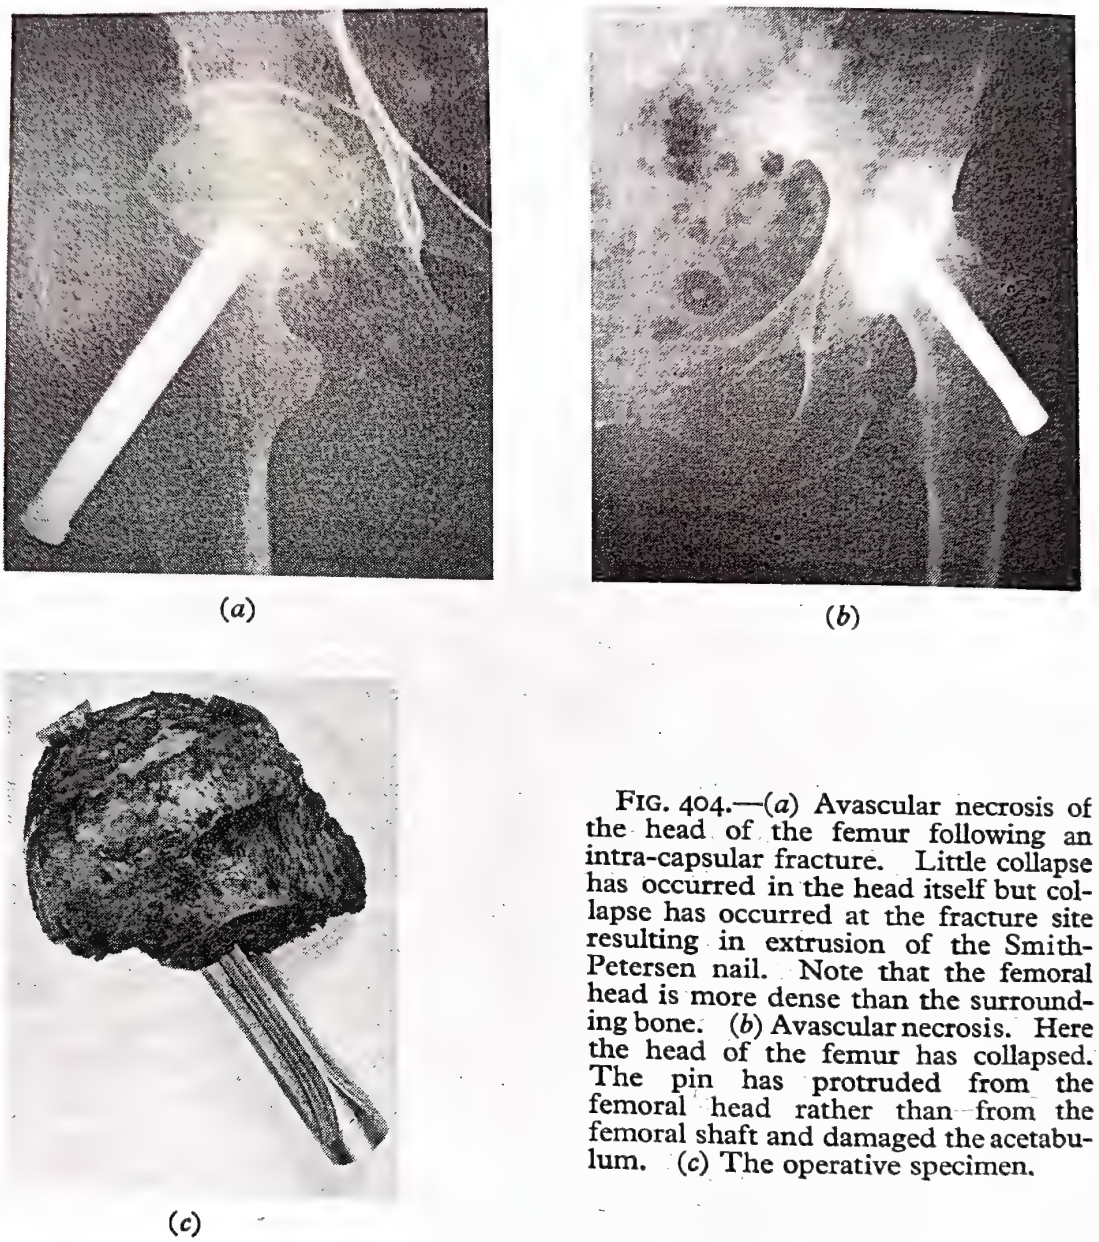
After operation the patient can be allowed out of bed in a few days, but weight-bearing is not permitted until some evidence of union is suggested in the X-ray—which may take 3 to 4 months.

In unimpacted fractures in patients over 65 (or in younger patients with a shortened expectation of life) the chance of non-union or of avascular necrosis is substantial, and the ability of the patient to withstand a second operation (see ' Complications ') is slight. Thus these fractures are treated primarily by replacement of the head and neck with a prosthesis (fig. 403).

Marius Nygaard Smith-Petersen, 1886–1953. Professor of Orthopædic Surgery, Harvard University Boston, Mass., U.S.A. Introduced the tri-flanged nail in 1931.
Sir Reginald Watson Jones, 1902–1972. Orthopædic Surgeon, The London Hospital.

Complications

Non-union occurs in approximately 30 to 40% of all intra-capsular fractures, partly because adequate immobilisation is difficult to achieve even by internal fixation and partly because the proximal fragment frequently has a poor blood supply. Non-union can be treated by:



(*a*) (*b*) (*c*)

FIG. 404.—(*a*) Avascular necrosis of the head of the femur following an intra-capsular fracture. Little collapse has occurred in the head itself but collapse has occurred at the fracture site resulting in extrusion of the Smith-Petersen nail. Note that the femoral head is more dense than the surrounding bone. (*b*) Avascular necrosis. Here the head of the femur has collapsed. The pin has protruded from the femoral head rather than from the femoral shaft and damaged the acetabulum. (*c*) The operative specimen.

1. *Replacement of the head by a prosthesis* (Thompson or Moore prosthesis). This is the treatment for the elderly, and for the young if the head is avascular.

2. *Subtrochanteric Osteotomy* with displacement of the shaft under the head. In this way the shearing stresses produced by weight-bearing are taken off the fracture and union may occur between the proximal fragment and the shaft. This method is only suitable for young adults and forms an alternative to bone grafting.

Frederick Roeck Thompson, Contemporary. Professor of Orthopædic Surgery, New York Polyclinic Medical School, New York, U.S.A.

Austin Talley Moore, 1899–1963. Orthopædic Surgeon, Columbia Hospital and the Moore Clinic, Columbia, South Carolina, U.S.A. Described this method of treating fractured hips in 1935.

3. *Insertion of a fibular bone graft* into the neck across the fracture site and, at the same time, renewal of the internal fixation to ensure that it is adequate. This method is indicated if the head is viable with an intact blood supply, and the patient is young.

Avascular Necrosis.—In this condition part or the whole of the femoral head, having become avascular, gradually collapses. The commonest cause of infarction of the femoral head is a femoral neck fracture but the condition also occurs in alcoholics, patients receiving steroid therapy, after irradiation, and spontaneously. Infarction itself is symptomless but weeks later infarction is suggested by a relative increase in radio-density of the infarcted bone, and months later its presence is proven by collapse of the infarct (fig. 404). At this stage the condition is termed avascular necrosis.

This process is painful, and because the femoral head becomes irregular in outline it predisposes of osteo-arthrosis. If pain cannot be relieved by a stick and a raise to the shoe, the femoral head is replaced with a prosthesis. The acetabulum should also be replaced if it has become secondarily damaged, for example as in fig. 404 (*b*) and (*c*). Avascular necrosis is commonly complicated by non-union.

Extra-capsular Fractures of the Proximal Femur

These fractures are divided anatomically into basal cervical, and pertrochanteric. In the latter the fracture is always comminuted and the main fracture line runs somewhere through the trochanteric mass. Both anatomical varieties have the same prognosis and are treated in the same way.

In contrast to intra-capsular fractures, all the bone involved in extra-capsular fractures—especially in those fractures involving the cancellous bone of the trochanters—has a good blood supply so that non-union and avascular necrosis of the femoral head are almost unknown. The proximal fragment can be controlled conservatively and hence operative treatment, although frequently used, is not mandatory.

Pertrochanteric fractures in the elderly are probably due to a sideways fall producing a blow over the greater trochanter. In the young they occur following violent trauma—for example in road traffic accidents. Basal cervical fractures are probably due to the same mechanism as that producing other cervical fractures.

Clinically the diagnosis is made, as in the case of the intra-capsular fracture, by the combination of external rotation and shortening of the leg, tenderness over the fracture, and the patient's inability to raise the leg from the examination couch. In pertrochanteric fractures the leg tends to be more externally rotated than in fractures through the neck.

Treatment.—It is a relatively simple matter to treat a pertrochanteric fracture without operation, merely by applying traction to the limb and confining the patient to bed for 3 months until the fracture is clinically united. The traction will restore length, and the deformities of adduction and external rotation are corrected by abducting and internally rotating the leg. This method of treatment is perfectly acceptable for young adults. Most of these

fractures, however, occur in the elderly and in this age group 3 months of bed rest would frequently result in *bed sores, pneumonia, venous thrombosis, pulmonary embolism and death.* Hence in this age group the fracture is invariably fixed internally so that the patient need not stay in bed.

A simple nail (such as the Smith-Petersen) is inadequate since it gains no purchase on the distal fragment. Accordingly a 'pin and plate' is used in which the 'plate' is screwed to the shaft and the 'pin' is driven into the neck of the femur (fig. 405).

The implant is inserted with X-ray control as described for intracapsular fractures. The patient is allowed out of bed, to walk non-weight-bearing on crutches, within a few days of operation.

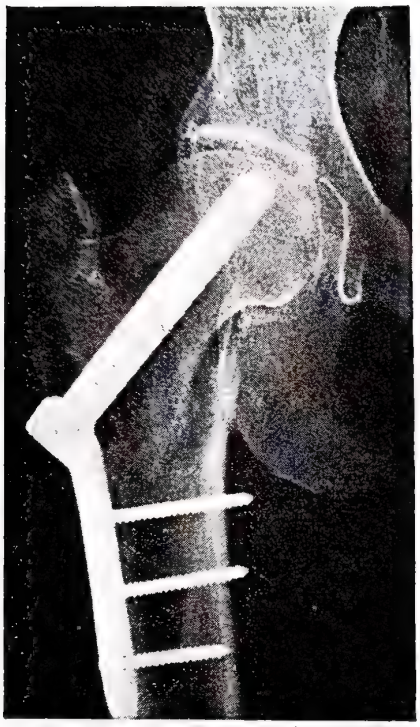


FIG. 405. — Inter-trochanter fracture treated by a pin and plate.

Avulsion of the Lesser Trochanter.—This injury is sometimes caused by sudden contraction of the ilio-psoas muscle, and is common at about puberty. The condition is unlikely to be diagnosed without the assistance of X-rays. Treatment consists in immobilising the limb for 4 weeks in slight flexion.

DISLOCATION OF THE HIP

This injury is relatively uncommon because of the depth of the acetabular cavity and the strong support afforded to the joint by its ligaments and muscles.

The injury usually occurs when the hip is flexed, especially if it is also adducted, because in this position the head of the femur is covered posteriorly by capsule rather than bone so that a force applied in the long axis of the femoral shaft may dislocate the head over the posterior lip of the acetabulum. Such a force is commonly provided either by a weight falling on the back of a person in a stooping position, as may happen if a coal-miner is struck by a 'fall of roof', or, more commonly, in car and motor cycle accidents in which, for example, a front seat passenger in a car is thrown forwards so that the knee strikes the dashboard.

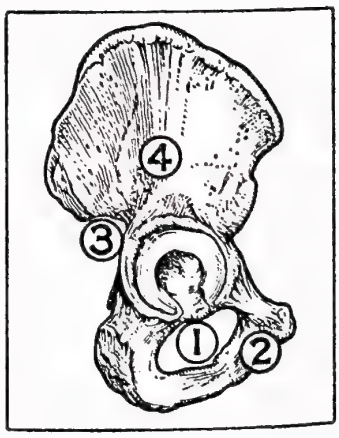

FIG. 406. — The positions taken up by the head of the femur following dislocation of the hip. 1. Obturator. 2. Pubic. 3. Sciatic. 4. Dorsal.

Posterior Dislocation of the Hip

In the usual posterior dislocation, the head of the femur escapes into the sciatic notch (where rarely the sciatic nerve may be damaged), and then passes up on to the dorsum of the ilium (fig. 406). The leg is flexed, adducted, and internally rotated, so that the sole of the foot rests upon the opposite instep. Pain is sometimes referred along the sciatic

nerve, which may be involved by direct injury. X-rays should always be taken to confirm the dislocation and to detect any associated fracture.

Reduction is usually easy provided that the injury is recent, and the anæsthetist obtains full muscle relaxation. The patient is placed on a mattress on the floor, and the iliac crests are steadied by an assistant. The surgeon stands over the limb and flexes the knee and thigh, bringing the head of the bone beneath (i.e. posterior to) the acetabulum. The femur is then adducted and pulled vertically upwards so as to draw the head forward from its posterior position. The essence of the reduction lies in the vertical lifting of the femur. Usually reduction will occur with this vertical traction alone but sometimes the hip must be internally rotated while upward traction is being exerted before the head of the femur suddenly snaps into its socket.

Usually the reduction is quite obvious when it occurs, and if the acetabulum is intact the reduction is stable—especially so when the hip is extended, abducted and internally rotated. Reduction is maintained by skeletal traction through the tibial tubercle for 3 to 6 weeks and during this time the hip is mobilised.

About 10% of dislocations are followed by avascular necrosis of the femoral head (p. 391). This complication cannot be predicted at the time of injury and therefore the patient should not bear weight on the injured limb until avascular necrosis can be excluded, that is to say if possible for 6 months after injury.

Two fractures may be associated with posterior dislocation: fracture of the femoral neck (rarely) and fracture of the posterior lip of the acetabulum. The first fracture must be treated by operation since in no other way can the fracture and the dislocation be reduced. Avascular necrosis is almost invariable. The second fracture is usually reduced by the same manœuvre as that which reduces the dislocation. The reduction however is unstable and its accuracy cannot be guaranteed. Therefore unless the fragment is very small, it is best to treat the injury by open reduction and internal fixation of the fracture with a screw. Damage to the sciatic nerve is a rare but serious complication of this fracture.

Anterior Dislocation of the Hip.—This is rare. The femoral head may lie either in the obturator or pubic position (fig. 406): in both cases the limb is in a position of flexion, abduction, and external rotation.

Central Dislocation of the Hip

This may be caused by a blow on the greater trochanter, driving the head of the femur through the floor of the acetabulum. This injury amounts to a comminuted fracture of the acetabulum and is often accompanied by other fractures of the pelvis.

Treatment is difficult and unsatisfactory. The femoral head can often be pulled out to its anatomical position by traction on the leg (sometimes combined with a side pull applied via a wire or nail in the greater trochanter). Unfortunately the weight-bearing part of the acetabulum rarely reduces with the head of the femur and, even if it does, the floor of the acetabulum does not accompany the reduction. The fracture can be reduced by operation but this is difficult. Therefore probably the best form of management is to accept the displacement and mobilise the hip with tibial skeletal traction as

soon as pain allows. Osteo-arthrosis usually develops eventually, regardless of treatment.

THE PELVIS

Fractures of the pelvis comprise fractures of the iliac crests and of the true pelvis.

Fractures of the Iliac Crests.—These are not of any significance because displacement is slight, as the iliacus muscle on the inner side, and the gluteal muscles on the outer side, support the bone. The patient is confined to bed till symptoms have settled, which usually takes 2 to 3 weeks.

Fractures of the Pelvic Ring

These fractures are due to a blow applied either directly to the pelvis, commonly so as to crush it, or indirectly through the thigh.

The pelvis is a rigid osseo-ligamentous ring. If it is broken in only one place, no significant displacement can occur at the fracture site and the only treatment which is needed is for the patient to rest until the pain has settled. This usually takes about 6 weeks and by this time the fracture has invariably united. If a single fracture in the pelvis runs through the acetabulum, the outcome may be far less satisfactory, for the slightest displacement leads to incongruity in the hip and hence pre-disposes to osteo-arthrosis (p. 221).

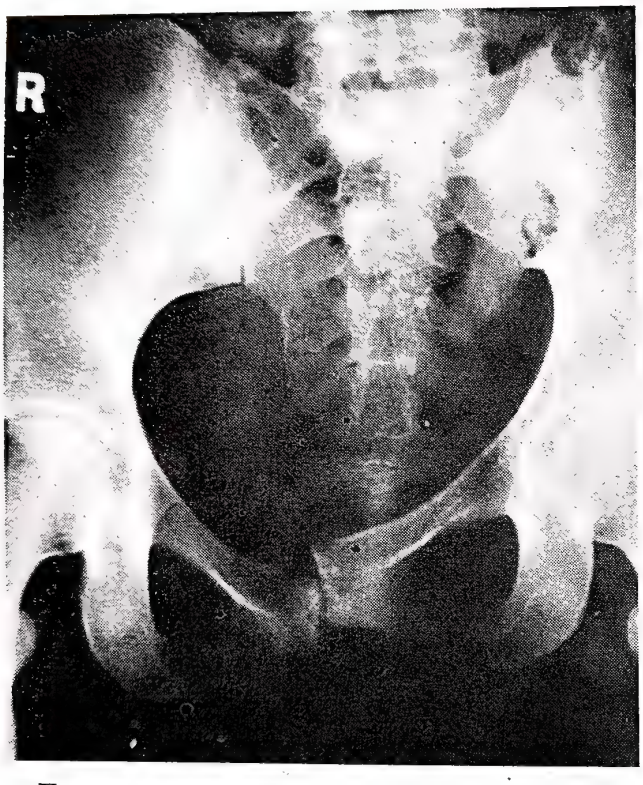

FIG. 407.—Fracture of the pelvis. Since the two halves of the pelvis are displaced relative to each other at the symphysis pubis, there must be a fracture elsewhere in the pubic ring. In this case the fracture, in the left ala of the sacrum, could easily be missed.

Fractures through two places in the ring constitute a far more serious injury since (1) the pelvis is no longer a stable weight-bearing structure, (2) the separated fragment may be displaced and (3) the fracture may be difficult or impossible to reduce. The fractures may traverse the pubic rami on both sides leaving a free central fragment, or they may traverse the rami, the acetabulum or pubic symphysis and the sacro-iliac joint (fig. 407). Dislocation of the sacro-iliac joint almost invariably results in persistent back pain.

The diagnosis of a fractured pelvis is suspected on the history, and the findings of localised tenderness and pain on stressing the pelvis. It is proved radiologically.

Other Injuries.—The most important aspect of fractures of the pelvis is the liability to severe, internal and therefore concealed hæmorrhage, and to injury of the viscera—the male urethra commonly, the bladder in both sexes occasionally, and the rectum and vagina rarely. Systemic signs of blood loss should be sought and blood transfused if necessary. After anterior fractures the patient should be instructed not to attempt to pass urine until an exploratory catheterisation can be made under fully aseptic conditions (Chap. 55). Blood escaping from the external urinary meatus in the male immediately suggests rupture of the urethra (Chap. 57).

A rectal examination is made, and in rare cases a fragment of jagged bone may be encountered, in which case laparotomy and a defunctioning colostomy are necessary. Wounds of the vagina are rare and can usually be sutured.

Having methodically excluded or dealt with visceral lesions, attention can be directed towards the fracture, although if the patient is seriously ill from visceral complications, no special measures are needed for the fracture. When separation of the symphysis occurs, the pelvis can be compressed by suspending it in a pelvic sling from an overhead beam. In some cases, nursing the patient between sandbags or on his side will close a separated symphysis without any external apparatus. Skeletal traction through the tibia may be necessary if a free lateral fragment is proximally displaced. If the absence of displacement makes such measures unnecessary, the patient is treated by bed rest, maintaining as full a range of movement as possible at the hips and spine, for at least 8 weeks.

The Coccyx

The coccyx may be fractured as a result of kicks or falls. Pain, which is often severe, occurs on walking, sitting or with actions which involve contraction of the levator ani, such as defæcation or coughing. Rectal examination reveals local tenderness and occasionally deformity. No specific treatment is needed and the symptoms settle spontaneously in about 6 weeks.

If symptoms persist for months, in spite of adequate rest and symptomatic treatment by sitting on soft cushions or anæsthetic injections, excision of the coccyx may have to be considered. There should be no haste in making this decision as persistent symptoms are often psychological in origin. In some cases these symptoms occur without fracture or even of injury. This condition, known as *coccydynia*, is of unknown ætiology. The treatment of the pain is the same as that for pain occurring after fracture.

CHAPTER 24

THE HEAD (SCALP, SKULL AND BRAIN)

THE SCALP

THE **scalp** consists of four layers—skin, subcutaneous tissue, epicranial aponeurosis or galea, into which is inserted the occipito-frontalis muscle, and the subaponeurotic areolar layer. The scalp is well supplied with blood-vessels, and the walls of the arteries are adherent to the fibrous tissue in the subcutaneous layer. Therefore scalp wounds bleed freely, as the muscular coat of a divided artery cannot retract readily when the vessel is severed.

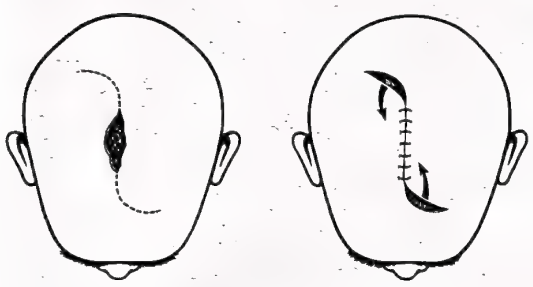

FIG. 408.—Letter S scalp plastic incision.

Wounds of the scalp are treated by adequate shaving of the surrounding scalp. The wound is excised, hæmostats applied to the galea are allowed to fall back over the skin edge. The scalp is closed in two layers, galea to galea and skin to skin, with interrupted black-silk sutures. In the case of tissue loss the gap is closed by making a reversed 'S' incision, by which means most defects in the scalp can be closed (fig. 408). This leaves the pericranium exposed at the ends of the incision. Healing occurs by granulation from the pericranium, which should be protected with tulle gras, and subsequent epithelialisation of the granulated area.

Owing to its rich blood supply wounds of the scalp heal readily (p. 4). Many cases are on record where the scalp has been avulsed almost completely, but after cleansing and suturing into position, union has occurred in a satisfactory manner.

Hæmatoma of the scalp may be subcutaneous. Subaponeurotic hæmatomas spread extensively beneath the epicranial aponeurosis and are only limited by the attachment of the aponeurosis around the base of the calvarium. Subpericranial hæmatomas are limited by the suture lines which border the underlying bone, to which the pericranium is attached.

Infection of the Scalp.—In the subaponeurotic areolar layer infection is circumscribed only by the attachment of the epicranial aponeurosis, and may extend from the superior curved line of the occipital bone behind to the supraorbital ridge in front, and laterally be bounded by the zygomatic arch, temporal ridge, and upper border of the mastoid process. The subaponeurotic areolar tissue is the 'danger area', since intracranial infection may

occur secondarily (p. 422) via the emissary veins. Treatment is by chemotherapy and incisions parallel to the main vessels and nerves.

Sebaceous cysts (*syn.* wens) (p. 103) are often multiple (fig. 409). The surrounding scalp becomes bald if pressure interferes with its blood supply. Infection and ulceration are described on p. 104.

FIG. 409.—Sebaceous cysts of the scalp.

Lipomas arise from fatty tissue incorporated with the areolar layer (fig. 51).

Cirsoid aneurysm is rare. Capillary nævi sometimes occur in the skin, beneath which abnormal arteries communicate directly with distended veins. The superficial temporal artery and branches are most commonly affected. The underlying bone becomes thinned by pressure which also causes the hair to fall out. Radiography may show perforations in the skull which indicate that part of the tumour is intracranial. These tumours tend to enlarge slowly with a risk of serious hæmorrhage if ulceration occurs.

Treatment consists in extirpation of the tumour in the early stages (ligation of one or both external carotid arteries is advisable as a preliminary step to local excision). If its size forbids such radical treatment, then the main vessels are ligated, but this is often unsuccessful, as a large tumour on the surface usually possesses intracranial connections which maintain the blood supply.

Dermoid Cysts are most frequent over the external angular process (fig. 502). X-ray shows bone defect with a sclerotic margin (fig. 410). Although congenital they may not appear until the patient is some years old or in adult life. Communication with an intracranial dermoid may take place by a narrow neck which passes through the inner table and which is visible on X-ray. An impulse on coughing is only detected if the communication is wide.

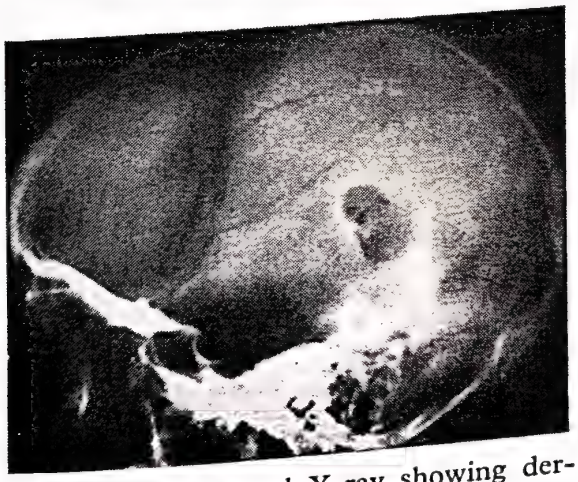

FIG. 410.—Lateral X-ray showing dermoid cyst of the diploe. The inner table has been penetrated by intracranial extension.

Treatment.—Superficial cysts are excised locally. Extensions are approached by osteoplastic craniotomy. The intracranial portion may be larger than the superficial.

Papillomas are common and cause discomfort on combing the hair. Constant irritation of this nature encourages malignant changes.

Fibrosarcoma has already been described (p. 55).

Epithelioma of the scalp is not common and presents no special features.

Melanomas may be unrecognised, owing to the small growth being hidden by hair. If malignant changes supervene, the appearance of secondary deposits should lead to the discovery of the tumour.

THE SKULL

Microcephaly may be associated with agenesis of the brain and imbecility, or result later from premature synostosis in a normal child.

Oxycephaly (*syn.* steeple-head, Gk. *oxus* = sharp) is a condition in which the skull is egg-shaped, following premature obliteration of sutures. Most cases develop increased intracranial pressure.

Treatment.—*Cranioplasty* by Gigli saw cuts between burr holes and wrapping the bone edge in tantalum foil allows normal skull expansion and cerebral development to proceed.

Meningocele.—*Clinical Features.*—Protrusions of a pouch of dura mater through a congenital defect in the skull can occur at the root of the nose or over the occipital bone. Trans-sphenoidal projections protrude through the base of the skull into the naso-pharynx and have been mistaken for nasal polypi: attempted removal has resulted in meningitis. A meningocele is present at birth, and forms a tense rounded swelling which is translucent and sometimes pedunculated, and which yields an impulse when the child cries or coughs. Growth of the skull may occlude the neck of a small sac; in this case a cyst remains which is non-pulsatile and unaffected by coughing.

FIG. 411.—An encephalocele. A myelocele is also present.

An encephalocele is a similar condition, but some portion of the brain is also extruded (fig. 411). Should this cerebral extrusion contain part of a ventricle, it is known as a *hydroencephalocele*. In these conditions vascular pulsation is present. The child may be stillborn, or some degree of idiocy or deformity will be associated.

Treatment.—The skin surface should be protected with padding and tulle gras to prevent ulceration and infection. If at the age of a month the child shows normal development, operation is performed under local anæsthetic the child being tied to a cross and given a feeding bottle during operation. A curved incision is fashioned in one margin of the sac, so that when the wound is sutured the incision will not overlie the bone defect. The neck of the sac is defined, transfixed, and ligated and the sac and excess skin removed. Muscle and fascia are brought together over the bone defect. Many cases have a small encephalocele at the base. This is removed with the sac, without harmful effect, as the tissue is functionless.

Skull Fractures.—See Cranio-cerebral Injuries (p. 399).

INFLAMMATION OF CRANIAL BONE

Osteomyelitis occurs as a result of infection of the diploe from:—

(i) *Direct infection*, such as a compound fracture.

(ii) *Local extension* of infection from the frontal sinus, mastoid antrum or cellulitis of the scalp.

Leonardo Gigli, 1863–1908. Obstetrician. Director, Santa Maria Nuova Hospital, Florence, Italy. Introduced his saw for pubiotomy in 1894, and adapted it for craniotomy in 1898.

(iii) *Blood-borne* infection by circulating organisms is practically unknown, except when rarely it follows bruising of the bone in young children.

Acute osteomyelitis of the skull is a serious condition. Infective thrombosis of emissary veins, extradural abscess, subdural abscess, brain abscess, and meningitis are grave complications (p. 422).

Treatment.—Antibiotics are effective in controlling both acute and chronic osteomyelitis. Wide excisions of both tables of the skull, at one time practised in the acute stage, are seldom required.

In the chronic stage, sequestra are sterilised under antibiotic treatment, and then excised. Bare areas in the overlying scalp are treated by skin grafting.

Tuberculous disease of the skull is uncommon, but occasionally occurs in association with tuberculous lesions elsewhere. As with other bones, the infection commences either in the pericranium or in the medulla, i.e. the diploe. The diseased bone should be removed widely, otherwise abscesses are likely to form and erode the scalp. Antituberculous drugs are given (p. 32).

Syphilitic pericranitis is nowadays a rare affection. Localised swellings occur which are slightly tender and fixed to the bone. Under suitable treatment disappearance is usual, although a small bony swelling occasionally remains.

NEW-GROWTH OF THE SKULL

Innocent tumours are rare. An *ivory* osteoma occasionally arises in the region of an air sinus (p. 241).

Malignant new-growths resemble those of other bones. *Pericranial sarcoma* forms a tumour, the consistency of which depends upon its vascularity and rate of growth. Thus it may be pulsatile or of an almost bony hardness. *Osteoclastoma* occasionally develops in the diploe.

The commonest malignant tumour is secondary carcinoma, usually derived from primaries in the breast, thyroid, prostate, or suprarenal.

Hypernephromas produce rapidly growing vascular tumours, which pulsate when the outer table is eroded. Secondary deposits usually produce a single clear area on the skull X-ray with irregular margin (fig. 412). Deposits from carcinoma of the breast are often multiple.

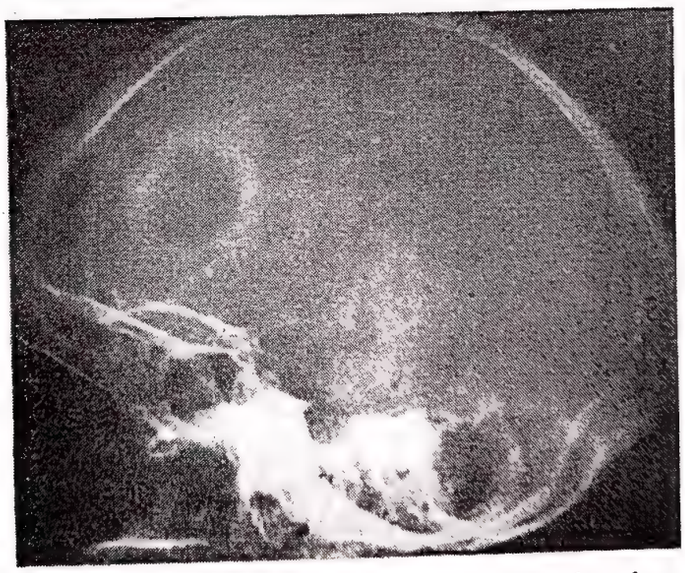

FIG. 412.—Lateral X-ray showing irregular clear area produced by a secondary deposit from carcinoma of the breast.

CRANIO-CEREBRAL INJURIES

Head injuries are injuries of a composite structure in which, according to the mechanism, either the brain, the skull, or intracerebral vessels may be injured separately or together. Some degree of brain injury, either minor

or major, is usually inflicted at the moment of impact producing a neuronal lesion, the effects of which determine the immediate clinical picture and often the outcome of the case. The epiphenomena of skull fracture, œdema and intracranial hæmorrhage are superimposed upon this basic picture of neuronal injury. In the mechanism of intracranial injury the direction and plane of the injuring force and its velocity are, in general, as important as the magnitude of the forces involved. The serious complications of intracranial hæmorrhage in particular are produced by relatively minor forces acting in a certain plane.

INJURIES OF THE BRAIN

Mechanism and Pathology.—At the moment of impact a diffuse neuronal lesion is inflicted on the brain which is responsible for the immediate clinical picture of brain injury. Secondary changes of œdema or intracranial hæmorrhage take time to develop. The rise in pressure resulting from these causes leads to a deterioration in the patient's level of consciousness a few hours after injury; the clinical picture in the early stages results from the neuronal lesion alone. All degrees of brain injury resulting in loss

FIG 413.—Suspension of the brain in the slings formed by the superior cerebral veins.

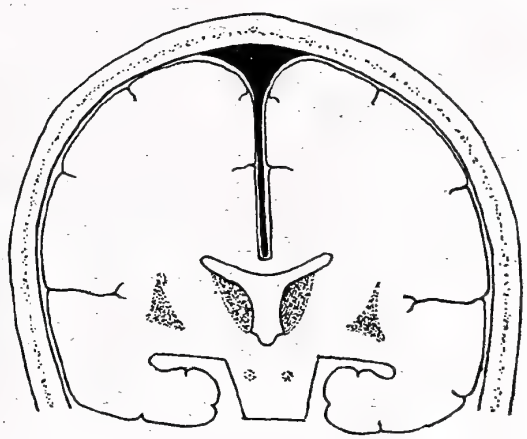

FIG. 414.—The midline septum of the falx.

of consciousness, concussion, contusion, or laceration of the brain are produced by one mechanism, namely displacement and distortion of the cerebral tissues occurring at the moment of impact.

The brain is not a perfect fit within its membranes ; it is capable of a degree of antero-posterior riding movement within the spaces of the cerebrospinal fluid in which it is suspended by slings formed by the superior cerebral veins (fig. 413). Lateral displacement of the brain inside the skull is restricted by the midline septum of the falx (fig. 414).

Blows on the front or back of the head lead to the maximum displacement of the brain, with proportionately severe cerebral injuries, the cerebral hemispheres being displaced in relation to the brain stem and hypothalamic region; in this displacement one hemisphere may be distorted in relation to the other, with the resulting stretch and strain on the junctional tissues of the

commissures and corpus callosum. Laterally directed blows severe enough to fracture the skull cause less cerebral displacement, and therefore less associated diffuse injury of the brain.

The lines of force set up by cerebral distortion act chiefly upon the region of the third ventricle and hypothalmus and brain stem (figs. 415 and 416).

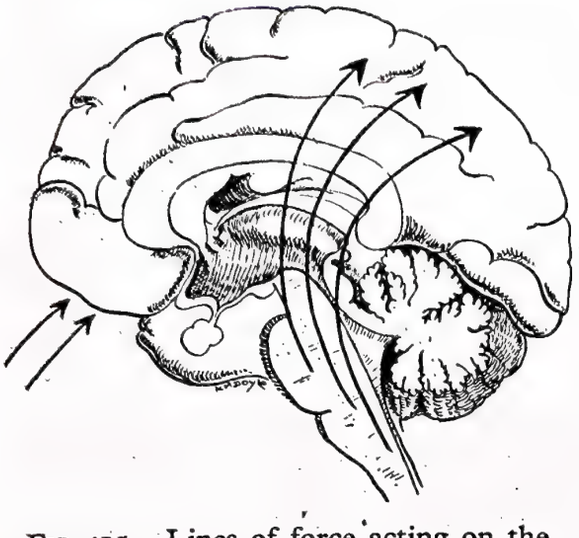

FIG. 415.—Lines of force acting on the hypothalamus and brain stem as the result of posterior displacement of the hemisphere.

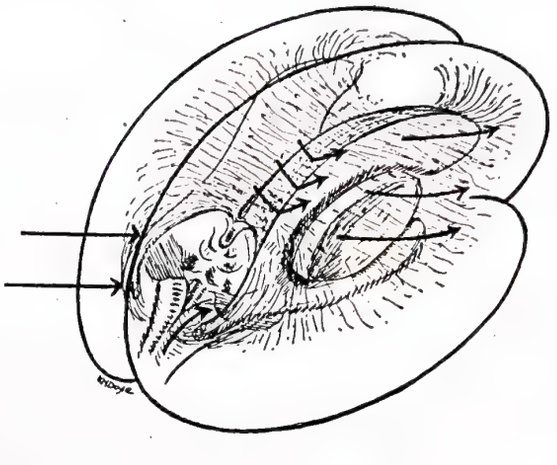

FIG. 416.—Lines of force acting on the corpus callosum and one peduncle as the result of anterior displacement of one hemisphere.

The severity of these forces is such that in deaths from boxing injuries, the medulla may be torn across. It is difficult to understand how stretch exerted upon the brain stem can disturb consciousness, unless it is realised that consciousness is not maintained exclusively by the cerebral cortex, but is also maintained by the basal areas and hypothalmus. After removal of both cerebral hemispheres at a level immediately above the thalamus (Goltz's dog experiment), an animal is deprived of all volition, but it can stand, and will respond to any stimulus by a show of violent and uncontrolled rage, a reaction which is curiously similar to that seen in post-traumatic delirium following brain injury. Since imperfect consciousness is maintained following a lesion at this level in the brain, it follows that for consciousness to be completely lost, a lower level of the brain stem must be affected, and patients are, in fact, rendered completely unconscious by the effect of distortion acting upon the brain stem and affecting ascending stimuli which maintain the central excitatory state of the cortex. The most serious injuries are those which affect the brain stem to the greatest degree.

In all cases the instantaneous loss of consciousness which occurs at the moment of injury, whether short or long lasting, is produced by paralysis of conduction in the brain stem following distortion, and this occurs quite independently of any change in intracranial pressure whatsoever.

The clinical terms which are used to describe brain injury, concussion, contusion, and laceration of the brain merely indicate minor and major degrees of this process and do not imply any individual difference in pathology.

Friedrich Leopold Goltz, 1834–1902. Professor of Physiology, Halle, Germany

In cerebral concussion the stretch is slight. There is a brief temporary physiological paralysis of function without organic structural damage, which results in a transient loss of consciousness, followed by complete recovery.

In cerebral contusion the stretch is severe. There is rupture of fibres producing multiple lesions at various levels of maximum stress (see below). Unconsciousness is more prolonged, the initial recovery is imperfect, or death may result from the effects of the lesion on the vital areas of the brain stem acting independently of any change in intracranial pressure ; indeed, many fatal cases die with an abnormally low intracranial pressure.

In severe cases of cerebral contusion there is an additional sliding movement of the grey matter in relation to the white, with damage to nerve cells and axons. Degeneration following rupture of axons accounts for the post-contusional state associated with defective memory and personality change in patients who survive.

Histological Changes.—In fatal cases there may be no visible surface injury, but section reveals rupture and degeneration of axons and pyknosis of nerve cells. Ring hæmorrhages produced by bleeding into the perivascular spaces of Robin-Virchow are produced by rupture of vessels at the points of maximum stress in the region of the commissures, corpus callosum, and deeply in the third ventricle and substantia nigra in the brain stem. Cloudy swelling is seen in the choroid plexuses, and results in reduction of cerebrospinal fluid formation and the low intracranial pressure found in many fatal cases.

In cerebral laceration the internal changes are the same as those seen in contusion, but the brain surface is torn, with effusion of blood into the cerebrospinal fluid owing to laceration against bony ridges and the edges of dural septa during brain displacement. Lacerations are common on the inner aspect of the hemisphere against the falx, on the under aspect of the frontal lobe, and tip of the temporal lobe, the latter producing traumatic anosmia. They are less common at the occipital poles, producing blindness or hemianopia. Frequently surface injuries are situated at a point diametrically opposite the site of of impact (*contre-coup*), and are produced by displacement of the brain.

Clinical Features.—*Cerebral concussion* produces either a momentary loss of consciousness or a short period of unconsciousness and cerebral shock of minutes only, which is then followed by a complete and perfect recovery with no residual signs. No treatment is required other than rest and analgesics for headache, provided that there is no associated evidence of skull fracture (p. 414).

Cerebral contusion is diagnosed when unconsciousness is prolonged, if the patient recovers to a state of imperfect consciousness, such as confusion, irritability, or delirium, or if physical signs of focal damage are revealed on examination. During the initial period of unconsciousness the patient is pale, with shallow respiration, the pulse is increased in rate and feeble. The temperature is subnormal, musculature is relaxed, and the reflexes are diminished. Following this state of cerebral shock, which is also seen for a short while in concussion, a phase of reaction develops, the respirations

Charles Filippe Robin, 1821–1885. Professor of Histology, Faculty of Medicine, Paris.
Rudolf Ludwig Karl Virchow, 1821–1902. Professor of Pathological Anatomy at Wurzburg (1851–1858) and Berlin (1858–1902).

become deeper, the pulse increases in tension and the face becomes flushed. On recovery of consciousness patients complain of headache or photophobia and often vomit and exhibit confusion, irritability, or delirium, indicating damage to the cortical or hypothalamic levels of the brain.

In cerebral irritation the body assumes a position of flexion, the patient curls up in bed with knees drawn up and arms flexed and interference of any kind is resisted verbally or physically. In serious cases of brain stem injury deep coma persists from the moment of injury and decerebrate rigidity develops. Dilated and inactive pupils, Cheyne Stokes' respiration and irregular pulse are serious prognostic signs. On recovery marked slurring of speech and gross ataxia may persist, polyuria and polydypsia are also occasionally observed.

In contusion of the hemispheres physical signs such as anosmia, aphasia, or hemianopia, may be detected on recovery of consciousness but not before. If the brain surface is lacerated the patient may suffer from stiff neck, pain in the legs, and retention of urine due to the irritation of blood in the cerebrospinal fluid. Retrograde amnesia involving loss of memory for events prior to the accident and post traumatic amnesia vary in duration according to the severity of the injury. In cerebral contusion post traumatic amnesia continues for many hours or days after apparent recovery of consciousness has been observed.

Secondary pathological changes leading to a rise in intracranial pressure occur at an interval after injury and include:

(*a*) Local swelling in the region of surface bruises or severe œdema in infarcted areas of the brain whose blood supply has been cut off by thrombosis or rupture.

(*b*) Retention of fluid in the lateral ventricles from blockage of the cisterns and arachnoid granulations by effused blood, with defective absorption of cerebrospinal fluid.

(*c*) Massive intracranial hæmorrhage, extradural, subdural, or intracerebral.

These additional factors may produce a fatal cerebral compression in a patient whose neuronal injury could otherwise have been survived.

Analysis of the mortality of head injury shows that deaths in the early stages are usually produced by the effect of the neuronal lesion alone representing an immediate mortality which is irreducible, but that in deaths occurring after twenty-four hours there are many cases of unrecognised cerebral compression.

The treatment of closed head injury consists of:

(1) Immediate clinical examination to determine the severity of the neuronal lesion and establish a base line for observation.

(2) Nursing care to counteract the effects of the neuronal lesion by posture, attention to airway, nasal feeding, and catheterisation when required.

(3) Continuous observation to detect the onset of œdema or intracranial hæmorrhage and the necessary measures to deal with these complications (p. 404).

(4) The treatment of skull fracture, and its complications, if present (p. 414).

John Cheyne, 1777–1836, and William Stokes, 1804–1878. *See footnote, p. 95.*

Clinical Examination.—The head is examined for evidence of surface bruising or fracture. An X-ray of the skull is essential in all cases from the medico-legal aspect, if not from the clinical. The neck is tested for stiffness. Cervical spinal injury may be present in head injury. The central nervous system is examined in so far as the state of consciousness permits. Particular attention is paid to the level of consciousness, the duration of unconsciousness, the size, equality, and reaction of the pupils, the movement or paralysis of either side of the body. *Physical signs are carefully noted, so that the subsequent appearance of new signs can be checked.*

Nursing Care.—The patient must be placed in a position where regular observation can be maintained by the nursing staff. Seclusion in a dark room is only justified in a patient who has recovered consciousness and complains of photophobia (abnormal sensitivity to light).

Posture.—Unconscious patients are nursed on their side so that secretions drain from the mouth. Patients may drown in their own secretion, become cyanosed, and deeply unconscious if allowed to remain on their backs (this may be fatal during transport over long distances). Careful attention is given to the airway to be sure the tongue is not swallowed. If the patient is bubbling, the throat must be cleared by suction. The patient is turned regularly. Physiotherapy and postural drainage in Coleman's position for an hour at a time help to prevent pneumonia supervening (fig. 417). *Tracheostomy* is required to keep the airway clear in cases of brain stem lesion when reflexes are lost and unconsciousness is prolonged.

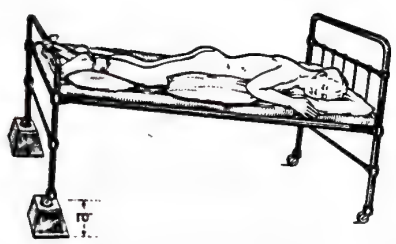

FIG. 417.—Coleman's postural drainage for the unconscious. The position is maintained by pillows, and bandages anchor the ankles to the foot of the bed.

The delirious patient should not be forcibly restrained; restraint provokes aggression. A cot bed covered with netting beneath which the patient may move at will is the best solution.

The conscious patient should be propped up or lie flat, according to which relieves his high- or low-pressure headache.

Elderly patients with chest injuries or complications must be treated propped up.

Catheterisation is performed if necessary; a full bladder induces restlessness.

Nasal tube feeding is required if unconsciousness is prolonged.

Continuous observation includes a half-hourly record of the pulse and regular observation of the state of consciousness, of the size and reaction of the pupils, and the power of movement on the two sides of the body.

Progressive slowing of the pulse and deterioration of consciousness from co-operation to confusion, to stupor, to coma, indicates cerebral compression, probably due to œdema or hæmorrhage.

A deterioration of consciousness, with the *appearance of new localising signs*—e.g. pupil changes or paralysis occurring at an interval after injury *—indicates focal compression by hæmorrhage* and should be regarded as an

Claude C. Coleman, 1879–1953. Professor of Neurological Surgery, Richmond, Virginia.

absolute indication for immediate burr-hole exploration, at the site indicated.

In doubtful cases where the patient is deteriorating and there are no new signs, lumbar puncture, echo-encephalography, and arteriography may be needed to establish the cause.

Lumbar Puncture is helpful as a diagnostic measure to determine the pressure by manometry and to establish whether pressure is abnormally high or abnormally low. Raised pressure with crystal clear fluid is strongly suggestive of hæmorrhage outside the membranes, for in cerebral contusion the fluid is usually slightly blood stained and the pressure high. In serious brain stem lesions the pressure is often abnormally low. If focal hæmorrhage can be excluded a phase of compression due to secondary œdema is treated by dehydration therapy. Dehydration will remove that part of the syndrome produced by secondary compression but the effect on the level of consciousness will not to be to return the patient to normality but to return him to the level permitted by the underlying neuronal lesion, thus a patient originally confused and disorientated who became stuporose and comatose will return to a state of confusion.

Dehydration Therapy. An increase in the osmotic tension of the blood diminishes cerebrospinal fluid formation at the ventricles, and increases absorption at the lacunæ, with reduction of intracranial pressure. 50 ml. of 50% sucrose may be given slowly i.v. 4 times in 24 hours; the effect lasts 6 hours. Mannitol, 1 g. per kg. body weight may be given as a drip slowly or fast according to the effect required. For rapid administration in a cerebral tumour, the dose may be given in ½ hour. In head injuries it may be given in the course of one to two hours and repeated if necessary. These measures should not be continued for longer than 3 days owing to the risk of altering the sodium-potassium balance by prolonged dehydration (p. 77).

The diuretic action of urea may be used for dehydration in patients whose renal function is normal. Increased concentration of urea in glomerular filtrate hinders reabsorption of fluid at the renal tubules and therefore diuresis results. A 30% solution in 10% invert sugar should be freshly prepared. Stored samples must not be used after ten days storage at 2–5°C. The solution is given slowly at not more than 60 drops per minute, which is sufficient to lower intracranial pressure markedly within 20 minutes. The method is useful in the treatment of head injuries when the patient is stuporose or comatose, when the lumbar pressure is known to be high and large clots have been excluded. It is also of value in reducing intracranial pressure at craniotomy, and relieving comatose patients suffering from intracranial tumour in whom the improvement resulting from lowering pressure may secure co-operation at examination or facilitate transport to a suitable hospital. Despite its advantages the method increases the bleeding experienced at operation from the scalp, the epidural vessels, and cortical vessels, owing to the increase in blood-pressure, and for this reason excessively rapid administration must be avoided. Dexamethazone is mainly of value in the treatment of brain tumours (q.v.). It is only of value in head injury when extensive œdema occurs in infarcted areas. 4 mg. may be given 6-hourly.

Hyperventilation of unconscious patients will lower intracranial pressure by reducing cerebral blood flow by elimination of the vasodilator effect of CO_2. Circulation in injured areas is relatively greater owing to the local vasodilator effects of the products of injury.

Therapeutic lumbar puncture on alternate days is employed to remove 4 or 5 ml. of the most heavily bloodstained fluid in cases of cerebral laceration with gross extravasation.

Special measures are required in cases of serious brain stem injury. The combined use of tracheostomy, intravenous aminophylline, and hypothermia, reduce some of the mortality from serious brain stem lesions. *Intravenous aminophylline*, 250 mg. intravenously, by its vaso-dilator action improves the

blood supply in cases of brain stem ischæmia and can relieve Cheyne-Stokes respiration. The respiration is also improved by dilatation of the bronchi.

Hypothermia.—The survival of serious brain stem lesions may be prolonged by the induction of hypothermia by the use of ice bags, regular cold sponging, and ice blankets. This serves not only to diminish the rise in temperature or hyperthermia, often seen in brain stem lesions, but also by diminishing the oxygen requirements of damaged tissue, improves the prognosis.

Drugs.—The fewer and the simpler, the better. Paraldehyde is required to control restless cases. Bromide should not be used, particularly in the elderly, as this is liable to provoke delirium.

Conscious patients require little more than aspirin for headache and, occasionally, barbiturates for insomnia.

Convalescence.—Minor contusions recover speedily, but in serious cases prolonged convalescence is needed. Account should be taken of the severity of the injury as measured by the duration of the post-traumatic amnesia; also the mental make-up of the patient and the amount of concentration associated with his occupation, in assessing the duration of convalescence. Usually some symptoms of the post contusional state consisting of headache, giddiness, defective memory, defective concentration, irritability, impaired emotional control, impaired sleep, or susceptibility to alcohol, persist for a period of eighteen months. In severe cases localising signs and symptoms indicate multiple lesions at various levels. Post-traumatic dementia constitutes a permanent handicap sometimes necessitating institutional care. Schizophrenia is a rare complication of even a minor injury.

Cerebral Compression.—The detection and treatment of lesions producing cerebral compression is the most important factor in reducing the mortality from head injuries. Cerebral compression gives rise to progressive deterioration in level of consciousness, slowing of pulse and slowing of respiration with or without, the appearance of new localising signs. Acute brain swelling and œdema in areas of infarction around contusions may produce urgent compression in patients who have already sustained a serious cerebral contusion. In such cases compression may occur without new localising signs and is treated by dehydration. Syndromes of traumatic intracranial hæmorrhage require urgent surgical intervention and may arise in patients who have only sustained an initial minor concussion followed by a period of recovery of consciousness after which the patient becomes drowsy and lapses again into unconsciousness with the appearance of new localising signs.

An unconscious footballer was carried off the field but later recovered sufficiently to finish the match; headache and drowsiness supervened so that he retired to bed early and was later found dead from middle meningeal hæmorrhage. Similar tragedies have occurred at school from cricket or on the links from golf balls.

The majority of cases of middle meningeal hæmorrhage are due to an injury associated with fracture of the temporal bone, bleeding from this

fracture line causes an extracranial extravasation producing boggy swelling deep to the temporal muscle, therefore all cases of even minor concussion must be under observation for 24 hours if there is any bruising in the temporal fossa. Focal compression produced by a clot is usually accompanied by the appearance of new localising signs produced by the local pressure.

When syndromes of hæmatoma formation develop in patients already deeply unconscious as the result of cerebral contrusion a lucid period is absent and the collection of the hæmorrhage can only be recognised by determining the alteration in the level of consciousness and the appearance of the new localising signs (pp. 409, 410).

A deterioration in the level of consciousness, with the appearance of new localising signs not observed at the original examination, must always be taken as an absolute indication for exploration of the area indicated by the localising signs. The formation of a burr hole opening under local anæsthesia is sometimes the only method of recognising or excluding a dangerous complication. Similar signs are occasionally produced by œdema spreading from adjacent bruises; but this cause should never be assumed until the possibility of hæmorrhage has been disproved. If acute compression should develop and there are no localising signs but a fracture is present, a burr hole must be made in the region of the fracture in case extradural bleeding has occurred from the bone. Even in the absence of signs or fractures, a progressive deterioration in consciousness, drowsiness, headache, and slowing of the pulse, is always an indication for urgent investigation. If available, an *ultrasonogram* is valuable, an echo-encephalogram will indicate a shift of the mid-line structures and suggest the presence of a unilateral expanding lesion.

Carotid arteriography may often demonstrate the site of the lesion:

1. By displacement of the cortical vessels away from the inner table of the skull in subdural hæmatoma.

2. By inward displacement of the middle cerebral artery and displacement of the anterior cerebral across the middle line in extradural hæmorrhage.

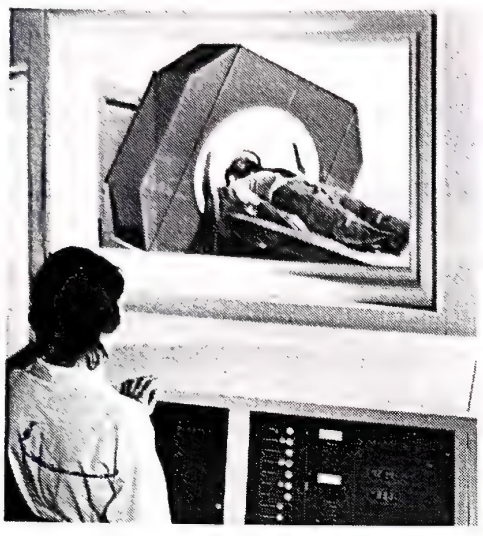
3. By upward displacement of the middle cerebral artery in œdema or subcortical bleeding in the temporal lobe or a subdural subtemporal hæmatoma.

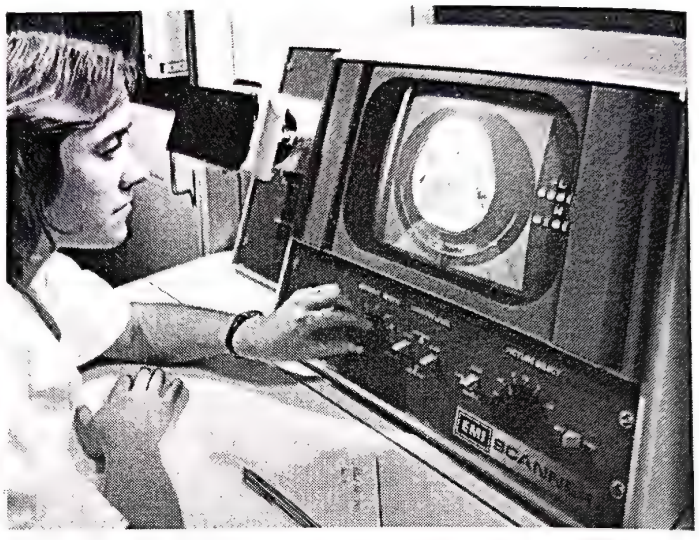
4. By transverse displacement of the anterior cerebral in acute swelling or subcortical hæmatoma in the frontal lobe. Only very rarely is compression due to an extensive area of indriven bone and in these cases evidence of compression is likely to follow immediately after the injury has occurred.

CT scanning of the brain (E.M.I. scan[1]) has revolutionised the investigation of head injury, intracranial hæmorrhage and infarction, and space occupying lesions. When available it displaces the use of arteriography and air study. The investigation causes no disturbance to the patient and eliminates exposure to conventional X-ray investigations.

[1] EMI-Scanner is manufactured by EMI Medical Ltd., 248 Blyth Road, Hayes, Middlesex, England. CT = Computerised transverse axial Tomography.

The patient lies on a motorised couch in order that the part to be examined can be positioned within the scanning gantry (fig. 418). The head is scanned from above downwards in a series of transversing planes like a tomograph from vertex to base of skull by tilting the X-ray tube and detector array within the gantry at each scan.





FIGS. 418 and 419.—The EMI Brain Scanner. Utilizing the technique of computerised tomography originated in 1968 in EMI's Central Research Laboratories, this scanner is specifically designed to give optimum results in an entirely non-invasive neuroradiological investigation. It is the only technique currently available for examination of the soft tissues of the brain and can clearly demonstrate the difference in density of grey and white matter.

The information is fed to a computer and produces a record in which high density objects such as bone, clot or tumour appear white, the brain substance appears grey, areas of œdema a dark mottled colour and the ventricular fluids black. Collectively the scanner produces a complete picture in which tumours, clots, infarction, ventricular displacement or hydrocephalus are readily distinguished (fig. 419).

Traumatic intracranial hæmorrhage is of three types: (1) Subcortical; (2) Extradural; (3) Subdural.

Subcortical hæmorrhage is produced by arterial bleeding either extending from an area of surface laceration or produced by rupture of a central artery. The bleeding may terminate rapidly and fatally by rupturing into the ventricles, causing hyperthermia and death by *intraventricular hæmorrhage*; it may, however, form a clot under the cortex.

Clinical features combine evidence of cerebral compression and epileptic fits. In the frontal lobe—cerebral compression associated with generalised epileptic fits and few signs. In the temporal lobe—cerebral compression, fits, and hemiparesis. Similar syndromes are sometimes produced by swelling of infarcted areas of the lobe following surface contusion without clot formation. Symptoms of clot formation are usually observed within the first twenty-four hours after the injury, or the onset may be delayed for

a further ten days if the artery ruptures late as a result of softening near a surface bruise (delayed apoplexy). Old clots may simulate a cerebral tumour months after the injury.

Treatment.—Arteriography may be required to localise the site of the lesion. Fluid blood may be aspirated through a ventricular cannula. Solid clots may be evacuated or removed by suction after exposure of the cortex through a small osteoplastic flap or a large trephine opening. Areas of acute brain swelling and œdema resulting from infarction are treated by local decompression and removal of softened areas by suction. Pre- and post-operative use of urea (p. 405) will reduce the need for removal of softened tissue.

Extradural Hæmorrhage of Arterial Origin.—Extradural hæmorrhage of arterial origin may arise from branches of the *internal maxillary* or *anterior meningeal* vessels torn by fractures of the anterior fossa. In such cases a deterioration in level of consciousness occurs in association with an antero-basal fracture, but usually there are no accompanying localising signs.

The classical syndrome of extradural hæmorrhage results from injuries of the anterior or posterior branches of the *middle meningeal artery*. In such cases the injuring force, which comes from a lateral direction, is often relatively trivial, such as a blow from a golf or cricket ball which strikes the thin bone of the temporal plate, inflicting a fracture which drives the dura inwards and in the case of anterior branch bleeding, snaps the meningeal artery at a point where it leaves the bony canal in the pterion and crosses to gain attachment to the dura mater. In the elastic skull of children the injury may occur without fracture, but in all adults, comprising 90 per cent. of cases, X-ray reveals a fracture line crossing the middle meningeal groove.

The detection of this fracture is an absolute indication for the admission of the patient for observation.

From the torn vessel blood passes in three directions:

(1) Outwards through the fracture to form a boggy swelling under the temporal muscle, the finding of which is an additional indication for the *admission for observation of a conscious patient*.

(2) Downwards into the middle fossa.

(3) Upwards over the motor cortex.

Clinical Features.—Usually a laterally directed blow of small magnitude causes a short initial period of concussion, followed by a characteristic **lucid interval**,[1] during which the hæmorrhage is collecting intracranially and also forming a superficial swelling under the temporal muscle. The importance of this sign cannot be overestimated, and one may frequently forecast the development of the complication on the basis of this sign alone. The next change is in the level of consciousness. The patient becomes confused and irritable, and at this stage is in danger of being arrested if found wandering and smelling of alcohol; therefore, beware of the patient brought

[1] When the complication develops in a patient who never recovers consciousness, it would be detected only by clinical signs.

to Casualty in a confused state with a bruise in the temporal region. Persons alleged to be found drunk have been locked in cells only to be found dead in the morning, the unconsciousness and stertorous breathing of compression being mistaken for a drunken stupor. Confusion changes to drowsiness, and at this stage pressure of the clot on the motor cortex produces cerebral anoxia, causing twitching, followed by paralysis of the face, then the arm, then the leg, on the opposite side of the body as the clot spreads upwards over the motor cortex. At the same time inward displacement of the temporal lobe causes the inner portion of the lobe to press against the third nerve above the edge of the tentorium (fig. 420(B)), causing restriction, rapidly followed by dilatation of the pupil on the side of the hæmorrhage. If the pressure is not relieved, displacement of the brain stem at the tentorial opening forces the opposite crus against the rim of the tentorium, producing further hemiplegia, which this time occurs on the side of the hæmorrhage (fig. 420(A)).

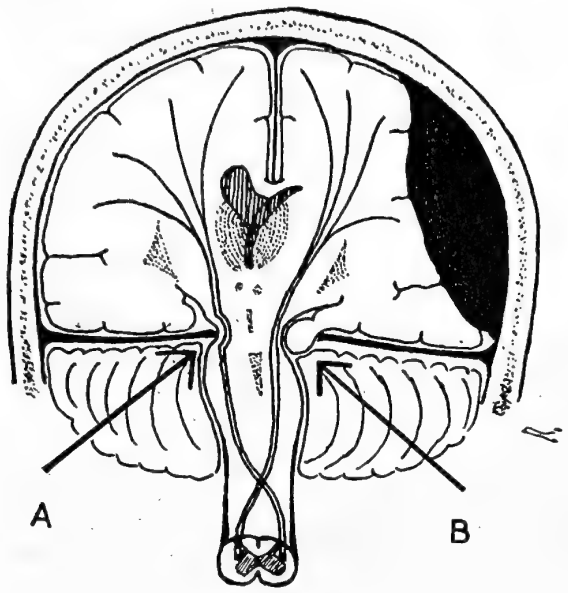


FIG. 420.—(A) Impaction of the opposite crus against the opposite rim of the tentorial opening. (B) Displacement of the inner edge of the temporal lobe (uncus) descending into the tentorial opening (mid-brain cone). (*G. B. Northcroft, F.R.C.S., London.*)

Finally, impaction of a mid-brain cone produces decerebrate rigidity and fixed dilatation of *both* pupils, at which stage the case is probably too late to remedy by operation.

In the presence of these confusing signs, the side of operation is determined by :

(*a*) The side of bruising in the temporal muscle.
(*b*) The side of skull fracture.
(*c*) The side of the initial dilatation of the pupil.

Posterior branch bleeding is less than one fifth as common. Here the clot is situated at a distance from the motor cortex, the surface bruising is situated farther back, or there may be a steady arterial hæmorrhage from the ear when the fracture line involves the middle ear. The level of consciousness deteriorates, and the patient passes into a stage of cerebral irritation or stupor with a dilated pupil from pressure inwards on the third nerve, but there may be no motor paralysis for several days, or the paralysis appears on the same side of the body as the hæmorrhage as the result of brain shift and impaction of the contralateral crus. The site of operation is determined by the site of the fracture, surface bruising, and dilatation of the pupil.

Treatment is an urgent matter. Patients may stop breathing within half to one hour of the onset of the first sign; therefore the dangers of transport must be assessed carefully. If possible, operation should be performed in the hospital where the complication is recognised, especially if the case is deteriorating rapidly. If the site of the hæmorrhage is definitely established,

half the head may be shaved. If there is any doubt or the possibility that an alternative exploration for a subdural hæmatoma may be required, the whole head should be shaved, as subdural hæmatomas are often bilateral.

A low temporal osteoplastic flap gives an excellent exposure of all branches and is far the best method of approach. Alternatively a craniectomy is performed through a curved hook incision (fig. 421 (*A*)) centred on a point 5 cm behind the eye and 5 cm above the zygoma which corresponds primarily to the anterior branch of

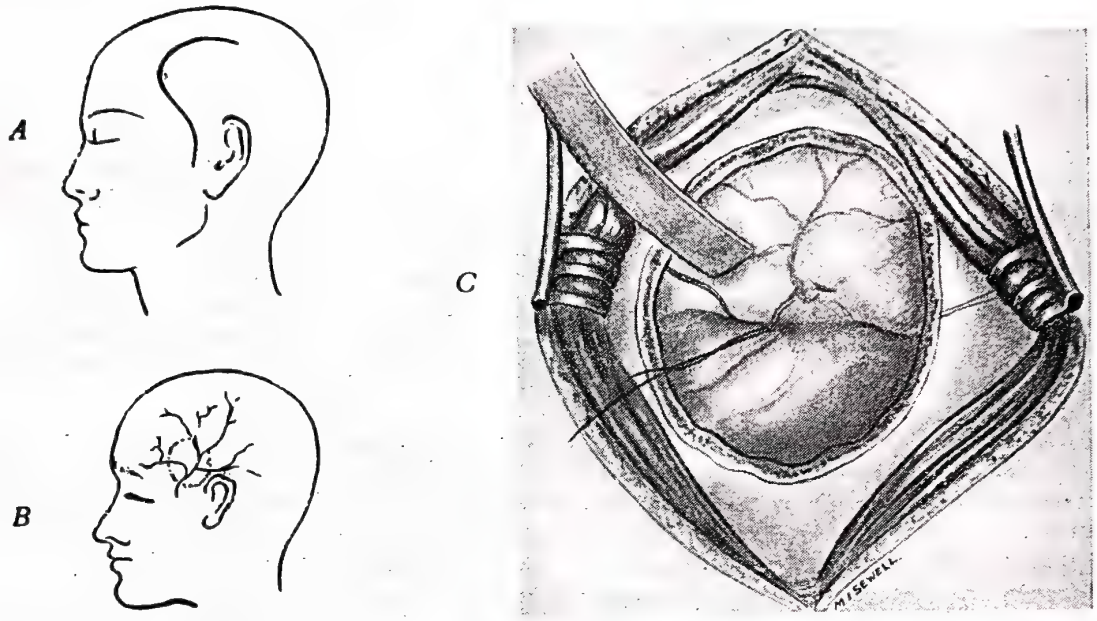

FIG. 421.—(*A*) Curved hook incision used to expose artery. (*B*) Position of bone opening. (*C*) Exposure of artery which is underrun by a dural stitch.

the artery. On division of the temporal muscle blood clots should be found between the muscle and the fracture line. If there is no fracture one should suspect an error in diagnosis and the compression will probably be found to be due to subdural hæmatoma. Normally, a burr hole is made beside the fracture and the skull is opened, the bone opening being enlarged with nibbling forceps as required. The bleeding point may be seen lying on the dura (fig. 421 (*C*)) and may be secured by underrunning with a fine curved needle or coagulated with diathermy. If the torn vessel is bleeding from the bony canal, the bone is plugged with Horsley's bone wax which stops the hæmorrhage. Alternatively, blood may continue to trickle in from the back of the opening, indicating that the posterior branch has been involved, and the bone excision must be extended in this direction until the bleeding-point is found. Occasionally an artery is ruptured near the foramen spinosum, where it must be arrested with diathermy. When the artery has been secured, bleeding continues from veins in the margins of the compression area if the dura has been seriously displaced. Venous bleeding is controlled by placing muscle, fibrin foam, or Oxycel over the bleeding-points and stitching the dura back firmly against the skull. Troublesome capillary oozing may continue from the dura, and it is often wise to drain for the first twenty-four hours.

Post-operative Treatment.—The patient should be kept lying flat in order to encourage the brain to re-expand. If the level of consciousness does not improve rapidly and the patient shows signs of persistent coning with dilated pupil, a diagnostic lumbar puncture should be performed. If the pressure is abnormally low, sterile saline should be injected intrathecally in order to raise the pressure to the normal level of 120 mm of cerebrospinal fluid or slightly above, and so produce a free rise and fall on jugular compression. This may necessitate an injection of 90 or 100 ml. of saline; when successful it will occasionally relieve cone formation and result in rapid restoration of consciousness. It probably does so by floating the brain stem up into its normal position, thus straightening the vessels supplying the stem.

Sir Victor Alexander Haden Horsley, 1857–1916. Surgeon, University College Hospital, London.

Extradural hæmorrhage of venous origin is produced by fractures which injure the major sinuses. Injury of the superior longitudinal sinus produces a massive subgaleal hæmatoma, together with evidence of clot compression, causing deterioration of consciousness with generalised epilepsy if the clot lies over the frontal areas, or unilateral or bilateral leg weakness with extensor plantar responses if the clot is over the upper end of one or both motor cortices.

Extradural hæmorrhage of the posterior fossa is produced by injury to the transverse sinus. Surface bruising appears behind the ear. There is a deterioration of consciousness occurring at an interval of days after the injury. Signs of cerebellar compression are few; often there is merely a reduction of tone and reduction of reflexes on the side of compression.

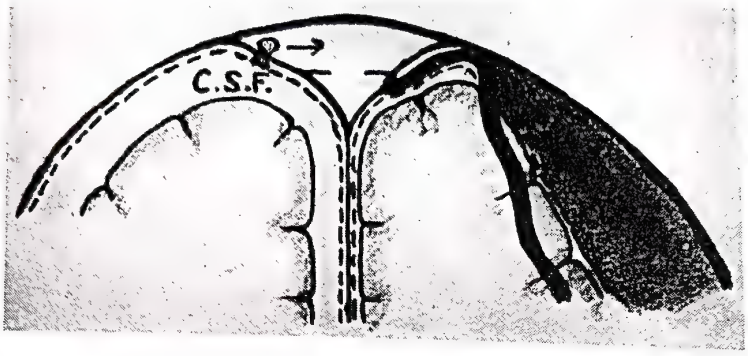

FIG. 422.—Position of a subdural hæmatoma produced by tearing of the superior cerebral veins at the level of the arachnoid. The diagram also shows the partial or occasionally complete septum which divides the superior sinus. Cerebrospinal fluid drains into the upper compartment through the arachnoid granulations. The superior cerebral veins drain into the lower. (*G. B. Northcroft, F.R.C.S., London.*)

Treatment.—Clots of this type are evacuated after elevation of the causative fracture, hæmorrhage from the sinus is arrested by holding a muscle graft firmly against the aperture whilst it is secured by an overlying letter-'N' stitch.

Subdural hæmorrhage is produced by rupture of the veins passing from the cerebral hemispheres to the venous sinuses as the result of displacement of the brain inside the skull. Usually the superior cerebral veins are ruptured, producing hæmorrhage over the convexity of the hemispheres; very rarely veins passing from the temporal lobe to the sphenoid or petrosal sinuses may produce clots which collect on the under-aspect of the brain. This complication, which is potentially fatal, is at least six times as common as middle meningeal hæmorrhage and is produced particularly by blows of small magnitude applied to the front or back of the head which may be insufficient to produce even transient concussion, but which are sufficient to move the brain suddenly. Cerebral atrophy renders this displacement easier, and hence the condition becomes commoner with advancing age. The superior cerebral veins pass from the convexity of the hemispheres and pierce the arachnoid membrane before crossing the potential subdural space to join the inner aspect of the dura 2·5 cm or more from the middle line; they then run inwards to drain into the lower compartment of the superior longitudinal sinus.

One end of the vein is fixed to the dura, the other to the mobile hemisphere. Sudden displacement may snap the vein at the level of the arachnoid, allowing blood to pass downwards into the potential subdural space between the arachnoid and dura. Frequently, corresponding veins on both sides are affected and the condition is bilateral in 50 per cent. of cases. The hæmatomas are often large, bilateral collections up to 60 ml. a side or unilateral collections of 120 ml. being quite usual.

In the acute form the clots produce symptoms of cerebral compression within hours or days of the injury; in the chronic form not until months after the injury. The normal pressure in the superior cerebral veins is extremely low; hence venous bleeding by itself could never compress the brain and overcome arterial pressure without one of the following additional factors. Vomiting after injury may force blood out at a high pressure and account for the acute onset of pressure occurring in a period of hours. In the subacute or chronic cases, the pressure increases as a result of the osmotic traction of the blood in the subdural space drawing fluid from the cerebrospinal fluid system through the semipermeable arachnoid, so that the cyst increases steadily in size and produces compression symptoms in days or months after the injury.

Clinical Features.—The symptoms may follow a preceding concussion, but owing to the slight nature of the force required to produce displacement, this complication may occur without preceding loss of consciousness and without the head being even struck. It can follow a sudden jolt, as when a driver is thrown against the steering-wheel of a car, or be produced by knocking the head against the lintel of a door, or landing heavily on the feet when jumping from a height; it has followed dental extraction and electroconvulsive therapy.

In the acute form developing within hours the onset of coma, hemiplegia, and dilated pupil readily attracts attention and simulates an extradural hæmorrhage without appropriate evidence of skull fracture. In subacute or chronic syndromes however, the symptoms are undramatic and consist of (1) Headache which is unduly severe or unduly prolonged, following a blow on the front or back of the head. (2) Cerebral anoxia, causing mental apathy, slowing of cerebration, slowness of response to questions merging into stupor. (3) When the stupor develops, it comes and goes as the brain volume varies, the patient being inaccessible at times and then rousing sufficiently to answer questions accurately, but very slowly and after a considerable pause. When this phase passes on to coma as the result of the formation of a mid-brain pressure cone, the operative mortality rises from nil to 30 per cent.; hence the significance of these early symptoms.

Physical signs vary. Acute compression may cause hemiplegia in young subjects. In older patients, where more room is available and if the cyst collects slowly, there may be no signs, or at most a unilateral or bilateral extensor plantar response from pressure on the motor cortex or brain-stem displacement. Pupillary changes occur last when the brain stem is affected and pressure-cone formation is imminent. Lumbar puncture shows a fluid at low pressure with protein increased to 120 mg/100 ml (1·2 g/l), often stained yellow from the transudation of pigment, but no cells. Papillœdema is exceptional. Success in treatment comes from acting on suspicion and employing arteriography, or the formation of exploratory burr holes in any suspicious case in which excessive headache or stupor follows upon an appropriate injury without waiting for physical signs which may never develop or may only develop later when the patient has a potentially fatal pressure cone.

Treatment.—Bi-parietal burr holes are made under local anæsthesia to expose the dura, which is often stained blue-green from the blood pigment. On incising the dura, black tarry blood is removed by suction through a soft rubber catheter (fig. 423), which should be passed downwards and also

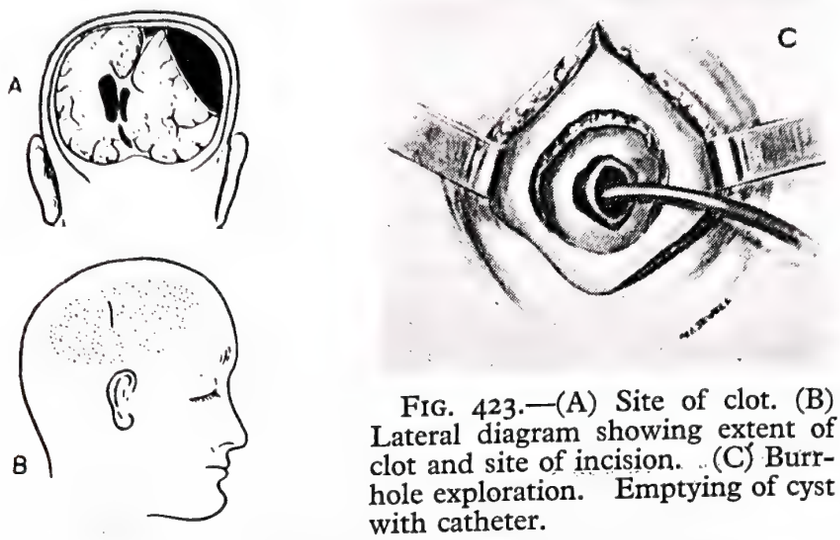

FIG. 423.—(A) Site of clot. (B) Lateral diagram showing extent of clot and site of incision. (C) Burr-hole exploration. Emptying of cyst with catheter.

backwards in the subdural space. If the blood is thick, bi-frontal burr holes are fashioned and the subdural space is washed through with saline. Solid clots must be removed by craniotomy. The results are excellent if the operation is performed before a mid-brain cone develops.

Post-operatively, the patient is nursed with the head low in order to encourage expansion of the brain. Repeat X-rays show absorption of air from the subdural space. Rarely, repeat of the puncture is required if the brain is not expanding or if symptoms persist, indicating that the clot has only been partially evacuated.

FRACTURES OF THE SKULL

Mechanism.—Fractures of the vault and base of the skull are produced: (1) by compression of the sphere; (2) by local indentation; (3) by tangential injury. These mechanisms vary, not only in their local effect upon the skull, but also in the severity of the cerebral injury that accompanies the fracture. The mechanism can be visualised when interpreting the skull X-rays.

Fractures of the vault produced by compression of the sphere are the commonest skull fractures, and result from distortion of the skull when it comes into contact with a hard flat surface. Usually closed linear fissures are produced which, although not important in themselves, are often associated with severe diffuse cerebral injury resulting from brain displacement occurring at the moment of impact. Contact with a flat surface renders the spherical skull more ovoid. The fracture line starts at the points of maximum convexity thus produced and spreads through thin areas of bone, being deflected at an obtuse angle from the bony buttresses of the temporal and occipital crests towards the base of the skull; hence many fractures of the base are produced by the extension of fissures starting in the vault.

Fractures of the vault produced by local indentation give rise to closed or compound depressed fractures according to the surface area of the injuring agent.

Blows from large rounded objects produce *closed pond depressed fractures*; the scalp is bruised but remains intact. The skull fractures at the points of maximum convexity; it is dented but not indriven, the underlying dura remaining intact. The brain surface is bruised under the intact dura, but not penetrated. This bruising may cause local signs, such as paralysis or aphasia. Healing occurs by absorption of the tips of damaged convolutions forming a shallow erosion on the brain surface, surrounded by a zone of reactive gliosis. The risk of epilepsy is about 4 per cent. (fig. 424).

Blows from small round objects produce *compound* depressed fractures. The scalp is irregularly torn by the indentation. The fractured bone is depressed, lacerating both the dura and subjacent brain. Fragments of bone may separate from the inner table and lodge in the brain. There is immediate risk of infection, and a later risk of epilepsy resulting from the contracting fibrous scar through the open dura, which increases the incidence of epilepsy to 25 per cent. in untreated cases (fig. 425).

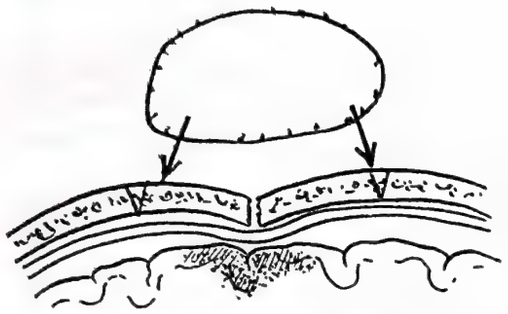

FIG. 424.—Pond fracture produced by large round object.

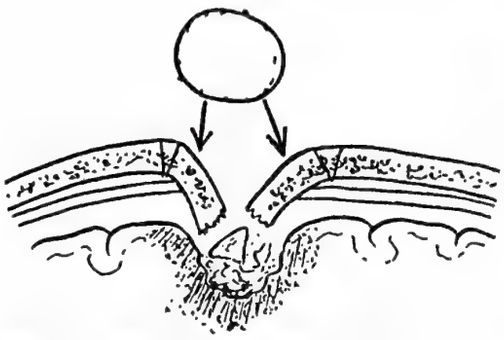

FIG. 425.—Compound fracture produced by small round object.

Fractures of the Vault by Tangential Injury.—Tangentially directed violence may secure a grip on the skull and prise up large segments of bone, which are elevated leaving the dura intact.

When a window cleaner, falling to earth, catches his brow on a window ledge, the vault of the skull can lift like a lid of a coffee pot, a horse-shoe fracture surrounding the calvarium. Such injuries are compound and the skull X-ray is alarming, but there may be little or no associated cerebral injury, as the injuring force was not directed on to the brain. In one case the swinging door of a railway wagon, striking above the right ear, prised up both frontal plates and the frontal sinuses which were hinged laterally on the left temporal muscle, but the patient was unconscious for only half an hour.

Treatment of fissured fractures of the vault is governed by the degree of associated injury to the brain. A careful watch is maintained for evidence of cerebral compression, indicative of bleeding from the fracture line.

Closed depressed fractures of the vault are rare. The scalp is relatively non-elastic and an injury sufficient to fracture and depress the bone is almost certain to lacerate the scalp. Hæmatomas in the scalp sometimes simulate depressed fractures. Clotted blood in the margin of a hæmatoma may, on palpation, resemble the edge of a fractured zone (fig. 426) but the edge of the clot can sometimes be indented, often X-ray is required to distinguish the two conditions.

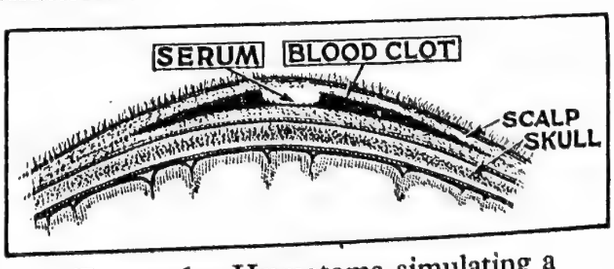

FIG. 426.—Hæmatoma simulating a depressed fracture.

The **treatment** of a closed depressed fracture depends on the extent and site of the depression. Operation is not indicated if the fracture is small provided that there are no sharp spicules of bone which have penetrated the dura (fig. 427) and the fracture does not overlie an important cerebral area. Surgical intervention is required if the fracture lies over the speech or motor areas, or if the X-ray suggests that spicules may have penetrated the dura mater, when scarring may cause adhesions between the brain and membranes, with risk of subsequent epilepsy (p. 420).

Operation.—Merely to trephine and elevate the depressed bone is quite inadequate in this case as a proper examination of the brain and membranes is not possible. An osteoplastic flap, which includes the fracture, is raised, and the depressed bone is either moulded into position or removed with suitable forceps. The dura is examined, penetrating spicules are removed, and the membrane is then opened. Pulped brain is carefully removed by gentle suction at the site of penetration. Adhesions are separated. Hæmostasis is secured and the dura is carefully sutured, if necessary a fascial graft being inserted to prevent the ingrowth of fibrous tissue. The flap is then replaced and the wound closed.

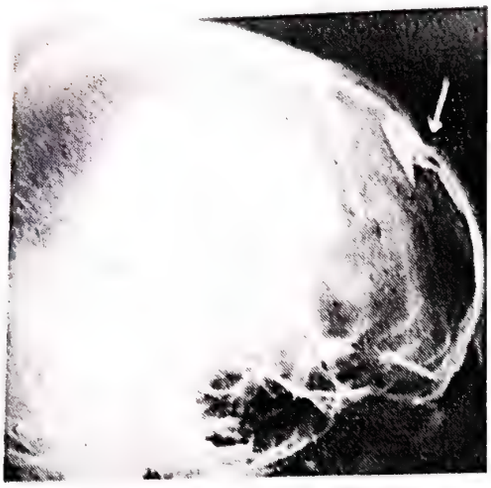

FIG. 427.—Sharp bone spicules penetrating the dura.

Pond-shaped depressions occur in infants, as a result of prolonged pressure of the head against the promontory during birth, or of direct injury during the first few months of life. Spontaneous elevation usually occurs within a few weeks. Early elevation is required if an extensive depression overlies the speech or motor areas or if there are signs of compression. Operation is also indicated if a depression anterior to the hair line constitutes a cosmetic deformity which does not undergo a spontaneous elevation within six weeks. As the formation of an osteoplastic flap would lead to extensive damage to the extremely thin dura of an infant, a simple elevation is performed by means of a guarded gimlet, i.e. silk is wound around the gimlet to within 6 mm. of its point. A small incision is made over the centre of the depression, and the skull is perforated by the gimlet. An aneurysm needle is introduced through the aperture, and by this means traction is applied to the depressed bone. The elastic skull of the infant readily yields and springs back to its normal position.

Compound fractures of the vault vary in severity, from severe crushes, with the escape of cerebral substance, to relatively insignificant compound fissured fractures. High-speed motor-cycle accidents produce the worst examples of severe frontal crushes, many are rapidly fatal. Severe cases which survive exhibit serious disability, such as hemiplegia or mental deterioration from loss of cerebral substance. The incidence of these injuries has been reduced by the wearing of crash helmets.

When the velocity of impact is low, large compound depressions can occur with less diffuse cerebral injury, particularly when produced by blows from the side—in which the midline septum of the falx will limit the associated brain displacement.

Rarely, if the skull is fixed at the moment of impact, as when the head is trapped against the edge of a kerb, the skull may be crushed, with injury to cranial nerves, without any loss of consciousness at all, because the brain is not suddenly displaced.

Clinical Features.—An irregular lacerated wound of the scalp is associated with a boggy subgaleal swelling produced by blood escaping from the fracture line, which is partly exposed in the depth of the wound. A normal suture line should never be mistaken for a fissured fracture, for a suture line is irregular and free from oozing blood. All scalp wounds should be explored adequately in order to exclude or discover a fracture. In compound depressed fractures the fracture lines extend far laterally beyond the

limits of the surface wound (fig. 428), and this must be allowed for in planning the requisite exploration.

Treatment.—Operation should be undertaken as soon as possible to avoid infection unless the patient's condition is so precarious that delay is advisable, in which case antibiotics should be given in full doses.

Pre-operative X-ray is essential to determine the extent of the fracture.

The head is shaved well beyond the margins of the fracture.

Unconscious patients may be operated upon under local anæsthesia.

In frontal fractures severe bleeding from the nose must be cleared by suction.

The field of operation is infiltrated with 1:100,000 adrenalin in saline to diminish scalp bleeding. Small compound fissure fractures may be exposed by extending the primary scalp wound after excision of its edges. Extensive depressions are exposed by forming a horseshoe scalp flap around the margins of the fracture site after previous excision and suture of the scalp wound (fig. 429). A burr hole is formed beside the fracture to permit unlocking of the fractured particles (fig. 430). Bone which has been contaminated by dirt is discarded. Clean bone is preserved. The dura is inspected. If intact, it is not opened. If penetrated, indriven material and damaged brain tissue are removed by suction and the dura is then sutured. Clean portions of bone may now be moulded into place, the wound being then sutured and antibiotic treatment commenced. Careful judgement is required concerning the discarding of bone. If a tangential injury has lifted up large areas of the vault, the frontal plates, or roof of the orbit, far beyond any *exposed wound*, it is only necessary to remove contaminated areas in the wound. Removal of the entire detached area of bone would produce enormous unsightly deformities which could not be adequately repaired.

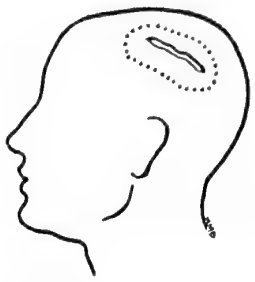

FIG. 428.—Relative extent of the fractured area (shown by dotted line) in comparison with the surface wound.

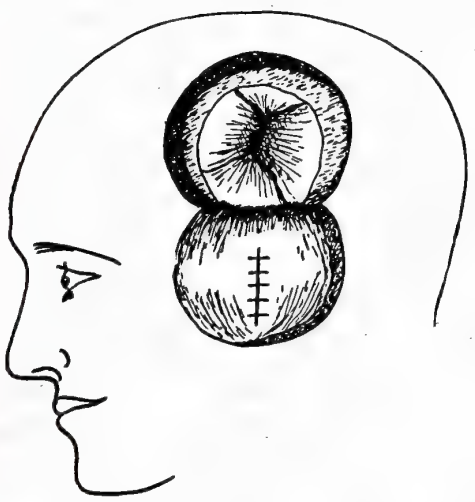

FIG. 429.—Exposure of depressed compound fracture. The original scalp wound has been sutured and a horseshoe scalp flap reflected to expose the full extent of the fracture. (*G. B. Northcroft, F.R.C.S., London.*)

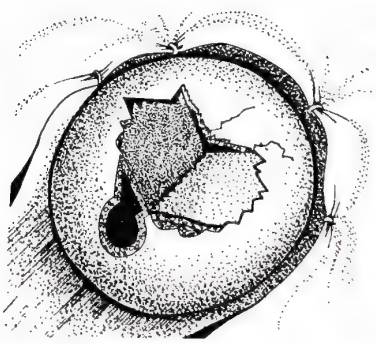

FIG. 430.—Formation of burr hole beside a fractured area to allow unlocking of the bone fragment.

Compound fractures of the frontal sinus become infected from the nose; hence the sinus must be obliterated. After excision of depressed bone and removal of the mucous lining a pressure pad is applied over the site to cause the scalp to sink into the depression resulting from excision of the sinus and to close the cavity by adherence to the dura. Three months later the sinus area is exposed by turning a scalp flap forward, the scalp is freed from the dura, and the deformity is restored by skull reconstruction.

Skull Reconstruction.—Areas of skull defect are restored at intervals of three to six months after injury, by the insertion of moulded tantalum plates or acrylic inlays. Slow setting acrylic powder and monomer when mixed together form a plastic dough which gradually hardens to form a sheet having the consistency of rubber. Within thirty minutes this may be cut to shape and inserted to fill a bone defect over an intact dura. Adaptation to the local curvature of the dura produces a perfect reconstruction of the skull outline when the acrylic hardens *in situ* during the following twenty-four hours. Concealed horseshoe or transverse incisions within the hair line are used for these purposes.

Head Wounds due to Missiles.—The outcome depends on the explosive impact of the missile in the cranium, which is the commonest cause of fatality, and the relation of the wound track to the great vessels and the ventricles. Through-and-through tracks, from side to side or front to back, may be survived. Survivable injuries can be transported to a suitable hospital. Projection of the swollen brain through the dura at the site of entry or exit forms a hernia cerebri, which seals off the subarachnoid space during transport (fig. 431). A pressure dressing is applied.

Operative treatment consists of the excision of the surface wound and suction, cleansing, and removal of foreign material from the track. The dura is closed by suture or grafting at entry and exit points. Intrathecal penicillin treatment will then prevent serious infection unless an infected track crosses the ventricles or median fissures (see also p. 423).

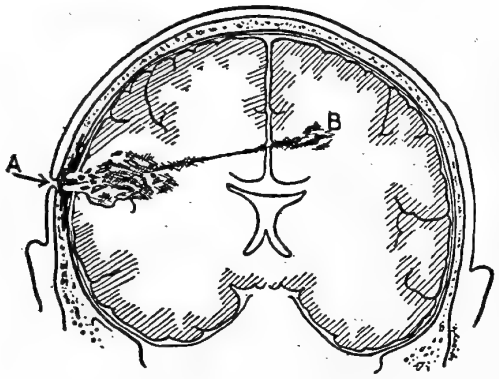

FIG. 431.—Transverse penetrating wound, entry at (A) showing: (1) Protrusion of brain through the dura at entry site forming hernia cerebri. (2) Pulped brain and bone close to entry. (3) A metal fragment at (B) has crossed the open superior fissure.

Penetrating wounds produced by sticks are always to be regarded very seriously. Although scissors or pokers may enter the roof of the orbit when a child falls and thereafter be successfully withdrawn, a stick which goes in through the orbital roof, or backwards behind the orbit into the temporal lobe, cannot be withdrawn intact; portions which are left behind may, from previous contact with the ground, be infected with gas gangrene or tetanus, with probable fatal infection.

Fractures of the base of the skull are usually produced by compression of the sphere and extension of fissures radiating from the vault. The complex fracture lines thus produced are accounted for by deflection of the fissure from the buttresses of the petrous bones, the basi-sphenoid, and the sphenoid wings, which can only be crossed respectively at the weak points formed by the cavities of the middle ear, the sphenoidal air sinus, and the sphenoidal fissure. Elsewhere the fracture lines tend to wander into the foramina for the exit of cranial nerves. The fractures become compound at the middle ear, accessory air sinuses, and the cribriform plates, but the evil reputation of fractures of the base is derived from the severe brain injury accompanying the fracture rather than from the risk of sepsis, which has been greatly reduced by modern methods of treatment.

Fractures of the Base by Local Indentation.—A ring fracture sometimes forms around the foramen magnum from the upward impact of the spinal column in fatal head-on collisions. Violence transmitted from the maxilla to the internal angular process may rotate the cribriform plate upwards on to its side, with laceration of the anterior fossa dura, a common cause of cerebrospinal rhinorrhœa in association with injuries of the middle third of the face. Rarely, the roof of the orbit may be penetrated by direct violence from sticks, umbrella ferrules, scissors, or similar objects.

Fractures of the Base produced by Tangential Injury.—The mastoid process is sometimes knocked off by an oblique blow, e.g. from the edge of a kerb; this is a very painful but relatively harmless lesion.

Clinical Features.—The essential features are:

(1) The escape of cranial contents, i.e. blood, or cerebrospinal fluid, or rarely, brain.

(2) Injury to cranial nerves. All cranial nerves may be involved but the twelfth is rarely affected. As the condyloid foramen is protected by a stout ridge of bone, the fracture line is usually diverted into the foramen magnum. Laceration of nerves in fracture lines produces an immediate paralysis which will not recover. Compression of nerves by blood clot produces paralysis which, after a period of a few days, usually recovers. Paralysis occurring after a period of weeks is produced by contraction of scar tissue or callus and will not recover.

ANTERIOR FOSSA FRACTURES

(1) **Escape of Cranial Contents.**—Epistaxis occurs if the cribriform plate is involved. Should the fracture extend into the orbit, an effusion of blood follows. This is distinguished from a ' black eye ' by the following features:

(*a*) The skin round the orbit is not damaged.

(*b*) The orbital effusion occurs some hours after the injury.

(*c*) The eye is sometimes pushed forwards, as the extravasation occurs into the tissues at the back of the orbit.

(*d*) This extravasation impedes the action of ocular muscles, and movements of the eyeball are limited.

(*e*) Should subconjunctival hæmorrhage follow, the patch is wedge-shaped with the apex in front, and the posterior limit cannot be seen.

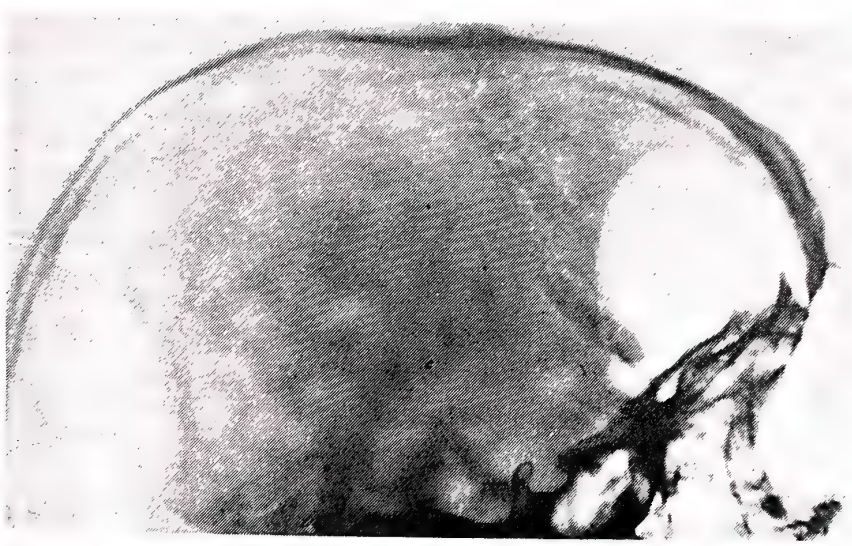

FIG. 432.—Intracranial ærocœle collecting in the frontal lobe from a fracture involving the posterior wall of the frontal sinus.

Cerebrospinal fluid trickles through the cribriform plate, often in surprising quantities, a condition referred to as ' traumatic rhinorrhœa '.

Traumatic rhinorrhœa may persist for several weeks. Air may enter the cranial cavity producing an **intracranial ærocœle** (fig. 432). In view of the risk of meningitis, operative closure is indicated, the torn dura being sealed with a patch of fascia lata.

Injury to Nerves.—The olfactory nerve is frequently torn, but unless its fellow is also damaged, the partial anosmia is likely to pass unrecognised. The optic nerve usually escapes, but if it is contused, any loss of vision will be permanent. The

third, fourth, first division of the fifth, and sixth nerves may be involved at the sphenoidal fissure. Third nerve palsy produces a dilated pupil in a conscious patient.

MIDDLE FOSSA FRACTURES

Escape of Cranial Contents.—Epistaxis occurs if the fracture involves the nasal sinuses.

Escape of cerebrospinal fluid and blood from the ear is common. Blood from torn tympanic membrane will clot, but when blood continues to drip for days, it is because it will not clot, owing to mixture with cerebrospinal fluid.

Serious arterial hæmorrhage from the ear may follow injury to the posterior branch of the middle meningeal artery (p. 410).

Injury to Nerves.—The facial nerve is commonly injured at the time of the accident. Usually the nerve is torn and facial paralysis is permanent. Occasionally paralysis occurs at an interval of a few days after injury from compression by blood clot. Recovery is to be anticipated if the facial muscles are supported and treated by electrical therapy. If paralysis develops some weeks after the injury, it is produced by pressure from fibrous tissue or callus, and the paralysis will be permanent. The eighth nerve is sometimes injured, with resulting deafness. The sixth nerve is occasionally implicated, with resulting internal strabismus.

POSTERIOR FOSSA FRACTURES

Escape of Cranial Contents.—Extravasation of blood in the suboccipital region produces a boggy swelling at the nape of the neck, or discoloration posterior to the mastoid process.

Injuries to Nerves.—The ninth, tenth, and eleventh nerves are occasionally damaged at the jugular foramen, but the hypoglossal nerve usually escapes, as it is protected by a bony buttress.

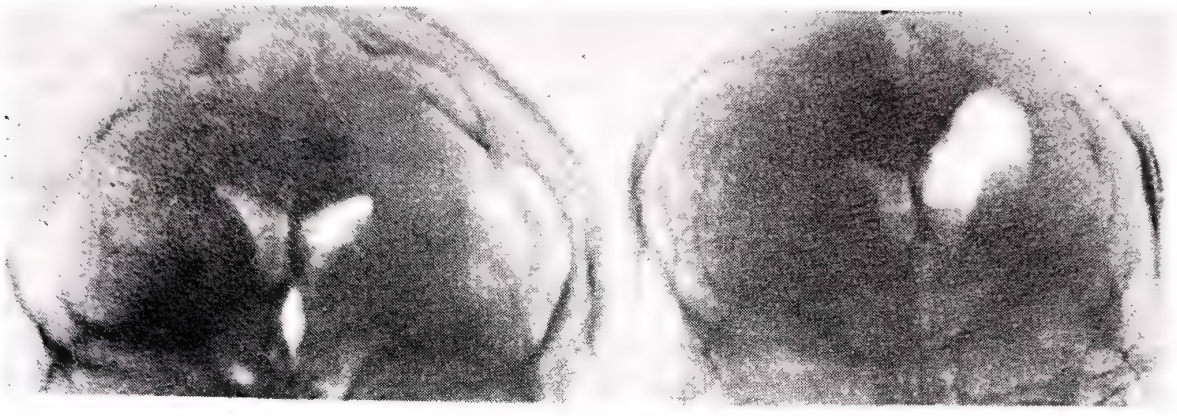
Treatment of a fractured base is that of the associated brain injury. The patient is propped up to lower pressure and diminish the escape of cerebrospinal fluid. Antibiotics are administered. If the discharge persists undiminished for ten days, fascial repair of the dural gap is required. The skull is X-rayed to see if an intracranial ærocoele has developed in association with cerebrospinal rhinorrhœa. Air collections may be observed either in the substance of the frontal lobe or in the subarachnoid space, occasionally filling the ventricle. Sepsis does not occur at first because the upper respiratory air cells are sterile, but later, septic granulation tissue forms outside the dura, and the moment the discharge of cerebrospinal fluid stops, meningitis arises from this source; hence an early repair is necessary.

LATE EFFECTS OF HEAD INJURY

Post traumatic headache is not always cerebral in origin. Referred pain of spinal origin resulting from associated strains in upper cervical joints may be referred through the great occipital and posterior auricular nerves to the vertex, forehead, or temple. This pain is increased by neck flexion, and since the neck is flexed during reading or writing, the pain may appear to be a post-traumatic headache which is made worse by mental concentration. Examination, however, reveals tenderness over the upper interspinous ligaments and great occipital nerves. Many cases respond well to local treatment by injection of local anæsthesia or occipital neurectomy. The post-contusional state with vertigo, defective memory and concentration, abnormal fatigue, irritability, and defective emotional control may result from temporary or permanent damage to neurons.

Post-traumatic epilepsy is of three types. (i) Symptomatic fits may occur in the first 24 hours or thereabouts from the effect of bruising and œdema in the brain and never recur after the bruising has subsided.

(ii) True post-traumatic epilepsy is produced by the formation of contracting fibrous scar tissue in the brain, or between the brain and the membranes (p. 415). Scar formation takes time to develop and the fits occur within six months to twenty-one years from the date of an injury which has been severe enough to lead to penetration of the dura mater or laceration of blood-vessels on the brain surface, thus allowing fibrous tissue to mingle with the normal gliosis of brain healing and so produce a contracting scar. (iii) When fits occur within days or weeks of a minor injury, they may be produced by activation of a latent idiopathic epilepsy which becomes evident for the first time following injury. This may be distinguished by finding gross bilateral abnormalities on electro-encephalography. In true post-traumatic epilepsy, the electroencephalogram is either normal or shows a focal lesion.



A B

FIG. 433.—(A) Normal air encephalogram. (B) Traction on and expansion of the lateral ventricles following injury. This lesion is too diffuse for excision.

Clinically, post-traumatic epilepsy may be Jacksonian in type. Attacks of uncontrollable twitching occur commonly in the hand or thumb, spreading progressively to other muscle groups and the arm and shoulder and face before consciousness is lost and the convulsion becomes generalised. Alternatively, focal lesions in the frontal lobes cause generalised convulsions exactly like idiopathic epilepsy. In other areas a typical aura precedes a generalised fit (p. 431). Recurrent temporal lobe epilepsy may give rise to recurrent explosive outbursts of violent behaviour in the post-traumatic syndrome.

Treatment: investigation by air encephalography shows whether the scar is focal or too diffuse to be excised (fig. 433). If a focal scar is present, the ventricle is drawn out to a fine point or spike at the site of contraction. Surgical treatment consists of the excision of the scar in the membranes of the brain down to the wall of the ventricle and the repair of the dura by fascial grafting or insertion of nylon membrane to prevent more fibrous tissue growing in from the surface (fig. 434).

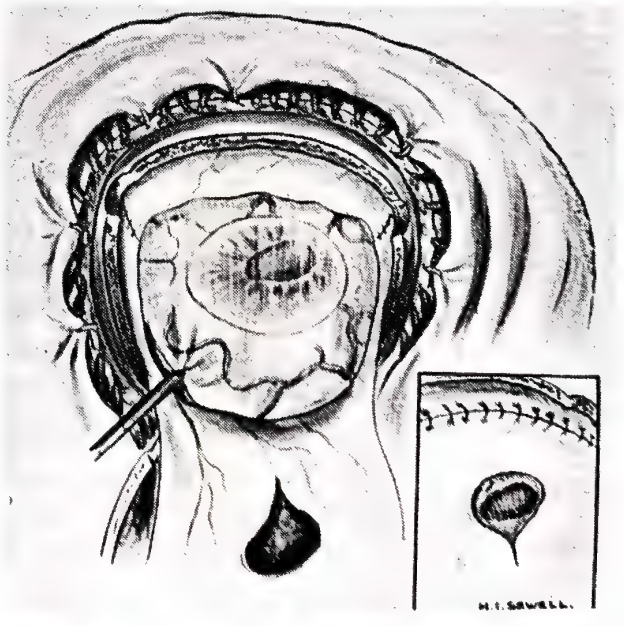


FIG. 434.—Operation sketch showing area of scar excised and insertion of nylon membrane.

Post-Traumatic Hydrocephalus.—Late deterioration with apathy and mental retardation may rarely be caused by post-traumatic hydrocephalus requiring the insertion of a ventricular shunt (see p. 444).

John Hughlings Jackson, 1835–1911. Physician to the London Hospital. Described unilateral epilepsy in 1863.

INFLAMMATORY CONDITIONS

Acute infective meningitis may result from implantation of infection in infected wounds and compound fractures, from local extension from adjacent disease of the ear, or sinuses, from the various types of intracranial abscess, or be blood borne from distant foci of infection, such as staphylococcal infection in acute osteomyelitis or pneumococcal infection following pneumonia. The condition is ushered in by headache and vomiting. Severe constitutional symptoms follow, and if meninges over the convexity are affected, convulsions, delirium, and photophobia are in evidence. Should the base of the brain be chiefly involved, head retraction, papillœdema, and implication of cranial nerves are the main features. Lumbar puncture is performed in order to clinch the diagnosis and to identify the causative organism.

Treatment consists in dealing with any causative lesion, e.g. an infected middle ear. Lumbar puncture and intrathecal penicillin administered daily (10,000 units) are valuable. Larger doses or more frequent injections are apt to cause complications, such as fits or retention of urine. Chemotherapy and antibiotics are administered according to the causative organism. The cerebrospinal fluid is examined regularly for cells and organisms. Intrathecal and systemic treatment is continued for at least ten days after the infection has subsided in order to sterilise outlying loculi and prevent relapses.

INTRACRANIAL ABSCESS

Intracranial abscess is of three types. (1) Extradural. (2) Subdural. (3) Intracerebral.

The first two varieties require immediate drainage to prevent infection of the subarachnoid space. Intracerebral abscess however must be allowed to localise. Hasty intervention in the acute stage will spread infection towards the ventricles.

Extradural abscess is produced by osteomyelitis of the skull (p. 398 for causes), and is usually secondary to spread from infection from the middle ear or frontal sinus. In the case of the middle ear, infection most commonly reaches the extradural space by extending through the tegmen tympani. Following frontal sinusitis, a large collection may form behind the frontal bone, infection having passed through the posterior wall of the sinus. Spread in the diploic veins may carry the infection to bone areas an inch or more above the ear or frontal sinus and cause local sequestration.

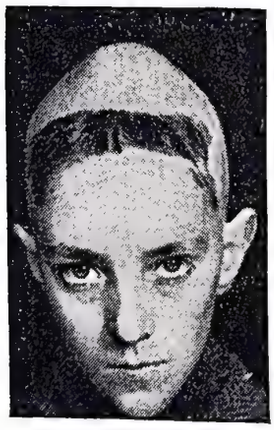

FIG. 435.—Pott's puffy tumour. *(The late Professor Lambert Rogers, F.R.C.S., Cardiff.)*

Clinical features are those of osteomyelitis. Acute localised pain, acute localised tenderness, and swelling occur as in the long bones, but in the skull these are represented by acute localised headache, tenderness on local percussion of the skull, and localised pitting œdema of the scalp over the affected area, as described by Percivall Pott and known as Pott's puffy tumour (fig. 435). There is a variable constitutional disturbance. These symptoms and signs alone demand urgent exploration. Only rarely, if the abscess is large, will there be evidence of pressure or focal neurological signs.

Treatment consists of drainage, the approach depending on the cause of the abscess. Many cases are dealt with by removal of the posterior wall of the frontal sinus or tegmen tympani during the course of an operation for

Percival Pott, 1714–1788. Surgeon, St. Bartholomew's Hospital, London. Described this condition in 1760.

frontal sinusitis or mastoiditis. Alternatively, a burr-hole opening is made at the site of the œdema. The dura is pressed slightly inwards to allow pus to escape. Twenty or 30 ml. may be removed by suction. Penicillin powder is insufflated and the wound drained for twenty-four hours. Antibiotic treatment serves to sterilise the bone infection.

Subdural Abscess.—This condition, at one time invariably fatal, can now be treated with a 30 per cent. mortality. It is produced by septic thrombophlebitis of the superior longitudinal sinus, spreading usually from infections of the frontal sinus or accessory air cells. Infection extends from the superior sinus to the superior cerebral veins, and thus infects the subdural space. The abscess extends in this space over the cerebral hemispheres, often bilaterally, and must be treated before it spreads to the inner or under aspects of the hemispheres. Successful treatment depends on early recognition and intervention.

Clinical features are distinguished by marked toxæmia or dehydration and the development of intracranial pressure, epilepsy, and paralysis within a matter of days. Following a heavy ' cold ' or ' influenza ', the patient runs a high pyæmic temperature, becoming sallow and dehydrated with wrinkled skin. Blockage of the superior compartment of the superior sinus (see fig. 422) into which cerebrospinal fluid is absorbed from the lateral lacunæ produces raised intracranial pressure with headache and later papillœdema. Blockage of the lower compartment receiving the superior cerebral veins may cause epilepsy and paralysis of sudden onset as additional features.

Treatment.—Bilateral frontal burr holes are made just within the hair line above the temporal crest. On opening the dura, thin pus is found in the subdural space and is allowed to escape. A fine catheter is now introduced to instil antibiotics into the space. Systemic treatment is given in full doses.

Intracerebral Abscess.—Success in treatment is determined far more by the pathological type of the abscess than by the method of treatment adopted. Some abscesses rapidly spread to infect the ventricle; others localise readily, becoming walled off, and pass into the favourable subacute or chronic stages.

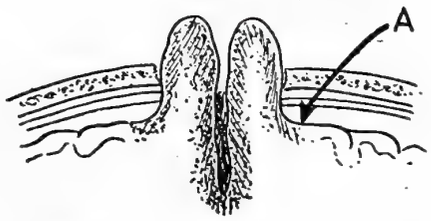

FIG. 436.—Protrusion of a hernia cerebri through a penetration of the dura, closing the subarachnoid space at A.

Intracerebral abscesses are produced by (1) implantation of infection; (2) by blood metastasis; and (3) by local extension of adjacent infection.

Implantation abscesses result from penetrating wounds and have, as a rule, a low mortality, except in the case of wounds from sticks (p. 418). The infecting organisms are normally derived from the skin surface and are of low virulence. The entry track is closed at the dural level by protrusion of a hernia cerebri, which seals the subarachnoid space and provides a pathway for the extension of the infection to the surface away from the ventricles (fig. 436).

Clinical features may consist of pyrexia and the progressive extrusion of a hernia cerebri during the acute stage following a penetrated wound, but many abscesses pass insidiously into a chronic stage and merely produce a discharging sinus, or evidence of an intracranial space-occupying lesion at the site of a wound years after

injury. Pietro de Marchettis, a monk in Padua, treated such cases successfully by the insertion of lampwick drains in 1665.

Treatment.—In the acute stage the track is explored from the surface, bone and foreign material are removed, and pus is evacuated by repeated aspiration or tube drainage. Antibiotic treatment is given freely. Chronic abscesses may be excised intact.

Metastatic abscess is a complication of lung abscess or bronchiectasis of pyæmic states and was at one time uniformly fatal. Infected clot from the lung passes to the left heart, thence via the carotid, usually into the middle cerebral circulation, which forms a direct continuation of the carotid syphon; hence the infection is implanted deep in the white matter of the parietal or temporal lobe close to the ventricle. The blood supply of the brain is poor in the white matter, but rich in the cortex ; tissue reaction is therefore feeble, and the septic encephalitis spreads rapidly and produces fatal septic ventriculitis within a matter of days.

Clinical Features.—The patient with a causative disease is seized with sudden headache, collapse, and pyrexia, and rapidly develops well-marked localising signs. Hemiplegia, hemianæsthesia, or hemianopia indicate widespread destruction of the white matter.

Treatment.—Under modern conditions antibiotic treatment may cause the infection to localise. After a few days an exploratory burr hole and cerebral puncture is made in case suppuration has occurred. If so, pus is aspirated and antibiotics are instilled. Further treatment is continued, as in the case of local extension abscesses. The average mortality is now approximately 30 per cent.

Local extension abscesses are produced by septic thrombosis spreading from foci of infection in the ear or frontal sinuses. Usually three out of five abscesses arising from the ear are situated in the corresponding temporal lobe; the others are in the cerebellum. Frontal lobe abscesses are usually on the same side as the infected frontal sinus.

Very rarely, aberrant abscesses may occur, for example, contralateral frontal abscesses produced by infection crossing the superior sinus, or frontal or parietal abscesses from ear disease. The site of implantation may be (*a*) subpial, or (*b*) subcortical.

Subpial Abscess.—The infection is conveyed as far as the cortex only. A minute abscess forms, which is covered on its surface only by the pia mater. This invariably ruptures into the subarachnoid space, producing meningitis without focal signs. It is probable that most cases of meningitis complicating ear or sinus disease are produced in this way ; hence the need for prolonged antibiotic and intrathecal therapy to sterilise the subpial abscess and prevent relapse.

Subcortical Abscess.—The infection is conveyed across the unobliterated subarachnoid space to lodge in the white matter beneath the cortex. Three stages may be recognised—acute, subacute, and chronic.

In the acute stage there is septic encephalitis without pus formation. This may extend to produce ventriculitis or localise to form an abscess.

The subacute stage commences at three weeks by the formation of a glial wall, the thickness of which is determined by the local blood supply and is therefore thickest towards the cortex and thinnest towards the ventricle. A unilocular or multilocular cavity is produced, containing active organisms. The wall becomes thick within six weeks and infecting organisms die, staphylococci living the longest. The pus gradually becomes sterile and extremely thick, at which stage the abscess is inert.

Clinical Features.—*In the diagnosis of intracerebral abscess, general features are more important than focal signs, which are few in number and of late onset.*

In the acute stage, persistent pyrexia and headache are the most important features and should lead to the suspicion of an abscess when seen in association with ear or sinus disease. The temperature and pulse-rate are raised at the commencement, but as the abscess enlarges, so intracranial pressure

Pietro de Marchettis, 1589–1673. Professor of Surgery, Padua, Italy.

rises also, with slowing of the pulse. Leucocytosis is present, but its significance must be discounted if some other active condition is also present. Headache, irritability, drowsiness, and vomiting are commonly in evidence. These symptoms demand investigation by lumbar puncture, which will show an increase in cells and a protein figure raised from the normal 40 mg/100 ml (0·4 g/l) to approximately 80 mg/100 ml (0·8 g/l).

Acute fulminating syndromes are rarely seen under antibiotic treatment. Many cases are undoubtedly sterilised and the abscess aborted at the acute stage of septic encephalitis without pus formation, as the result of the administration of antibiotics in the treatment of the primary focus of infection from which an abscess has extended. Focal signs are often absent in the acute stage except where there is extensive cortical thrombosis.

In the subacute stage the temperature and pulse often fall to a subnormal level and physical signs appear—these are few in number.

In frontal lobe abscess—a contralateral facial weakness only.

In temporal lobe abscess—a contralateral hemiparesis with absent abdominal reflexes and an extensor plantar response.

In cerebellar abscess—nystagmus, hypotonus, and inco-ordination on the side of the lesion.

Lumbar puncture shows a reduction in number of cells but increase in the protein figure to 120 mg/100 ml (1·2 g/l).

In the chronic stage intermittent headaches and ill health persist with pallor and cachexia. There may be no physical signs. The cerebrospinal fluid may return to normal, but the abscess continues to enlarge and gradually uses up available adaptation within the skull and then, when no more space is available, suddenly produces urgent pressure symptoms. The patient may then develop severe headaches and exhibit evidence of a threatened midbrain core with a dilated pupil, within a period of days, or even several years after the initial infection.

Often the symptoms and physical signs of a chronic abscess develop immediately or within a day after operation has been performed on the ear or frontal sinus for the relief of a chronic headache—in these cases operation reveals an abscess with thick walls. Clearly a subacute or chronic abscess was present at the time that the operation was performed, and was itself the cause of the head pain for which the operation had been conducted. The local disturbance of the operation causes a reaction in the abscess cavity, and stimulates the early post-operative onset of physical signs. It is important to realise that the presence of well-marked localising signs developing within a period of days usually indicates re-activation of a chronic abscess requiring immediate treatment.

In every case of suspected cerebral abscess it is important to examine all possible sources of infection. In many cases the probable cause is evident, but discharge from an ear may cease when intracranial complications develop, for hindrance to discharge by inspissated pus predisposes to the extension of infection.

Treatment.—Drainage, formerly the recognised method of treatment has, in the majority of cases, been replaced by repeated aspiration of the abscess cavity and occasional excision. For example, an abscess which complicates otitis media is no longer treated by opening the middle ear and draining the cavity by that route. Neurosurgeons now regard the primary

focus as of secondary importance, and means are taken to encourage the infection to localise. Drainage is only indicated if the abscess is superficial, as in the case of one which follows a penetrating wound.

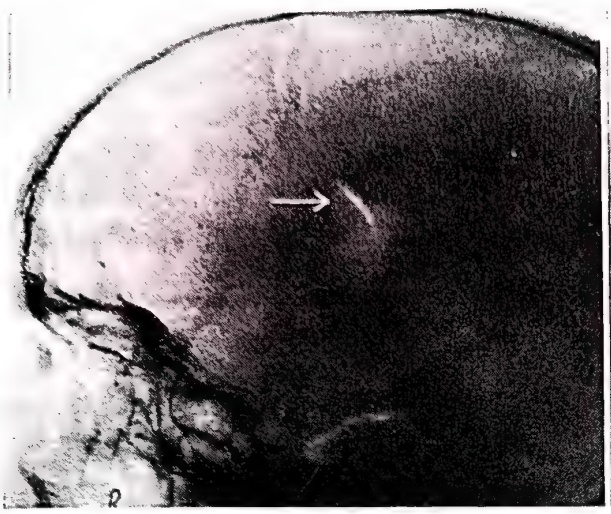

FIG. 437. — Ventriculography. Showing crescentic deformity of the frontal horn produced by a 30-ml. abscess in a child whose only symptoms were headache, cachexia, and wasting following a compound frontal fracture. The cerebro-spinal fluid was normal.

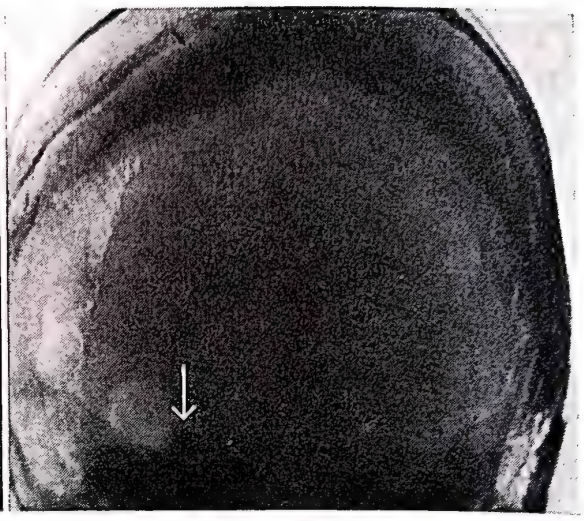

FIG. 438.—Skull X-ray in Towne's position showing thorotrast in a collapsed cerebellar abscess which is at the *apex* of the petrous bone.

In the early stages of cerebral inflammation antibiotics and chemotherapy are employed, and the infection may thus be overcome. Ventriculography may be required to determine whether an abscess is present or not after a course of antibiotics has been given (fig. 437). When an abscess has localised, or if signs are urgent, a diagnostic burr hole is made and the abscess is treated by aspiration and instillation of antibiotics.

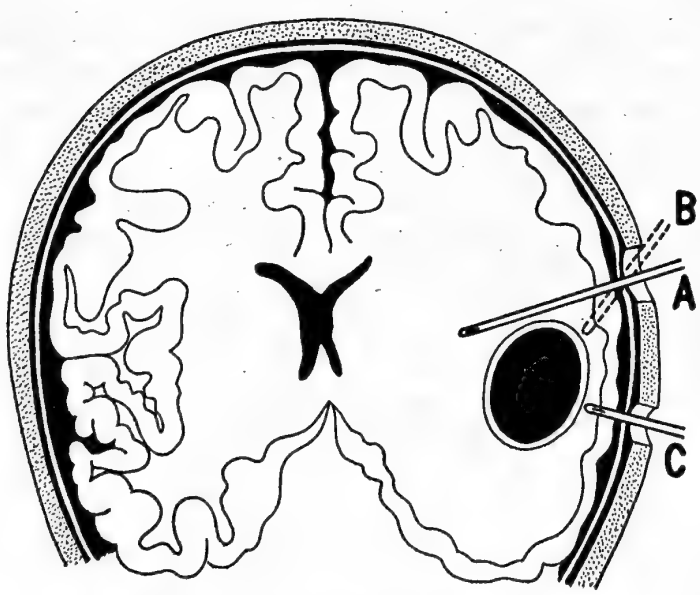

FIG. 439.—Method of localisation of metastatic abscess by burr-hole exploration. Needle at A encounters resistance at B. Puncture is performed by a second burr hole over the site of the abscess C.

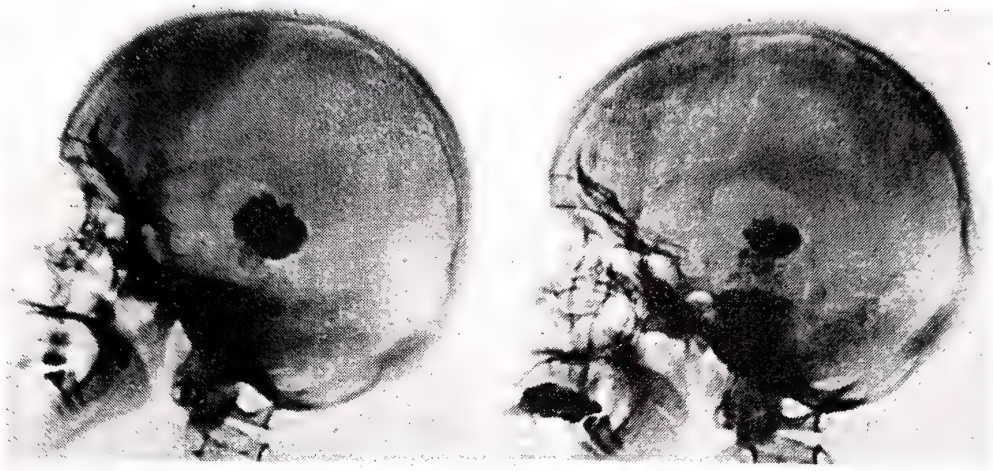
Burr-hole openings are formed: (1) Immediately within the hair line, tapping forwards and inwards for a *frontal abscess*. (2) Immediately above the down-turned ear tapping straight inwards for a *temporosphenoidal abscess*. (3) Over the occipital plate, tapping forwards and inwards for a *cerebellar abscess* (fig. 438). Metastatic abscess may have to be located by two exploratory burr holes (fig. 439). The dura is opened and a blunt ventricular needle is inserted and the resistance of an abscess will be felt. The cannula is pushed through the wall into the cavity and pus will either well up or have to be aspirated slowly. Thirty ml. is a common volume to obtain. Two hundred thousand units of penicillin and 1 ml. of thorotrast are then injected into the cavity. Pus is examined,

and if necessary a further puncture is performed the next day if other antibiotic treatment is required. A single injection of streptomycin may completely sterilise *Esch. coli* abscesses. The thorotrast is taken up into the wall of the abscess and demarcates its outline. Repeated X-rays are taken at intervals. If a multilocular cavity is seen on X-ray, or if the cavity is extending in size or signs are increasing, further aspirations are performed. After several taps, the cavity begins to diminish steadily in size and finally shrinks to the size of a pea (fig. 440).



(*a*) (*b*)

FIG. 440.—(*a*) and (*b*) Thorotrast in a temporal lobe abscess showing reduction in size on consecutive tappings.

Excision of the abscess is needed only for rigid abscesses which will not collapse, or for cerebellar abscesses which respond less satisfactorily to tapping and in which urgent symptoms may develop. If a cerebellar abscess does not respond to two aspirations, excision is indicated forthwith.

Other abscesses should be enucleated within the third month, as the wall is by then sufficiently tough to separate from surrounding brain tissue. Too long a delay results in excessive scar around the cavity, also formation of loculi is encouraged. Enucleation of a cerebellar abscess demands special care, as cranial nerves may be adherent to its wall.

INTRACRANIAL TUMOURS

Tumours arise in connection with the meninges, nerve sheath, or cerebral substance (gliomas). Tumours of the pituitary gland, vascular malformations, gummas, tuberculomas, blood-clots, and chronic abscess contribute to the total. Secondary carcinoma is far more common than primary intracranial tumour. Secondary deposits are most common from the lung, but may originate from any organ in the body and from the naso-pharynx. When these have been excluded, an average surgical series will be as follows:

Meningioma, 18 per cent.
Neurinoma, 8 per cent.
Glioma, 43 per cent.
Pituitary adenoma, 12 per cent.
Craniopharyngioma, 5 per cent.
Metastatic carcinoma, 6 per cent. (not previously excluded on clinical grounds).
Blood-vessel tumour, 2 per cent.
Granulomas and unclassified and rare tumours.

Meningiomas, 18 per cent., vary in structure and vascularity and include psammomas (calcified meningioma, usually spinal), fibroblastomas, endo-

theliomas, and angioblastic meningioma. They are usually globular (fig. 441), but occasionally form a flat carpet work, meningioma *en plaque*, which spreads widely in the meninges. Arising from the arachnoid, the tumour gains secondary attachment to the dura, the arteries and veins of which enlarge to provide a tumour circulation (fig. 442). Dilated emissaries between the bone and dura carry the venous return to the veins of the diploe and scalp, and along these veins tumour cells invade the bone, causing bone destruction and reactive hyperostosis (fig. 443).

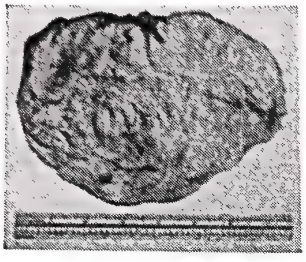


FIG. 441. — Characteristic globular meningioma. ($\frac{1}{3}$ scale.)

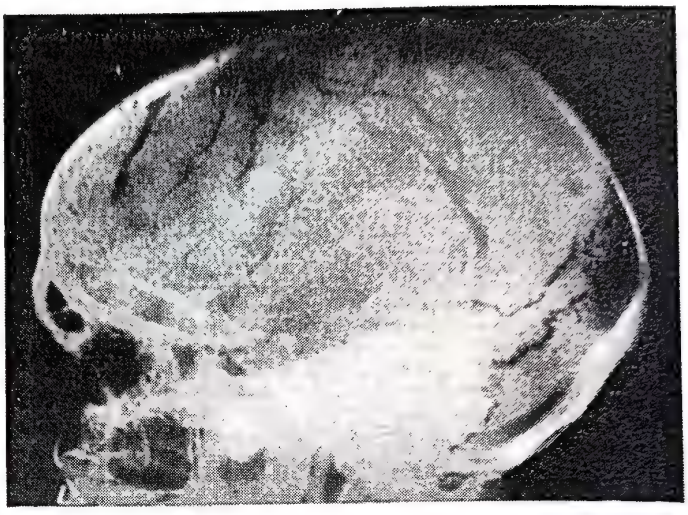

FIG. 442.—Converging vascular markings overlying a meningioma.

Meningioma occurs in the following situations :

(1) **Parasagittal**—arising from the lateral lacunæ and pressing down on to the upper aspect of the frontal parietal and occipital lobes.

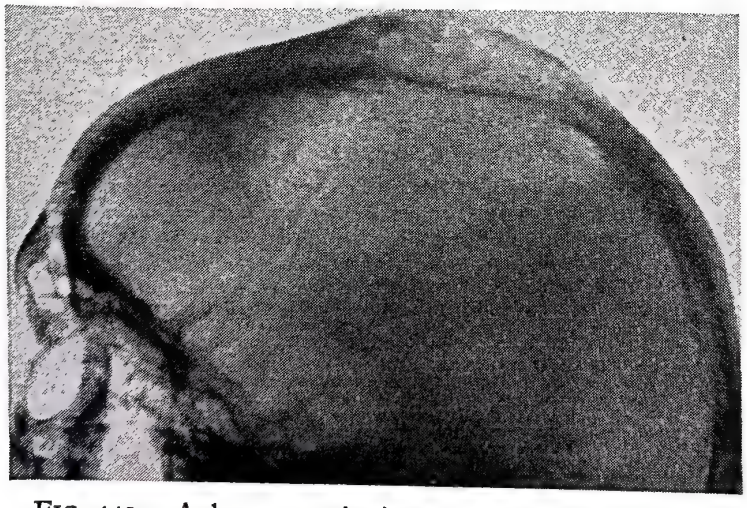

FIG. 443.—A large meningioma hyperostosis extending from the right to left parietal bones. Successfully removed together with underlying tumour. This necessitated a nine-hour operation.

(2) **Fronto-basal**—occurring on the cribriform plate, outer, middle, and inner third of the sphenoid wing and tuberculum sellæ, pressing on the olfactory, oculomotor and optic nerves as well as the brain.

(3) **Posterior fossa**—in the region of the cerebello-pontine angle and jugular foramen.

(4) They may also arise from the falx or from the choroid plexus within the ventricle, or may develop from the depth of a sulcus expanding subcortically as intracerebral 'hæmangioblastoma'.

Neurinoma, 8 per cent., is usually found on the sheath of the auditory nerve (eighth nerve tumour), and may be multiple in association with von Recklinghausen's disease and sometimes occurs in association with multiple cerebral or spinal meningiomas.

Friedrich Daniel von Recklinghausen, 1833–1910. Professor of Pathology, Strasbourg.

Gliomas, 43 per cent.—The malignancy of the tumour varies in proportion to the degree of reversion to the primitive type of cell.

Astrocytoma in its most adult form is composed of star-shaped cells which resemble adult neuroglial tissue. It occurs in three forms: (1) The diffuse or infiltrating, which cannot be totally removed as its margins are unrecognisable and it often affects the brain stem. (2) The solid, which can be completely excised from suitable areas, if necessary by lobectomy. (3) The cystic, in which the nodule of tumour secretes fluid from its surface, forming a cystic cleft between itself and compressed normal brain. The tumour projects into the cyst cavity, and removal of this mural nodule produces a complete cure. Astrocytoma occurs in the frontal lobes of adults and in the cerebral hemispheres of young subjects. However, most astrocytomas contain a variety of cells, the proportion of which varies in different parts of the same tumour. Biopsy from a single favourable point may thus give a totally erroneous impression of a tumour's malignancy. In the modern classification of Kernohan, astrocytic gliomas are classified Grades 1, 2, 3, 4, according to the proportion of adult and primitive cells which they contain. Grade 1 corresponds to the pure astrocytoma. Grade 4 to glioblastoma multiforme (*Bailey* and *Cushing's* Classification). Malignant gliomas affect particularly the middle central territory in male subjects and arise as a result of malignant degeneration in an astrocytoma nodule.

Oligodendro-glioma.—An adult cell tumour consisting of cells with short stunted processes affects the deep portions of the hemispheres in adults. It is prone to undergo central cystic degeneration, and forms a ragged cyst the walls of which consist of tumour tissue. Treatment is usually palliative by evacuation of the cyst.

Spongioblastoma polare arises from primitive uni- or bi-polar spongioblasts and affects inaccessible regions, such as the optic chiasma, third ventricle, and hypothalamus in young subjects. It is irremovable, somewhat radio-sensitive, and rarely produces seedling metastases in the cerebrospinal fluid.

Medulloblastoma occurs usually in young children, affecting the vermis of the cerebellum. It grows rapidly and produces seedling metastases throughout the meninges. Microscopically, it resembles a small round-celled sarcoma, and it is highly radio-sensitive.

Clinical Features.—All tumours have an initial silent period which varies in length according to position and rate of growth. If the tumour is not near any area which will produce symptoms or signs, it will take up space provided in the subarachnoid cisterns; it will flatten and displace the

CLINICAL COURSE OF CEREBRAL TUMOUR

Stage 1	Stage 2	Stage 3	Stage 4
Initial period of silent growth.	Focal syndromes. Epilepsy.	Raised intracranial pressure.	Brain displacement. False localising signs. Cone formation.

ventricle and brain until it can gain no more room, and it will then produce symptoms of raised intracranial pressure, such as morning headache, effortless vomiting, and papillœdema. It may be several years or more before this occurs in the case of a meningioma. If the tumour is situated in an important area, it may, by its local effect, produce symptoms of epilepsy or

James Watson Kernohan, Contemporary. Emeritus Consultant in Pathology, Mayo Clinic, Rochester, U.S.A.
Percival Bailey, 1892–1973. Professor of Neurology, Chicago, Ill., U.S.A.
Harvey Cushing, 1869–1939. Professor of Surgery at Johns Hopkins and Harvard University.

progressive neurological syndromes before any evidence of intracranial pressure is produced. Hence the absence of headache, vomiting, and papillœdema does not exclude a tumour.

Epilepsy arising for the first time in adult life should always be suspected as being due to a tumour until this possibility has been disproved (fig. 444).

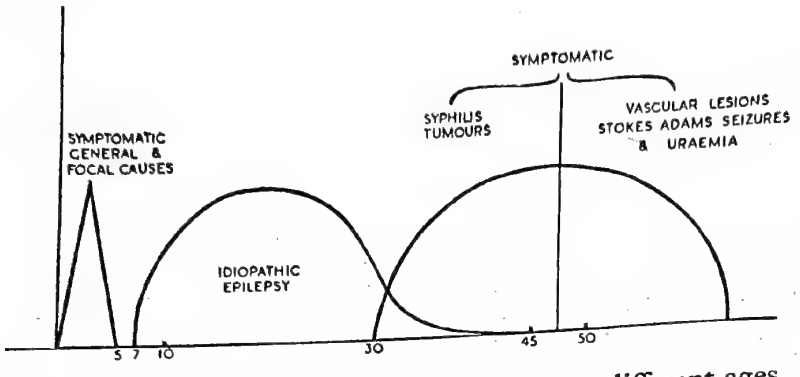

FIG. 444.—The principal causes of epilepsy at different ages.

Idiopathic epilepsy does not occur before the age of six. Ninety per cent. of cases of idiopathic epilepsy have their first seizure before the age of thirty. After the age of thirty, epilepsy is usually symptomatic, and in patients between the ages of thirty and fifty tumour is a common cause.

Progressive focal syndromes should likewise be regarded as indicating a tumour until this possibility is disproved. Degenerative conditions such as disseminated sclerosis are characterised by periods of remission and exacerbation. Vascular lesions occur instantaneously and are followed by some degree of improvement. If repeated on several occasions, as in multiple emboli, an appearance of steady progression is produced, but there is only one condition that will produce a steadily progressive syndrome, and that is a tumour.

The stage of raised intracranial pressure can develop in association with focal symptoms or be the sole evidence of tumour formation. Pressure symptoms occur late in the case of tumours in the frontal lobes which push the ventricles back. They occur earlier in tumours in the temporal and parietal lobes which partially obstruct the outflow of fluid from the adjacent ventricle. They occur earliest in midline and posterior fossa tumours which obstruct the flow of fluid from both ventricles, producing an internal hydrocephalus. Tumours of these types add to their own bulk the effect of the retained ventricular fluid. The effects of pressure include headache, vomiting and papillœdema, bradycardia, and retarded cerebration. The headache often wakes the patient in the early morning, and is aggravated by coughing and straining, which promote cerebral congestion. Vomiting occurs without warning, and is not preceded by nausea or related to food. Papillœdema may cause blindness.

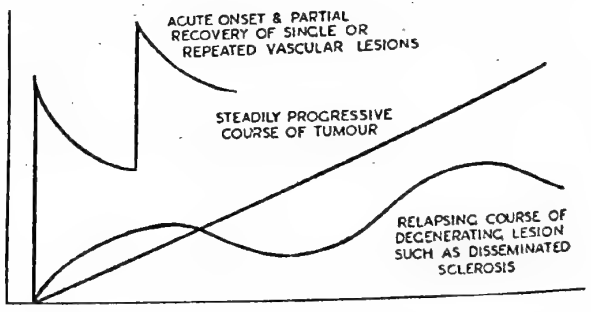

FIG. 445.—Clinical courses of vascular, neoplastic and degenerative lesions.

The Stage of Cone Formation.—Certain patients do not present until cone formation is imminent. When intracranial pressure becomes high, the inner border of one hemisphere may be forced under the falx plugging the superior longitudinal fissure and blocking the pathway for the cerebrospinal fluid absorption. The temporal lobe may be forced down from above into the tentorial opening. The cerebellar vermis may be pushed up into this opening or the cerebellar tonsils may be forced down into the foramen magnum. Ominous signs of a threatened cone include violent paroxysmal headache, drowsiness, slow cerebration, slow pulse, and neck stiffness. Unilateral pupillary dilatation is an urgent sign. *Lumbar puncture must be rigidly avoided at this stage.* (See fig. 420).

Frontal lobe tumours if deeply situated produce a progressive change, in personality, with lack of insight, neglect of normal pastimes, occupations, and duties, and an alteration in emotional reaction particularly noticeable to relatives, consisting usually of a simplicity and unwarrantable cheerfulness (euphoria) or irritability. Epilepsy is generalised in type, and localising signs are limited to contralateral facial weakness.

Parietal lobe tumours produce Jacksonian epilepsy and progressive hemiparesis. Examination reveals loss of touch analysis resulting in astereognosis. Deeply situated left-sided tumours may exhibit defects of special relationship and loss of power of calculation (acalculia).

Occipital lobe tumours.—Epilepsy is generalised in type, preceded by an aura of flashing lights in the contralateral visual field. Signs, other than homonymous hemianopia, are few.

Temporal lobe tumours on the left side may produce progressive aphasia or visual or auditory hallucination sometimes with generalised convulsions. Lesions of the uncinate region produce uncinate hallucination of smell and taste and dreamy states of unreality. Right-sided lesions may cause similar uncinate attacks of generalised epilepsy without aura. Localising signs include hemiparesis and superior quadrantic hemianopia.

Parasagittal meningioma overlying the various lobes produces similar syndromes but with characteristic skull X-ray changes (figs. 442 and 443).

Basal meningioma produces involvement of the olfactory and optic, oculomotor, and trigeminal nerves, in addition to pressure on the brain. Bone changes in the region of the orbit may cause proptosis or fullness in the temporal fossa.

Midline tumours always produce bilateral internal hydrocephalus with pressure symptoms.

Tumours of the third ventricle.—Colloid cysts at first cause a ball-valve obstruction producing intermittent blockage of the foramen of Monro. Severe unilateral headache is produced by lying on one side of the head and relieved by turning to the other side. Later, persistent bilateral hydrocephalus is accompanied by severe pressure symptoms or progressive cerebral atrophy and dementia. Glioma of the floor of the ventricle causes hydrocephalus associated with endocrine disturbances, disturbances of sleep rhythm, and sexual precocity.

Pineal tumours by pressure on the quadrigeminal plate produce hydrocephalus with paralysis of the oculomotor nuclei with loss of upward, lateral, and downward movement of the eye.

Subtentorial Tumours.—Tumours of the posterior fossa produce hydrocephalus and cause raised intracranial pressure. The effect of the hydrocephalus varies with the age of the patient.

Cerebellar vermis tumours are usually medulloblastomas and occur in young children before the sutures have united. The hydrocephalus causes progressive enlargement of the head. At a later age, when the sutures have united, there are serious pressure symptoms and stiffness of the neck from herniation of both cerebellar tonsils into the foramen magnum. Since the vermis controls the co-ordination of

Alexander Monro, 1733–1817. Professor of Anatomy, Edinburgh.

trunk and legs, localising signs are only seen if the child is taken out of bed; it will then be seen to walk with the feet wide apart and have a tendency to fall over forwards when standing with the feet together.

Cerebellar hemisphere tumours are often astrocytomas. They produce hydrocephalus and pressure symptoms in older subjects. Since the hemisphere controls the co-ordination of the corresponding side of the body, there is deviation to the affected side on walking and unilateral inco-ordination of the arm. Nystagmus may or may not be present.

Acoustic neuroma grows from the auditory nerve at the internal auditory meatus and produces enlargement of this structure, visible on X-ray. Arising from the eighth nerve the first symptom is unilateral deafness, which is often first detected by the patient on the telephone. The tumour projects into the cerebello-pontine angle and presses upon the adjacent seventh, sixth, and fifth nerves, causing a syndrome of unilateral deafness, facial weakness, and sometimes squint. The corneal reflex is reduced from pressure on the fifth nerve. There may be trigeminal neuralgia from this cause or trigeminal anæsthesia. Later the tumour presses upon the cerebellum and brain stem, producing cerebellar signs and raised pressure. Finally it grows up into the tentorial opening from below, and here it not only blocks the up-flow of cerebrospinal fluid but assumes a position anterior to the brain stem coming into close relationship with the basilar artery and twisting the pons. Cerebrospinal fluid protein is always high, often over 200 mg/100 ml (2·0 g/l).

The investigation of cerebral tumour must define the site and nature of the tumour.

History taking.—The history alone will sometimes indicate the site of the tumour and also give a hint as to its pathological type. If symptoms have been long-standing, they suggest a slowly growing and favourable tumour. A short history may, however, be due to the final breakdown of adaptation in a slowly growing tumour or indicate a rapid malignant growth.

The history may suggest a primary disease to which the cerebral condition is secondary. Since metastatic carcinoma, especially bronchial, is far more common than primary cerebral tumour, particular attention must be paid to history of loss of weight, recent cough, or hæmoptysis. Secondary brain abscess is suggested by a history of lung abscess or bronchiectasis; chronic otitic abscess by symptoms of cachexia and a discharging ear. Weight loss is always suspicious, as there is no wasting with primary cerebral tumour.

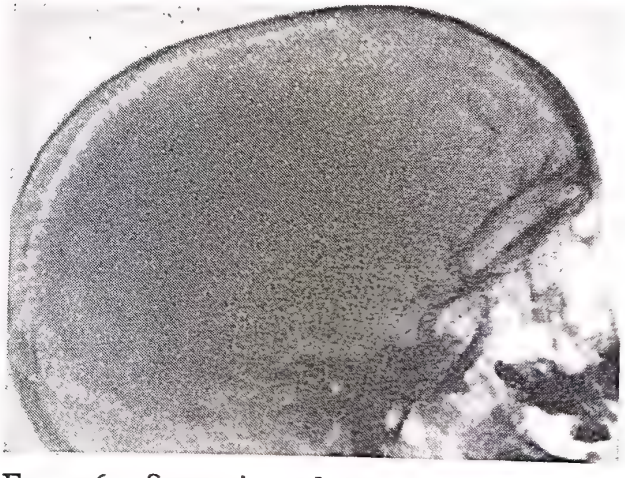

FIG. 446.—Separation of sutures, beaten silver appearance, and erosion of posterior clinoids.

Clinical examination must include the general examination in search of primary disease.

Neurological examination of cranial nerves and nerve tracts may localise *where* a tumour is, but never indicates what it is.

Accessory investigations are essential. X-ray of the skull, X-ray of the chest, and the erythrocyte sedimentation rate must be taken in every case. A high E.S.R. is strongly suggestive of secondary tumour.

An X-ray of the chest may reveal an unsuspected bronchial carcinoma.

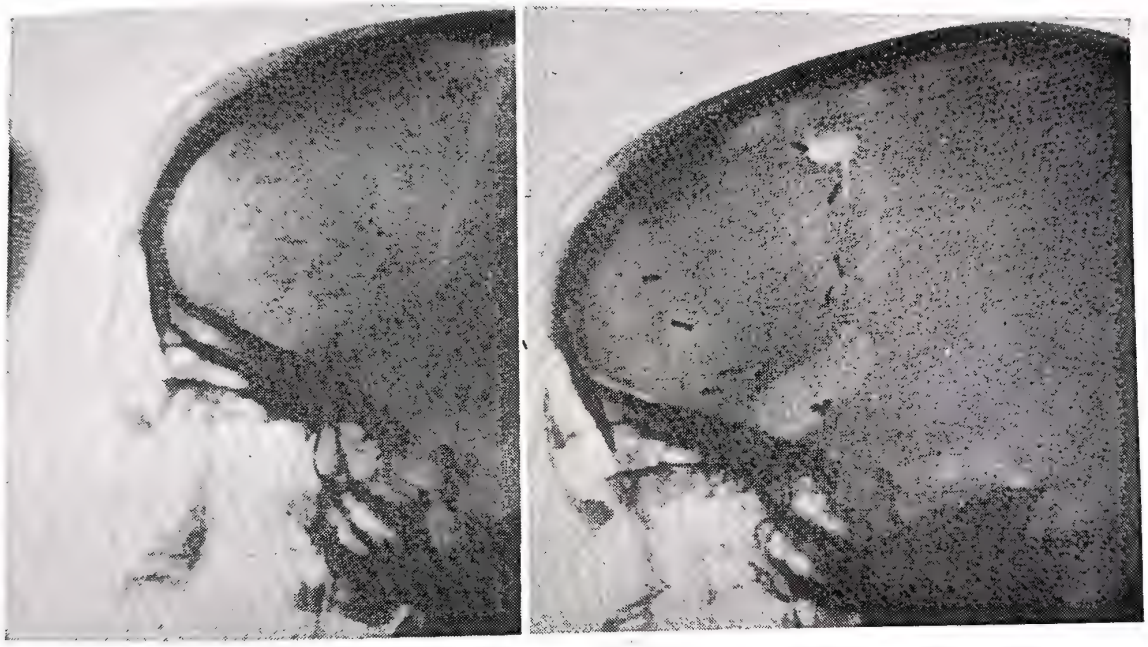
Thirty per cent. of bronchial carcinomas present with cerebral symptoms before any chest symptoms have occurred.

An X-ray of the skull may show that a tumour is present :

(1) By pressure changes including : (*a*) A beaten silver appearance of the vault from the pressure of tight convolutions (sometimes normal in thin skulls). (*b*) Separation of sutures in young subjects. (*c*) *Most important*—erosion of the posterior clinoid processes, a very valuable sign which indicates long-standing pressure and therefore a possibly removable tumour (fig. 446).

(2) By lateral displacement of a calcified pineal shadow indicating the side of the tumour.

(3) By characteristic intracranial calcification produced by astrocytomas, angiomas, 50 per cent. of craniopharyngiomas, and some meningiomas and tuberculomas (fig. 447).



A *B*

FIG. 447.

Calcified astrocytoma in frontal lobe. After removal by lobectomy.

(4) By alteration in skull vascular markings in meningioma, including converging diploic channels, and an increase in the size of the meningeal groove.

(5) By changes in the skull bones, including meningioma hyperostosis, local expansion at the site of a cyst, and evidence of bone destruction in secondary tumours.

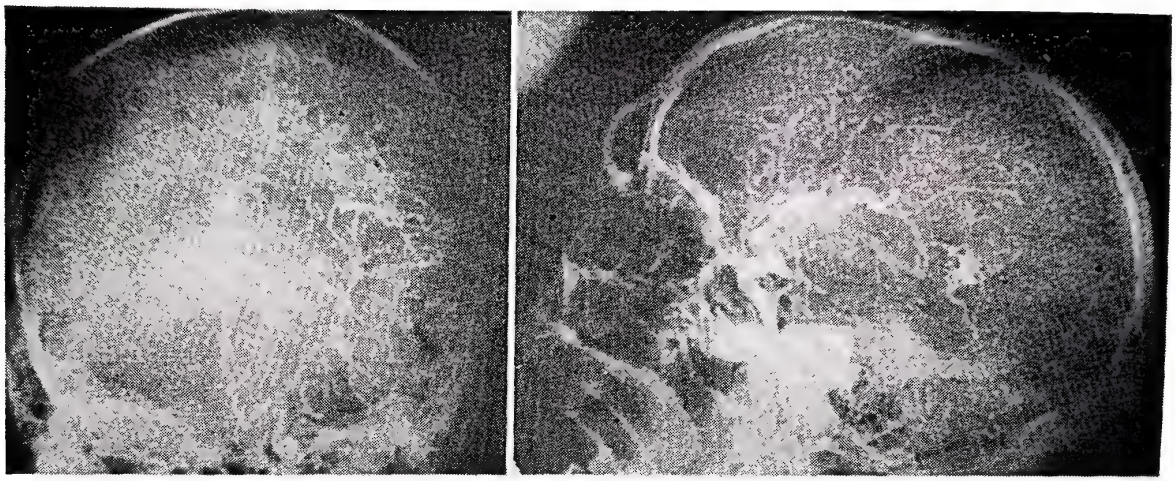
Electroencephalogram.—Characteristic wave-forms indicate the site or presence of focal or deep-seated tumours, and distinguish between epileptic seizures produced by focal lesions and idiopathic epilepsy.

Lumbar puncture is employed in early cases where it is necessary to exclude non-tumorous conditions. The pressure and content of the cerebrospinal fluid are recorded. An increase in pressure and protein suggests tumour. The W.R. is examined. Lumbar puncture is avoided in the presence of raised pressure and is absolutely contraindicated by threatened cone formation.

CT scanning (see p. 407), when available, provides reliable information concerning the presence of a tumour, and ventricular displacement or distension. It is possible to distinguish the type of tumour. Meningiomas appear densely white. Gliomas are less dense, any central necrosis shows as a dark area within the glioma shadow. Astrocytoma secretion cysts show a dark shadow with the lateral mural nodule indenting. It is possible to distinguish the vascular edge of malignant gliomas. Secondary tumours appear as multiple shadows or cysts. Intravenous contrast infusion enhances the reliability of scan interpretation.

Surgical investigation by arteriography or air study is employed to localise a silent tumour producing pressure but no physical signs, or indicate the extent of a known tumour, and to provide evidence of its type.

Arteriography was originated by Egas Moniz. Twelve ml. of 35 per cent. Pyelosil is injected into the common carotid artery either by percutaneous puncture or by open operation. Three lateral films are taken at intervals of one second to show



A *B*

FIG. 448.

(*A*) A.P. arteriogram showing inward displacement of the anterior and middle cerebral arteries and tumour circulation causing a blush in a meningioma at the outer third of the sphenoid ridge. (*B*) Lateral arteriogram showing primitive glioblastoma vessels in posterior temporal region.

the arteries and then the veins, and this is followed by a further injection to obtain antero-posterior films. This investigation is safe even in high-pressure cases, as it does not disturb the intracranial pressures. The site of the tumour is shown by the displacement of cerebral vessels, e.g. upward or downward deviation of the middle cerebrals or displacement of the anterior and middle cerebrals in the antero-posterior view. Pathological tumour circulation is seen in meningioma and glioblastoma multiforme. Meningiomas produce a diffuse blush; glioblastomas produce a group of very primitive and imperfect vessels (fig. 448).

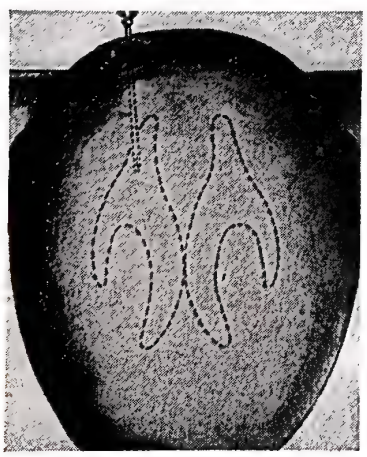


FIG. 449.—Diagram of ventriculography.

Investigation by Air Study.—Ventriculography was originated in 1918. Bilateral parietal burr holes are formed under local anæsthesia. A hollow ventricular cannula is inserted to a depth of up to 5 cm to puncture the vestibule of the ventricle (fig. 449). Available cerebrospinal fluid is removed and replaced with 10 per cent. less volume of air. Since air rises and fluid falls the patient is positioned in such a way that the portion of the ventricular system which it is wished to fill with air is brought to the highest level during arteriography, films being taken in various planes to show displacement and distortion of the ventricle. Investigation is

Antonio Cætano de Abreu Freire Egas Moniz, 1874–1955. Professor of Neurology, Lisbon. Introduced cerebral arteriography in 1927 and leucotomy in 1936.

dangerous as tapping of a displaced and expanded ventricle on the side opposite to the tumour may allow the brain to be pushed over causing cone formation as the temporal lobe sinks into the tentorial opening. Arteriography is therefore preferable.

Myodil ventriculogram in hydrocephalus will demonstrate the third and fourth ventricles and aqueduct after the injection of 3 ml. of Myodil.

Air Encephalography.—Thirty ml. of cerebrospinal fluid is aspirated slowly and replaced by air at cisternal or lumbar puncture. This method is highly dangerous in cerebral tumours and should be reserved for investigation of low-pressure cases with symptoms of epilepsy.

Investigation by Cerebral Puncture.—If investigation suggests the presence of an unfavourable lesion in which craniotomy is contraindicated, such as secondary carcinoma or malignant glioma, or if a cyst is suspected, a burr hole is fashioned over the tumour site and the tumour is aspirated by ventricular cannula. If a cyst is defined, air or thorotrast is injected into the cavity in order to produce a picture of the cyst (astrocytic growth).

A favourable cyst produced by astrocytoma or hæmangioblastoma contains golden-yellow clotting fluid.

A malignant cyst contains muddy non-clotting fluid like stale beer.

Astrocytic glioma Grade 3 and 4 renders the brain soft, necrotic, and highly vascular whereas meningiomas are resistant.

If stained smears show the presence of astrocytic glioma Grade 3, lobectomy can provide a useful decompression prior to X-ray therapy in favourable situations. Open decompression of the dura however is contraindicated as the tumour contains

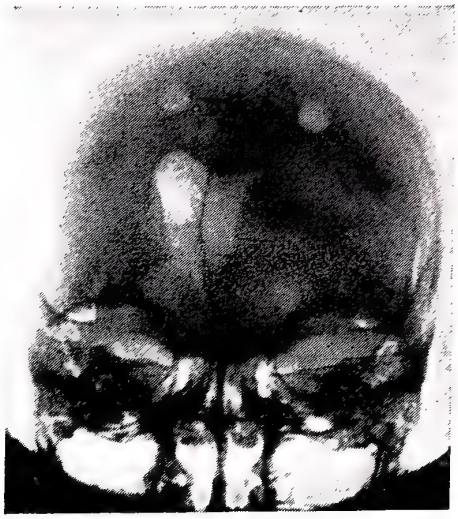

FIG. 450.—X-ray indicating dangers of ventriculography. Both ventricles are already on one side of the head. This is not unusual.

FIG. 451. — Antero-posterior ventriculogram showing flattening and downward displacement of left lateral ventricle by large para-saggital meningioma. The middle meningeal groove is enlarged on the left side.

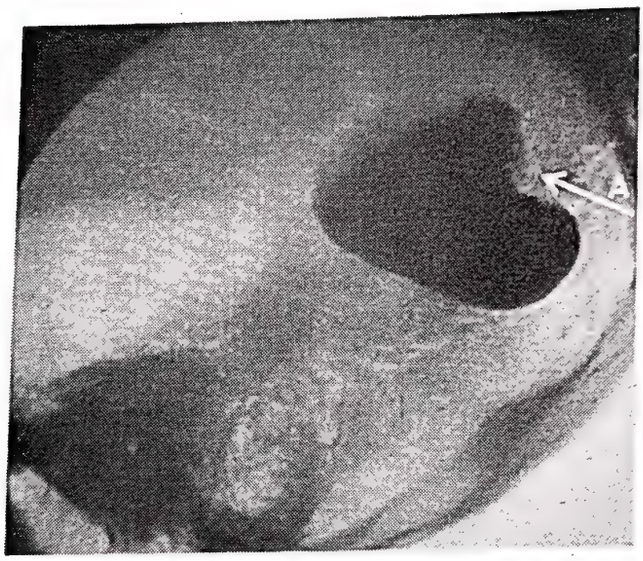
primitive vessels and will enlarge owing to acute œdema if the pressure of the dura is relaxed. This 'acute brain swelling' will cause additional symptoms of aphasia and hemiplegia. It may be possible to secure internal decompression by sucking out the necrotic centre of a tumour through a small dural opening prior to deep X-rays. Astrocytic glioma Grade 3 can be usefully palliated by internal decompression or lobectomy followed by radiotherapy, but any operation on astrocytic glioma Grade 4 is definitely contraindicated.

Treatment.—Temporary dehydration by urea or intravenous 50 per cent. sucrose (see p. 405) may be employed as a pre-operative measure if intracranial

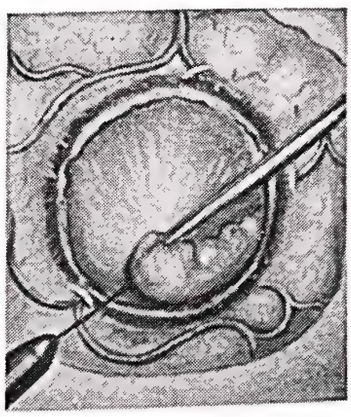
pressure is acute. Dexamethazone is very useful in the treatment of severe œdema. It is of little value in meningiomas but is most valuable in necrotic malignant gliomas and necrotic secondary tumours. In these the reduction of œdema may restore a comatose patient to consciousness and remove signs of paralysis and other localising phenomena. Repeated administration may prolong life. In frontal lobe tumours the relief of paralysis by dexamethazone will indicate that the paralysis is merely due to œdema and not to direct invasion of the motor areas by tumour tissue, providing an indication for removal of the tumour by frontal lobectomy. Regular administration of dexamethazone is also useful during X-ray therapy by countering the increased œdema occurring during treatment. If dexamethazone is given to reduce œdema around a tumour which is still present and if the treatment is stopped, sudden development of œdema may cause death from pressure cone in 24 hours.

Operation must not be delayed if pressure is high as sudden and unexpected collapse may occur. Improvement in neurosurgical technique permits a radical excision in many cases.

Craniotomy.—An osteoplastic flap is fashioned over the site of the tumour and must be sufficiently large to expose either the lobe to be excised or an adequate margin of normal brain around the tumour which is to be enucleated. In the case of meningiomas a length of the superior longitudinal sinus greater than the known length of the tumour must be displayed. Various scalp



A



B

FIG. 452.

Operative sketch of removal of tumour.

incisions are employed, transverse or horseshoe, all of which are hidden as far as possible within the hair line.

The field of operation is infiltrated with 1:100,000 of adrenalin in saline. The skin incision is outlined, the area of operation is sealed off by lint trephine cloth, which is gummed to the scalp with gum mastiche and cut through in the line of the proposed incision. The scalp is incised. The assistant and surgeon exert digital pressure with the fingers on either side of the cut. Before pressure is released, artery forceps are applied to the epicranial aponeurosis on either side; these are folded back so that the vessels in the scalp are bent on themselves, and each bunch of four or five forceps is secured with a rubber ring. By degrees the incision is enlarged and an extensive exposure can be obtained, almost bloodlessly, using a sufficient number of forceps. The scalp flap is now reflected and wrapped in a warm swab. Skin towels

are applied to the wound edge. Burr-hole openings are then fashioned in a suitable pattern, being placed at the summit of each convexity in order to reduce pressure on the dura when the saw guides are passed from hole to hole. Gigli guides and saws are now passed between the burr holes, and the intervening areas of bone are sawn through, the cut being fashioned obliquely, so as to form a mortise edge in the bone in order to prevent the bone flap sinking in when it is replaced. The base of the flap is designed to hinge on the temporal muscle. The bone flap is now elevated and the base fractured, the osteoplastic flap then being turned down on the hinge of temporal muscle and wrapped in a warm cloth. If a meningioma is being dealt with, the bone flap is extremely vascular, and on lifting the flap, hæmorrhage occurs from the torn emissary veins crossing between the bone and dura. The exposed dura mater is now inspected for an excess of vessels and torn emissary veins, indicating an underlying meningioma, or for surface evidence of underlying glioma, such as discoloration of the brain or widening of convolutions visible through the dura.

To delineate the extent of a subcortical tumour, ventricular needles are inserted at three or four points in order to detect the resistance of a tumour margin. When the position and nature of the growth have been decided, the dura is opened by a horseshoe flap, either with guarded scissors or a knife cutting on to a dural guide. Meningeal vessels of large size are secured with Cushing's silver clips.

Excision of a Meningioma.—Parasagittal.—The dural incision is completed all round the base of the tumour unless this invades the superior longitudinal sinus. The margin between the brain and tumour is defined, and vessels crossing this are secured with diathermy or silver clips; the tumour is then rotated upwards from its bed and dissected from the sinus.

Basal Meningioma.—Occasionally it is necessary to amputate the frontal lobe of the brain to expose tumours on the middle or inner third of the sphenoid ridge, otherwise the lobe of the brain is retracted and the bulk of the tumour is reduced by cutting out its centre with punch forceps and diathermy, following which the capsule is gently drawn away from important branches of the circle of Willis which surround it. Finally, the collapsed capsule is excised intact, together with the adjacent dura (fig. 453).

Excision of a Glioma.—(*a*) *By Enucleation.*—The tumour nodule is exposed either by opening a cyst or by ' uncapping ' the area of overlying cortex. A medallion

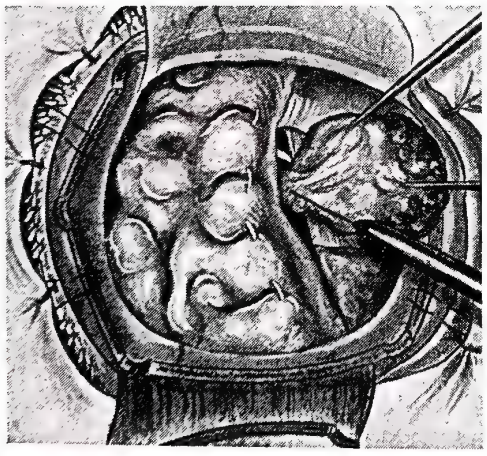

FIG. 453.—Excision of collapsed capsule of a basal meningioma exposed by frontal lobectomy.

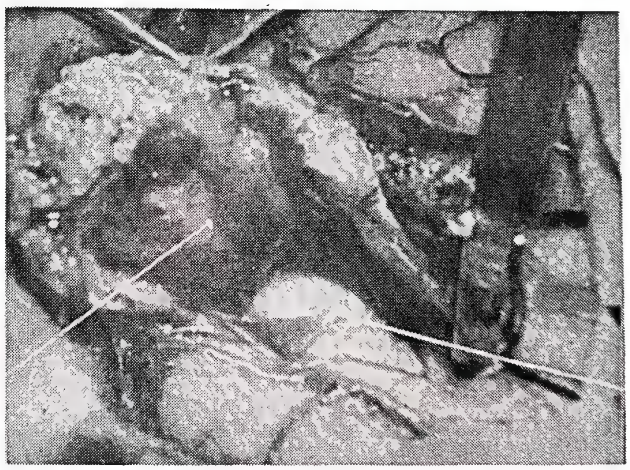

FIG. 454.—Excision of astrocytoma from cyst in parietal lobe showing (*a*) the dark mural nodule projecting into (*b*), the white-walled cyst whose walls consist of compressed cerebral tissue.

of cortex of adequate area is defined. Vessels entering this zone are secured with diathermy or silver clips, the defined area being then removed down to the level of the tumour margin. Vessels crossing from brain to tumour are gradually secured and the nodule is rotated from its bed (fig. 454).

(*b*) *By Lobectomy.*—Veins passing from the frontal or occipital lobe to the superior sinus are coagulated on a blunt hook, or secured with silver clips, and divided. Veins passing from the temporal lobe to the sphenoidal or petrosal sinuses are likewise

Thomas Willis, 1621–1675. Professor of Natural Philosophy, Oxford. Afterwards practised as physician in St. Martin's Lane, London. The drawings of the circle of Willis were made by Sir Christopher Wren.

secured. The plane of section is now defined, and vessels crossing this are secured with silver clips or diathermy. The incision is now deepened across the white matter to the opposite aspects of the lobe, where vessels are similarly dealt with and the lobe is excised.

If a tumour is irremovable, central necrotic areas are removed by suction in order to reduce pressure. In all cases hæmostasis must be complete before the wound is closed. The dura is sutured completely, and if necessary with the introduction of a graft of nylon membrane. If bone has been invaded by meningioma hyperostosis, it is excised. Finally, the scalp is sutured in two layers. Blood transfusion is required during operation in vascular cases.

POSTERIOR FOSSA CRANIECTOMY

Intratracheal anæsthesia is essential. The head is fully flexed and supported with the patient in the sitting-up position, which reduces venous congestion. A fine catheter is inserted into the lateral ventricle through a posterior parietal burr hole to provide ventricular drainage and reduce intracranial pressure. A midline incision is formed from above the external occipital protuberances to the level of the third cervical spinous process. The lateral skin flaps are raised from the occipital muscles, retractors are inserted and the ligamentum nuchæ is divided with diathermy to expose the arch of the first cervical vertebra. The occipital muscles are cut through 6 mm below their attachment and dissected with diathermy from both occipital plates. The arch of the atlas is removed. Both occipital plates are drilled through and then removed with biting forceps including the rim of the foramen magnum. This exposes the posterior fossa dura as high as the transverse sinus, the foramen magnum, and upper cervical dura. The dura is palpated, and if the pressure is high, it is reduced by releasing fluid from the ventricles or tapping the cisterna magna. The dura is incised transversely, the occipital sinus being secured with Cushing's silver clips, and a vertical incision is now made downwards in the midline to the upper cervical region to release the pressure cone at the foramen magnum. If both tonsils are forced down, the tumour will be found in the midline. If one tonsil is down, the tumour is in the corresponding hemisphere. Astrocytoma nodules are excised, but medulloblastomas are best left intact with an open decompression for deep X-ray treatment.

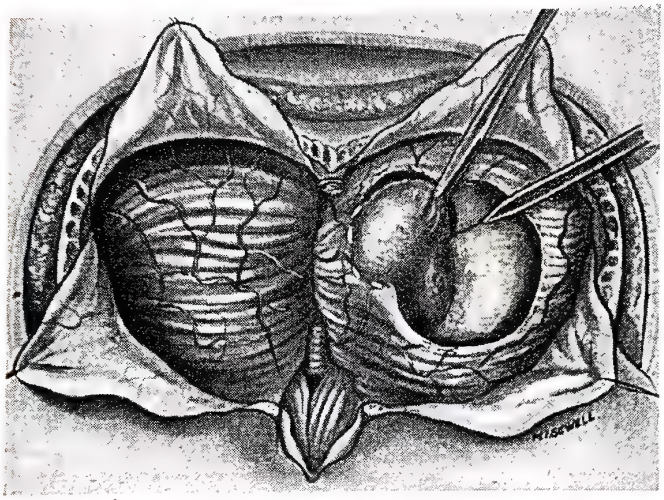

FIG. 455.—Removal of astrocytoma nodule of cerebellum.

Unilateral exposure may be performed through a hook incision extending up from the third cervical spine to the external protuberance and then laterally and finally downwards to the mastoid tip. The ligamentum nuchæ is split to expose the arch of the first cervical vertebra, and the occipital muscle is reflected downwards from the occipital plate, which is then removed. The cisterna magna is tapped to reduce pressure and the dura is opened.

Eighth nerve tumours are exposed by this route. The lower third of the cerebellar hemisphere is cut away and the tumour exposed anterior to the cerebellum. The capsule is incised, its contents are evacuated, and the capsule is gently drawn away from the side of the brain stem and downwards through the tentorial opening before being excised. A small portion is left over the facial nerve in order to prevent facial paralysis.

Large tumours are dangerous as they extend into the tentorial opening anterior to the brain stem, distorting and compressing the basilar branches. A fatal brain stem thrombosis may occur as a postoperative complication. Good results and

smooth postoperative recovery are claimed for the method of lateral extradural approach since retraction of the cerebellum is avoided.

Radiotherapy should be used only for tumours showing mitotic activity; medulloblastoma, astrocytic glioma Grade 3, and meningiomas exhibiting mitotic activity which may be liable to recur locally. It should not be employed in insensitive tumours as it produces endarteritis in the cerebral vessels, sometimes with serious symptoms.

Chemotherapy in Brain Tumours.—Chemotherapy has been employed in cases of malignant glioma treated by subtotal resection. Systemic chemotherapy is given pre- and post-operatively. Chemotherapeutic agents are introduced into the tumour bed during operation or postoperatively through a drainage tube. The value of these methods is at present uncertain.

TUMOURS OF THE PITUITARY BODY

comprise three varieties of adenoma; chromophobe, acidophil, and basophil, and congenital tumours derived from Rathke's pouch (craniopharyngiomas).

Chromophobe adenomas occur most commonly in female patients between the ages of twenty and fifty. The tumour is solid and slow-growing and expands steadily to form a mass the size of a walnut in a period of several years. Spontaneous involution may occur with cessation of growth and cystic change (cf. adenoma of thyroid). Occasionally highly cellular rapidly growing tumours assume the characteristics of local malignancy invading laterally into the cavernous sinus or extending into the lobes of the brain. Three stages of development may be recognised:

(*a*) The stage of intrasellar development.

(*b*) The stage of extrasellar extension.

(*c*) The stage of massive intracranial extension.

(*a*) *Intrasellar Development.*—In the sella turcica, the expanding chromophobe cells, which possess no active secretion of their own, compress the acidophil and basophil cells of the pars anterior and inhibit their secretions which are concerned with growth and sex functions. Since the tumour arises at an age when growth is complete, the effect is felt by the thyrotropic and gonadotropic hormones. The patient becomes fat and sluggish with a lowered metabolic rate, as in myxœdema, and amenorrhœa is invariable. Pressure on the diaphragma sellæ causes severe headache. X-ray of the skull reveals pressure changes of the sella (fig. 456). The floor is depressed towards the sphenoidal air sinus, lateral pressure on the petroclinoid ligaments leads to separation of the anterior clinoid processes, and the posterior clinoids become thin.

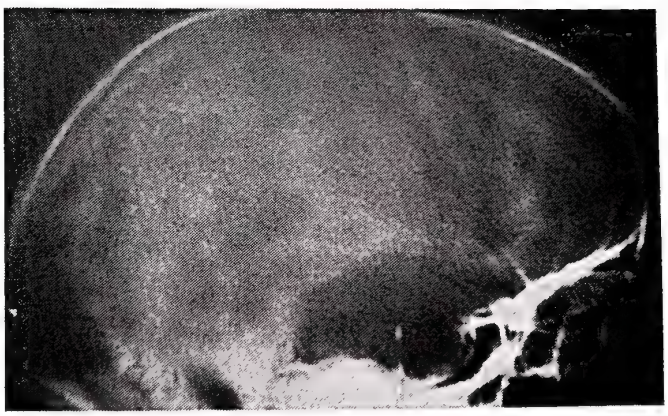

FIG. 456.—Typical X-ray appearances of enlarged sella in chromophobe adenoma.

(*b*) *The Stage of Extrasellar Extension.*—The tumour breaks through the diaphragm at a weak point between the anterior clinoid processes and extends

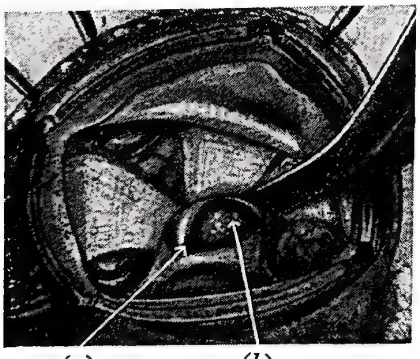
Martin Heinrich Rathke, 1793–1860. Professor of Zoology and Anatomy, Königsberg, which was in Germany, but since 1945 is Kaliningrad, U.S.S.R.

up in front of the pituitary stalk to press on the under aspect of the optic chiasma. Headache becomes less severe from relief of intrasellar pressure, amenorrhœa persists, and gradually bitemporal hemianopia is produced by stretching of the decussating fibres in the optic chiasma over the posterior border of the tumour. Involvement of these fibres which come from the inner half of each retina, leads to loss of vision towards each temporal side. Stretching of the optic nerves anterior to the chiasma produces primary optic atrophy with pale white optic discs. The diagnosis is usually made at this stage.

Acute infarction may rarely produce a sudden swelling of the tumour with rapidly increasing visual loss. The risk of infarction occurring after deep X-ray therapy or the implantation of radioactive Yttrium contraindicates the use of either method when the chiasm is compressed. Infarction may cause complete blindness and then be followed by atrophy and disappearance of the tumour.

(*c*) *The stage of massive intracranial extension* is rare. If the optic chiasma is in an abnormal position, either pre- or post-fixed, the tumour may slip by it without causing visual disturbance and enter the frontal lobe, or highly cellular rapidly growing tumours may spread laterally into the temporal lobe or upwards and backwards behind the chiasma into the third ventricle. These extensions will act as a space-occupying tumour and produce symptoms of raised pressure or epilepsy. Extension into the temporal lobe produces an additional homonymous hemianopia from involvement of the optic radiation.

Differential Diagnosis.—The syndrome may be simulated by a meningioma of the dorsum sellæ or an aneurysm of the anterior communicating artery. Arteriography is required in doubtful cases.



(*a*) (*b*)

FIG. 457.—Intradural exposure of pituitary tumour, showing (*a*) optic nerve and (*b*) pituitary tumour.

Treatment.—Few chromophobe tumours are radio-sensitive. Many alleged successes attributed to deep X-ray have been due to spontaneous cystic involution or an abnormality of the chiasma which allows the tumour to go on growing without serious visual loss developing. Years later the growth is found to have formed a massive intracranial extension.

Operation performed before the stage of massive extension has a mortality of 2 to 4 per cent.; after extension 30 per cent., hence early operation is advisable. Pre- and post-operative treatment by steroids is advisable in the presence of hypopituitrism in order to prevent post-operative adrenal deficiency.

In the stage of intrasellar development, if there is no evidence of involvement of the chiasma, radioactive seeds of Yttrium (^{90}Y) may be inserted into the tumour by stereotactic approach from above, or implanted across the ethmoids through a para-nasal incision under X-ray control. In the stage of extrasellar extension, the chiasma must be decompressed. The size of the tumour is first assessed by arteriography and air encephalography which will show the presence of any upward extension either by the stretching of the carotid arteries or indentation of the front of the third ventricle.

The tumour is exposed by frontal osteoplastic craniotomy, after opening the dura and elevating the frontal lobe. The extradural approach dividing the dura at the

sphenoid wing gives less adequate exposure. The tumour looks like a dark plum stretching the optic nerve like a white ribbon around its margin. Cysts are opened or solid tumour is removed by punch forceps. The capsule of the tumour is then drawn down from behind the chiasma and excised. This step is essential to prevent post-operative hæmorrhage into a nodule lying beneath the third ventricle which stimulates the temperature centres and causes death from hyperthermia. Relief of pressure on the basophil cells restores sex function, and pregnancy may take place after operation. Post-operative deep X-ray is required to prevent recurrence in highly cellular growths.

Acidophil adenomas are small in size and rarely cause pressure on the optic chiasma except in cases of fugitive acromegaly, in which the tumour reverts almost to a chromophobe type. Normally the symptoms are due to excessive production of growth hormone by the acidophil cells and inhibition of the basophile sex secretion.

In children the tumour causes gigantism, while patients whose epiphyses have united develop acromegaly (a term which implies enlargement of the extremities).

Acromegaly is characterised by thickening of the subcutaneous tissues of the scalp, lips, and tongue, the face, hands and feet, and overgrowth of the frontal sinuses, jaw, and distal phalanges. There is also overgrowth of hair and sebaceous glands. Asthenia causes slackening of ligaments with kyphosis, so that the enlarged hands hang below the knees. This combined with the atavistic appearance produced by the beetling brow, prognathous jaw, and overgrowth of hair on the chest, produces the 'ape man' of the circus. Fatty degeneration of the heart and herniæ are associated conditions.

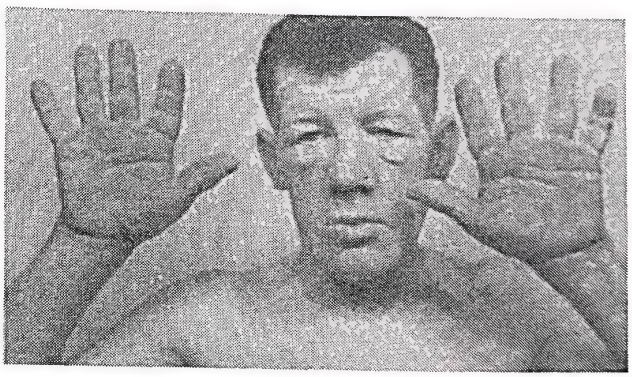


FIG. 458.—Acromegaly.

Treatment is by deep X-ray, to which the tumour is sensitive, or intrasellar implantation of radioactive Yttrium. Operation is only rarely required, which is fortunate, since the patients are poor operative risks on account of the heart and chest condition, and approach is difficult, owing to enlargement of the frontal sinuses, which may necessitate a lateral or trans-sphenoidal operation.

BASOPHIL ADENOMAS AND CUSHING'S SYNDROME

Basophil adenomas are small, usually only a few millimetres across; their effects are produced by secretion of adreno-corticotrophic hormones leading to excessive production of hydrocortisone.

Cushing described a syndrome associated with basophil adenomas, although a similar condition may be due to adrenal dysfunction (adreno-genital syndrome, p. 625). Females are more commonly affected. Fat accumulates on the trunk, neck, and face which becomes red and moonshaped but the limbs remain normal. Purple striæ appear in considerable numbers on the skin, which is thin and atrophic. Hirsutism, arterial hypertension and glycosuria develop early. There is moderate polycythæmia and atrophic changes affect the bones of the os calcis and pubis. A psychotic state of schizophrenia sometimes develops.

Harvey Cushing, 1869–1939. See footnote, p. 429. Described this disease in 1932.

Treatment is directed to reduction of the secretion of hydrocortisone either by adrenalectomy or by operation on the pituitary. Russell Fraser has shown that these tumours may be effectively treated by the intrasellar implantation of radio-active Yttrium 90.

Craniopharyngioma.—Remnants of Rathke's pouch may persist at four sites: (1) In the sphenoid bone; (2) in the sella turcica; (3) in the pars nervosa; (4) in the floor of the third ventricle, from all of which tumours may develop. Although congenital in origin, a proportion of cases do not produce symptoms until late in adult life.

FIG. 459.—A large craniopharyngioma.

The term craniopharyngioma describes these tumours best. In structure, the growths form large masses in which cystic cavities lined with ciliated epithelium and containing cholesterol crystals are separated by areas of connective tissue. More than 50 per cent. of these growths are calcified and may form coral-like masses filling the inter peduncular space and extending backwards to the pons. Since they are adherent to the basal arteries and adjacent nerves, they are irremovable. Occasionally single cysts are found in or above the sella, but the term suprasellar cyst describes only this one variety and is deceptively encouraging, as it suggests an invariably removable lesion. In fact, these tumours are by no means always suprasellar, nor are they necessarily cystic.

Clinical Features.—The symptoms depend upon the site of the tumour and the age of the patient.

(1) Intrasellar craniopharyngioma cysts produce symptoms like the inert chromophobe tumour, but in young subjects they inhibit growth by compression of the acidophil cells as well as inhibiting sexual maturation. The result is a fat, impotent dwarf, who may subsequently develop bitemporal hemianopia from upward pressure on the chiasma (Fröhlich's syndrome). Intrasellar calcification is often visible in X-ray.

(2) Suprasellar craniopharyngiomata in young subjects, by downward pressure on the sella, also produce a Fröhlich syndrome, but in this case involvement of the optic tract behind the chiasma causes homonymous hemianopia (fig. 460).

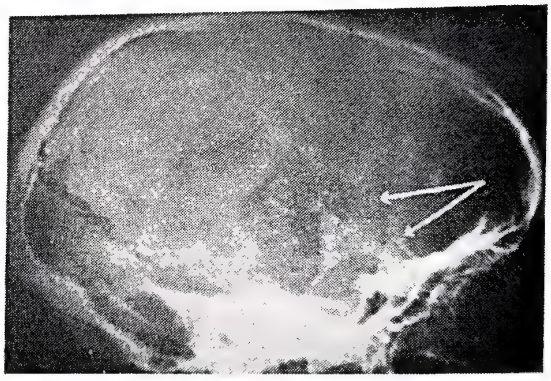

FIG. 460.—Arrows indicate suprasellar calcification in craniopharyngioma.

Pressure on adjacent centres of the hypothalamus, which control sleep and water metabolism, produce pathological somnolence and diabetes insipidus, so that the subject is liable to fall asleep during the day, and to drink and pass abnormal quantities of fluid. Similar symptoms may occur at a later age in adults.

Intraventricular tumours may produce blockage of the third ventricle with symptoms of acute intracranial pressure, headache, vomiting, and papillœdema, without localising signs; or an organic confusional state and dementia from cerebral atrophy following long-standing pressure.

Thomas Russell Cumming Fraser, Contemporary. Professor of Clinical Endocrinology, Royal Postgraduate Medical School, London

Alfred Fröhlich, 1871–1953. Formerly Professor of Pharmacology, University of Vienna, described his syndrome in 1901.

Treatment.—Cystic tumours in and above the sella may be evacuated by frontal craniotomy. When large masses block the third ventricle, the cerebrospinal fluid may be short-circulated to the cisterna magna by leading a catheter from the ventricle through a burr opening in the skull, thence under the skin and occipital muscles to drain into the cisterna magna, which has been exposed above the foramen magnum (Torkildsen's operation)—ventriculo-cisternostomy.

Simmonds' disease, 'pituitary cachexia', results from depression of pituitary secretions affecting the gonads, adrenals, and thyroid gland following destruction of the anterior lobe of the pituitary by local thrombosis, hæmorrhage, cyst distension, post-partum necrosis, head injury, abscess, or tumour. The condition has also been caused by swabbing out the pituitary fossa with sclerosing fluid following local operation. Amenorrhœa, impotence, or persistent infantilism occur in a patient whose skin is typically yellow, smooth, dry, and atrophic with loss of hair. Unlike Fröhlich's syndrome, the patient is thin and cachetic from anorexia, suffering from weakness, lack of energy, and apathy, with low blood-pressure causing syncopal attacks and hypoglycæmia which occasionally gives rise to coma.

HYDROCEPHALUS

Hydrocephalus is usually spoken of as being congenital or acquired. Subdivision of these two groups is useful from a clinical point of view. When the ventricular system is sealed off at some point, which may be as caudal as the exit foramina of the fourth ventricle, then the hydrocephalus is described as non-communicating. If the distended ventricles communicate freely with the subarachnoid space then the hydrocephalus is communicating.

Congenital hydrocephalus is often associated with other abnormalities of the neuraxis, such as spina bifida or myelomeningocœle. It is produced by defective absorption of, or obstruction to, the cerebrospinal fluid. The commonest cause is failure of development of the arachnoid villi through which absorption takes place and a communicating hydrocephalus is thereby produced. Obstruction of the cerebrospinal fluid pathways most often occurs at points of normal anatomical narrowing, i.e. the various foramina and the aqueduct of Sylvius. The commonest causes are the Arnold-Chiari malformation, in which the roof of the fourth ventricle lies below the level of the foramen magnum and there is obstruction of the exit foramina and, at a higher level, congenital stenosis of the aqueduct of Sylvius (fig. 461).

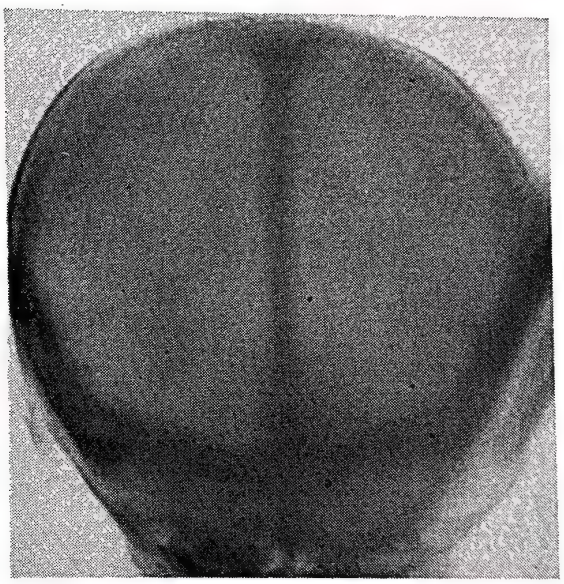

FIG. 461.—Ventriculogram showing enormous size of ventricles in congenital hydrocephalus.

Clinical Features.—The enlargement of the head may be pre-natal and constitute a rare cause of obstructed labour. After birth, rapid enlargement usually occurs. The scalp veins become distended, the fontanelles widen and are abnormally tense and the brow overhangs the roof of the orbits giving the eyes a 'sunset' appearance. Although the ventricles become

Hans Chiari, 1851–1916. Professor of Pathological Anatomy, Strasbourg University.

enormously dilated and the cortex reduced to a mere shell, there are no motor symptoms. A certain minority of cases stabilise spontaneously, and intelligence is then preserved despite the enormous size of the head. Secondary endocrine effects result from pressure of the distended third ventricle in the pituitary fossa. Congenital stenosis of the aqueduct may not produce serious symptoms until the age of six or much later. It then causes raised intracranial pressure which may be associated with secondary endocrine disturbances.

Acquired Hydrocephalus

Non-communicating hydrocephalus is produced by obstruction within the cerebrospinal fluid pathways either by a tumour or as the result of a previous inflammatory process. Obstruction most commonly occurs at the points of anatomical narrowing (*vide supra*) and that part of the ventricular system cranial to the block dilates. This dilation may be unilateral in the case of obstruction of one foramen of Monro, or bilateral and symmetrical in the case of midline tumours, e.g. colloid cysts of the third ventricle, craniopharyngiomas, pineal and cerebellar tumours, and arachnoid cysts over the roof of the fourth ventricle. Communicating hydrocephalus is usually post-inflammatory in origin and complicates acute or chronic meningitis and sarcoidosis

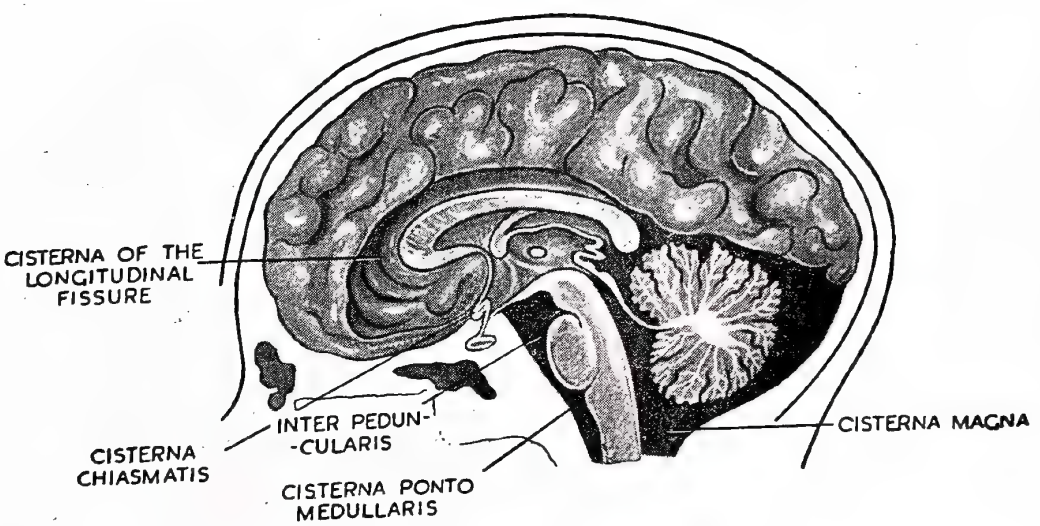

FIG. 462.—The principal arachnoid cisterns.

which has failed to respond to treatment, e.g. with antibiotics, or in tuberculous meningitis with PPD and streptomycin, or in sarcoidosis with ACTH. In acute meningitis surgical treatment consists of the formation of bi-frontal burr holes through which the ventricle can be tapped to relieve acute pressure symptoms or induce antibiotics, or in sarcoidosis with ACTH and in meningeal involvement in acute lymphoblastic leukæmia which has failed to respond to cranio-spinal irradiation and Methotrexate intrathecally. In acute meningitis surgical treatment consists of the formation of bi-frontal burr holes through which the ventricle can be tapped to relieve acute pressure symptoms or induce antibiotics. Where prolonged treatment is required a rubber

reservoir with a tube leading through the burr hole to the ventricle (Ommaya) may be inserted under the skin, injection or aspiration being performed through this reservoir. In chronic cases blockage of the basal cisterns, cisterna interpeduncularis and cisterna chiasmatis, by inflammatory exudate or arachnoiditis secondary to the inflammatory process or subarchnoid hæmorrhage, throws a dam across the main channel for the ascent of cerebral spinal fluid to the absorption areas, and hence leads to stasis in, and distension of, the lateral ventricles, which nevertheless remain in communication with the subarachnoid spaces. An uncommon cause of communicating hydrocephalus is superior sinus thrombosis which may occur as a result of infection, trauma, or spontaneously due to some defect in the coagulation mechanism as may be seen in some females taking the contraceptive pill.

In the above types of hydrocephalus the intra-ventricular pressure is usually very high. An interesting type of acquired communicating hydrocephalus is becoming increasingly recognised in which the ventricular pressure is either normal or low. This type of hydrocephalus, usually discovered during the course of investigations for dementia, appears to be a latent effect of either trauma or some degenerative process.

Treatment.—The type and cause of hydrocephalus is determined by air or myodil ventriculography. In cases of obstructive hydrocephalus the cause of the obstruction is removed if possible, e.g. tumour. The treatment of all forms of hydrocephalus however has advanced considerably in the last few years. During this time various shunting procedures have been developed and refined and have now largely replaced the older operations of third ventriculostomy and choroid plexus fulguration both of which were technically difficult and carried a high mortality.

The shunting procedures are of two general varieties:—

Intracranial Shunts.—These connect the ventricles to other intracranial areas such as the basal cisterns. Ventriculocisternostomy, in which one or both lateral ventricles are connected to the cisterna magna by polythene catheters, was devised by Torkildsen for treating obstructive lesions in the region of the aqueduct of Sylvius (p. 443).

Ventricular or Lumbar Shunts.—The basic principle involved with this type of shunt is the diversion of the cerebrospinal fluid from the lateral ventricle into a body cavity or into the right side of the heart.

Shunts without valves into the pleural and peritoneal cavities still have a limited part to play in the treatment of hydrocephalus but most surgeons now use the ventriculo-atrial shunt utilising one of the several valves now available for this purpose. All these valves have a similar function of promoting unidirectional flow of cerebrospinal fluid from the ventricles to the heart. The most popular of these are the Pudenz-Heyer and Holter valves.

The operation is simple and carries a low mortality. A tube passes from the ventricle of the brain to beneath the scalp where it connects with the valve (Holter) or a pump (Pudenz-Heyer). A further tube then passes down beneath the scalp and into the neck where it enters the common facial vein and thence into the internal jugular vein and right atrium. In the Pudenz-Heyer valve the valve is situated at the lower end of the tube in the heart.

Ayub Khan Ommaya, Contemporary. Professor of Neurology, Georgetown University School of Medicine, Washington, U.S.A.

Robert Harry Pudenz, Contemporary. Neurosurgeon, Huntington Memorial Hospital, Pasadena, California, U.S.A. Heyer, Schulte Corporation. Santa Barbara, California, U.S.A.

John W. Holter, Contemporary. Engineer, Holter Instrument Company, Bridgeport, Pennsylvania. The valve was first used by Eugene B. Spitz, Neurosurgeon, Children's Hospital, Philadelphia, Pennsylvania, and is also known as a Spitz-Holter valve.

The great disadvantage of these shunting procedures is that they necessitate the implantation of foreign material into the body and are liable to become blocked and infected. Despite these drawbacks the ventriculo-atrial shunt is a satisfactory treatment for hydrocephalus irrespective of its cause.

INTRACRANIAL ANEURYSM

Intracranial aneurysms may be considered in two main groups:

(1) *Subclinoid.*—On the carotid syphon of the internal carotid artery within the cavernous sinus.

(2) *Supraclinoid.*—On the main branch of the carotid above the cavernous sinus and on the circle of Willis.

Subclinoid aneurysms are produced by weakening of the muscle coat of the internal carotid by uneven distension of its walls at the anterior and posterior curves of the carotid syphon leading to the protrusion of a sacular berry aneurysm. The condition is most common in women owing to the finer structure of their arteries.

These aneurysms are produced on the anterior and posterior bends, and hence anterior and posterior syndromes may be recognised which vary only in regard to the physical signs produced by pressure of the aneurysm sac on adjacent structures.

Symptomatology.—A female patient is suddenly seized with severe unilateral headache, resulting from stretching of nerve fibres in the wall of the distending carotid artery. This ceases only when the wall of the artery comes against the wall of the cavernous sinus and receives support from this structure. The headache ceases, but soon additional symptoms appear from pressure on the nerves in the lateral wall of the cavernous sinus. These produce a combination of squint and trigeminal pain.

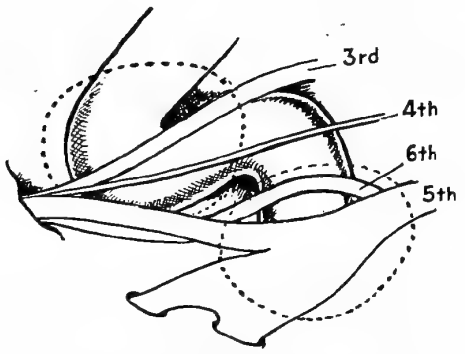

FIG. 463.—The relationship of aneurysmal sacs to structures in wall of the cavernous sinus.

Anterior Aneurysms.—The commonest type press on the third and fourth nerves and first division of the fifth, causing supraorbital pain associated with ptosis, a dilated pupil, and divergent squint, owing to paralysis of the third nerve and unopposed action of the sixth.

Posterior aneurysms press on the sixth nerve and the whole of the trigeminal, causing pain in the entire face with a convergent squint from sixth-nerve paralysis and unopposed action of the third, the eye remaining open.

Treatment is highly successful except in long-standing cases where the sac has filled with hard organised clot and cannot collapse. Ligation of the internal carotid might cause hemiplegia if the circle of Willis were sclerotic or if the anterior communicating artery were absent. Ligation of the common carotid, however, is employed with safety and with good effect. This reduces pressure in the sac and relieves the nerve symptoms without risk of hemiplegia, since there is a second-cross circulation above the level of the ligature. Blood passes across through the branches of the external carotid to reach the site of the ligature, then downwards to the carotid bifurcation above the ligature and upwards with the internal carotid with reduced force but in sufficient volume to prevent cerebral anæmia.

Arterio-venous fistula in the cavernous sinus may occur *spontaneously* from rupture of a subclinoid aneurysm or from the effects of *trauma* on the arterial walls in association with head injury. Acute back pressure in the veins draining into the cavernous sinus produces pulsating exophthalmos, distension of the orbital and supra-orbital veins, and bone erosion and enlargement of the orbit. A few cases heal spontaneously by aseptic thrombosis in the cavernous sinus occurring in the early stages. Usually, however, the condition will progress if untreated, and produce a terrible deformity, with extrusion of the eyeball.

Treatment.—Ligation of the internal carotid in the neck may be sufficient, but if the condition progresses as the result of cross circulation through the circle of Willis, the internal carotid must be occluded intracranially by the application of a silver clip inserted across the vessel above the level of the cavernous sinus.

Supraclinoid Aneurysms.—Congenital aneurysms of the circle of Willis may produce pressure on adjacent nerves. Rupture produces symptoms of subarachnoid or intracranial hæmorrhage with or without associated pressure symptoms. They may rarely produce multiple emboli causing a progressive syndrome of paralysis.

Pressure Symptoms.—Aneurysms on the posterior branches of the circle, posterior cerebral and posterior communicating, produce symptoms of third nerve palsy. Posterior cerebral aneurysms also cause hemianopia or pressure on the crus. Aneurysms of the anterior branches, such as the internal carotid bifurcation, anterior cerebral, and anterior communicating produce pressure on the optic tracts, optic nerves, and chiasma respectively, producing hemianopia, monocular visual loss, or bi-temporal hemianopia and optic atrophy.

Middle cerebral aneurysms produce symptoms of hemiparesis from involvement of the striate branches, often by emboli. These symptoms may occur alone or in association with subarachnoid or intracerebral hæmorrhage.

Subarachnoid Hæmorrhage

This condition arises from a variety of causes. Berry aneurysms, responsible for more than half of all cases of spontaneous subarachnoid hæmorrhage, are considered secondary to a congenital weakness of the muscle coat of an artery, usually at branchings. Though commonest between the ages of 40 and 60 and rare in infants, no age is exempt from hæmorrhage due to rupture of an intracranial aneurysm. The commonest sites are (1) On the internal carotid at its junction with the posterior communicating artery; these are named ' posterior communicating ' aneurysms whether or not the posterior communicating artery can be demonstrated angiographically. (2) Elsewhere on the internal carotid artery, on the internal carotid trunk above the cavernous sinus, sometimes at the origin of the ophthalmic artery, sometimes at the bifurcation of the internal carotid itself. (3) On the anterior communicating artery. (4) At the trifurcation of the middle cerebral artery. Of aneurysm at these sites, those on the posterior communicating, middle cerebral and anterior communicating complex are about equally common and together constitute about 80% of all berry aneurysms. 20% of the patients have more than one aneurysm.

Atherosclerotic aneurysms occur in middle and advanced age and are fusiform or irregular dilatations, commonest on the trunk of the middle cerebral, basilar or vertebral arteries. They may co-exist with congenital aneurysms.

Mycotic aneurysms are rare complications of bacterial endocarditis. Their rupture carries a high mortality.

Vascular malformations involving arterio-venous shunts are similar to cirsoid aneurysms elsewhere. Arterialised varices burst into the substance of the brain and only secondarily into the subarachnoid pathways. An intracranial bruit may be audible by the patient or examiner, and occasionally, apart from rupture, they may be responsible for epilepsy or unilateral migraine (*vide infra*).

Clinical features of Subarachnoid Hæmorrhage.—Sudden, intense, incapacitating headache, particularly in a patient not subjected to migraine, is best suspected as due to subarachnoid hæmorrhage, and should lead to admission to hospital. There is frequently vomiting, confusion, restlessness or convulsions; but ruptured aneurysms do not cause immediate hemiplegia unless complicated by catastrophic intracerebral extension of the hæmorrhage. The patient may fall unconscious before having time to complain of headache, or on recovery of consciousness be amnesic. Such a seizure is often understandably mistaken for epilepsy or syncope, but persistent severe headache then should lead the practitioner to suspect intracranial bleeding. Photophobia almost always appears early, but neck stiffness is not constant in the early stages. Within a few hours to 3 days drowsiness may deepen to coma, with or without an advancing hemiparesis, dysphasia, hemianopia, papillœdema, retinal hæmorrhages or bilateral extensor plantar responses. Major epilepsy is of bad prognosis. There may be albuminuria, glycosuria, or cardiac irregularities with E.C.G. changes; and the blood pressure is often boosted far above the patient's normal range.

Lumbar puncture must always be done. It is important to take at least two consecutive specimens into separate containers for comparison. In subarachnoid hæmorrhage from any cause the fluid is evenly blood stained, and the finding of xanthochromia in the supernatant fluid confirms the diagnosis.

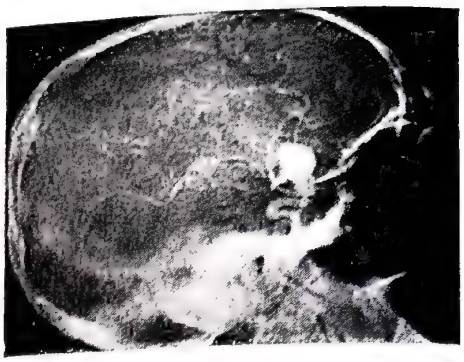

FIG. 464.—Large aneurysm of anterior cerebral artery, producing monocular blindness.

Prodromal symptoms are uncommon. There may be comparatively mild headache due to distension of the aneurysmal sac, lasting from a few hours to a few days before rupture. Unilateral supra-orbital pain, without tenderness or other signs of frontal sinusitis is suspicious of an enlarging posterior communicating aneurysm. Paræsthesia in a limb sometimes immediately precedes hæmorrhage from a vascular malformation.

Prodromal Signs.—The most important of these is unilateral 3rd nerve palsy, presenting as ptosis. When accompanied by the supra-orbital pain mentioned above it is an urgent warning of enlargement of a posterior communicating aneurysm demanding confirmative angiography and treatment before it ruptures. Rapidly advancing hemianopia or unilateral blindness may indicate enlargement of an internal carotid aneurysm adjacent to the chiasm. Subclinoid aneurysms may cause cranial nerve palsies (p. 446).

Treatment of Subarachnoid Hæmorrhage.—Unless the surgeon is fortunate enough to be presented with a case of aneurysm before it bursts, treatment is directed primarily towards preventing a repetition of bleeding; for without treatment more than half the patients admitted to hospital will be dead within 6 months. Recurrence is commonest in the 2nd, 3rd and 4th weeks after the first hæmorrhage, and after the elapse of 8 weeks the recurrence rate drops to 20%. Angiography may be followed by surgery as early as the third day if the patient is well enough. Aneurysms of the *internal carotid* artery, either posterior communicating aneurysms or elsewhere, are, in the opinion of most surgeons, treated best by closure of the common carotid artery in the neck, which usually reduces the pressure in the aneurysm sufficiently to make it safe from further bleeding. Since ligation of the common carotid artery carries up to 25% risk of hemiplegia within the first 5 days, one of the reversible methods of closure should be used. Screw clamps have been devised in an attempt to occlude the artery gradually; but though these are safer than outright ligation, they have proved unreliable, for not only is it difficult to be certain when the clamp is closed, but hemiparesis may become worse rather than better if it is opened. Closure by distortion has been advocated as a more certain method, with the advantage that no foreign body is retained permanently in the neck (J. R. Gibbs).

Cervical carotid occlusion is of limited value in the treatment of aneurysms other than those on the internal carotid, because of free anastomosis at the circle of Willis.

Middle cerebral aneurysms are best treated by direct attack—exposure of the aneurysm in the Sylvian fissure and either obliterating it with clips, or wrapping it with a protective layer of muscle, plastic or gauze. These aneurysms rarely have a narrow neck amenable to clipping, and the greatest danger of operation involving a complete exposure and wrapping, is vascular spasm, set up by the necessary manipulations; such spasm is liable to cause hemiplegia or even death.

Anterior communicating aneurysms, if presenting a narrow neck, may be treated by clipping. But most are globular, and the risk of complete exposure for wrapping is increased by the necessity of separating the frontal lobes, already damaged by hæmorrhage. Rupture of these aneurysms is particular liable to cause intellectual deficit, which may be exaggerated by operation. Many surgeons believe that clipping of the anterior cerebral artery on the side more readily filling the aneurysm at angiography is the safest procedure. Though it does not always protect the aneurysm from further bleeding it is less likely to cause infarction of both frontal lobes than is direct attack.

Aneurysms on the *vertebral and basilar systems*, constituting about 12% of berry aneurysms, carry particular dangers during operative approach. Operation is best undertaken for the least rare of these lesions, an aneurysm at the bifurcation of the

John Reynell Gibbs, Contemporary. Neurosurgeon, Brook General Hospital, Woolwich, London.

basilar artery. Techniques have lately improved, including the use of operating microscopes and bipolar diathermy.

Vascular malformations are treated by excision of that part of the lesion containing the actual arterio-venous shunt, including brain tissue immediately surrounding it. The risk of fatal recurrence from these lesions is much less than that from berry aneurysms, and treatment is neither so urgent nor so imperative. No attempts at removal should be made therefore, when the shunt occupies an essential area of the brain.

Intracerebral Hæmorrhage

The classical apoplexy, occurring typically in the ageing plethoric man with known hypertension and arteriosclerosis, is usually diagnosed correctly by the family doctor. Fatal cases present with sudden stupor, stertorous respirations and hemiplegia. In younger patients with no known arterial disease, rupture of a berry aneurysm is the commonest cause of such a picture, and the early hemiplegia is due to encroachment of profuse hæmorrhage from the subarachnoid space into brain tissue. In both these cases only limited success may be hoped for from the removal of the blood clot from the brain, for much damage to neurones has already been done at the time of the hæmorrhage, and removal of the mass, though it may save the patient from death due to raised intracranial pressure, is often disappointing as far as restoration of cerebral function is concerned.

The diagnosis of intracerebral hæmorrhage is confirmed angiographically by localised shift of cerebral vessels. Removal of the clot is done most effectively by excision of a disc of bone large enough to allow aspiration under direct vision, rather than by a brain needle through a single burr hole.

Intracranial angiomas are congenital malformations and not true tumours. Although an excess of blood passes through the large arterio-venous malformations, absence of a true capillary system causes defective nutrition of the affected area, with death of tissue, gliosis, and calcification. This may produce epilepsy and paralysis, often in adult life. Alternatively, the angioma may rupture spontaneously or following a minor trauma, producing apoplexy in young subjects. Common carotid ligation always reduces the rate of blood flow through the tumour bed, which may be completely filled by cross circulation.

SURGICAL TREATMENT OF MENTAL DISORDERS

The surgical treatment of mental illness has undergone refinement. The early crude beginning followed the observations by Egas Moniz in 1936, that the injection of alcohol into both frontal lobes would produce a diminution in the intensity of emotional distraction in severely disturbed psychotic patients.

The operation of pre-frontal leucotomy sought to secure a similar effect by subcortical division of the entire central cone of white matter in both frontal lobes by a vertical incision in front of the ventricles. Although this operation relieved symptoms of agitation and tension it caused extensive brain damage with serious blunting of intelligence, flattening of emotion, and a high risk of epilepsy and could therefore only be considered in seriously disturbed schizophrenic patients who seldom made a satisfactory response—fewer than one fifth being discharged from hospital, the remainder confirmed in mental hospitals to form a permanent source of discouragement to psychiatrists. However, it could be seen that if a similar reduction in the intensity of emotional reaction could be secured without damaging effect, surgical treatment might be extremely valuable in cases of incurable psychoneurosis such as suicidal depression, melancholia, anxiety states and obsessional syndromes.

Ablation experiments in monkeys showed that lesions in the region of the primitive agranular cortex on the mesial and orbital aspects of the lobe produced an alteration in emotional tone without intellectual defect, indicating that the future of surgical treatment would lie in operations that interrupted the connections of the agranular cortex in the limbic system.

Le Gros Clark's observations on the distribution of the thalamo-frontal and fronto-hypothalamic pathways concerned in emotional feeling and reaction, provided a target for selective operations on limited cortical areas of the cingulate, convexity and orbital cortex which were excised by lobectomy or isolated by undercutting whilst leaving the majority of the frontal lobe undisturbed in attempts to produce a reduction

Egas Moniz, 1874–1955. *See footnote, p. 434.*
Sir Wilfred Edward Le Gros Clark, 1895–1971. Professor of Anatomy, Oxford, England.

in emotional tension in psychoneurotic subjects. Certain of these operations, notably those that affect regions of primitive agranular cortex such as cingulectomy and restricted orbital undercutting, were highly successful in the treatment of obsessional illness and depression.

In 450 cases of Restricted Orbital Undercutting (Knight) the best results were among the depressions, over 60 per cent. of whom could be freed from medical care when psychiatric treatment had failed. Certain cases of chronic alcoholism and drug addiction were favourably influenced but the scar in the brain still produced a 10 per cent. risk of epilepsy and 3 per cent. risk of undesirable personality change. Observations indicated that the benefit was derived from the posterior 2 cm of the undercutting incision beneath the head of the caudate nucleus. At this site pathways which are concerned in emotional reaction can be selectively divided by small lesions which leave the rest of the frontal lobe intact and the thalamo frontal pathways of emotional feeling undisturbed at a higher level. Beneath the caudate, fibres from the cingulate and posterior orbital cortex to the hypothalamus can be divided together with certain amygdaloid connections and also those fibres from the frontal cortex to hypothalamus which pass beneath the caudate nucleus to influence the limbic system.

The operation of stereotactic tractotomy (Knight) destroys this limited zone by the insertion of radioactive seeds or electro-coagulation under X-ray control and eliminates the harmful effects of cutting in the brain. Satisfactory results are observed in depression, obsessional illness and anxiety states without epilepsy, mortality, or personality change. The accuracy of operation has produced cures in many cases of previous failed leucotomy.

SURGICAL TREATMENT OF PARKINSONISM

Parkinson's disease (*syn.* paralysis agitans) is a condition characterised by tremor, rigidity, and akinesia. Unilateral or bilateral rhythmic tremor, producing the typical pill-rolling movement of the fingers and thumbs, may also affect other sites, e.g. the face, jaw, palate, tongue, and lower limbs. Excessive muscular tonus causes a rigid, expressionless, mask-like facies, an unblinking stare, and limb rigidity. The shuffling Parkinsonian gait with short steps results from rigidity and akinesia. A variable degree of dementia is also present in some cases. It is necessary to estimate the part played by each symptom in causing disability.

The syndrome is produced by degenerative changes in the extrapyramidal pathways—particularly at the substantia nigra in the brain stem. Degeneration of the large pallidal cells of the corpus striatum may be responsible for excessive rigidity.

Surgical Treatment:[1]

Small discrete lesions in the globus pallidus or ventro-lateral nucleus of the thalamus are found by stereotactic technique. The target area is determined by air and myodil ventriculography which shows the position of the anterior and posteror commissures to which the globus pallidus and ventro-lateral nucleus bear definite measurable relationships. A burr hole opening is made in the skull in an appropriate situation. Special aiming apparatus is then fixed to the skull carrying a device adjustable in the sagittal and in the coronal plane, by which a needle or electrode is introduced through the burr hole and advanced towards the target for an appropriate distance, as measured from the X-rays. The position is checked by electrical stimulations, and when the correct site has been reached, small areas can be destroyed by electrocoagulation, by the introduction of radioactive substances, or by injection of alcohol.

Results suggest that tremor responds best to lesions in the thalamic nucleus, and rigidity to lesions in the globus pallidus and adjacent internal capsule. Combined lesions at both sites give the best results. Patients with unilateral syndromes sufficiently severe to interfere with their occupation respond best. Bilateral syndromes are treated in two stages, at an interval of months.

If mental impairment is prominent before operation, added mental inertia resulting from the operation may reduce the patient to inactivity, although symptoms are relieved.

---

[1] Just as the advent of hexamethonium in the 1950's edged out the extensive sympathectomy operations for hypertension, so too has the advent of L-Dopa reduced the need for this precision operation.—*The Editors.*

CHAPTER 25

THE SPINE

THE VERTEBRAL COLUMN AND SPINAL CORD

Sprains of the spinal column are of common occurrence. Spinal ligaments are injured as a result of a sudden jolt, as in car or railway accidents. Fibres of spinal muscles are torn by excessive muscular contraction as in lifting heavy weights. Severe localised pain follows, accentuated by any movement which stretches the damaged structure. Palpation reveals a tender spot, and if muscular fibres are torn some bogginess, due to extravasation of blood, is often detected. Treatment consists of rest and cold applications followed a few days later by massage and graduated movements. If the site of pain can be localised with accuracy, an injection of 5 ml. of procaine (2 per cent.) may cause immediate improvement. This is particularly true in relation to the interspinous ligaments which are liable to be overstretched in association with compression fractures of the vertebræ, or may produce long-lasting syndromes of chronic pain as a result of local injury to the ligament itself.

DISLOCATION

True dislocations can occur only in the cervical region, the oblique and vertical directions of the articular processes do not permit of dislocation without fracture in the dorsal and lumbar regions.

Dislocation following hanging occurs between the atlas and the axis.

Forward displacement of the atlas follows rupture of the transverse ligament, or less commonly fracture of the odontoid process. Death occurs immediately from injury to the brain stem and paralysis of the muscles of respiration. Dislocation at this level has also occurred from lifting a child by means of the hands encircling the neck from behind.

The base of the odontoid process may be cracked following head injuries and delayed displacement may occur after an interval of days. X-rays of the odontoid process, taken through the mouth, are essential where persistent occipital pain complicates head injuries.

Dislocations usually occur at the sites of maximum mobility, between the fourth and fifth, and fifth and sixth cervical vertebrae resulting from falls on the head when riding, or diving into shallow water, which causes excessive flexion of the upper part of the spine. The inferior articular process of the fifth vertebra is forced over the front margin of the superior articular process of the sixth. When bilateral there are usually some associated features.

When the dislocation is unilateral the head is turned towards the opposite side and all movements are restricted. Severe head pain occurs if a nerve is nipped in the intervertebral foramen. Unilateral dislocations are readily reduced under general anæsthesia, by further flexion of the head, followed by lateral flexion towards the opposite side. If reduction fails, the joint should be exposed and a minimum of bone removed in order to allow

unlocking. If the dislocation is unreduced, pain and deformity will persist. Involvement of the spinal cord is uncommon in one-sided dislocations.

In *bilateral* cases associated damage to the cord often occurs, usually of a complete nature. In more fortunate cases, owing to the large size of the cervical canal, the cord escapes serious injury. The head is displaced forwards, and obvious deformity is present. Pain is referred to the neck, or arms, along the compressed nerve roots.

Emergency reduction should be attempted under anæsthesia. If reduction is accomplished, traction is maintained and a plaster cast is then applied. Should manipulation fail, continuous skeletal traction is applied by means of a skull calliper. Only as a last resort is open operation performed. A minimal amount of bone is removed from the articular processes until unlocking is possible. To prevent recurrence the spinous processes should be wired together. The head and neck are immobilised in plaster for six weeks.

Pathological dislocation of the atlanto-axial joint occasionally complicates a retropharyngeal abscess, or even tonsillitis. Flexion of the head and torticollis are obvious signs. The condition is confirmed by X-rays. Traction is required for a few weeks, followed by plaster fixation, and the pharyngeal abscess receives appropriate treatment (p. 667).

FRACTURES

Incomplete fractures do not interfere with the continuity of the spinal column. They include fractures of the spinous and transverse processes, laminæ, and fissured or compression fractures of a vertebral body. Fractures of the processes or laminæ are usually due to direct violence. Fractures of the spinous processes are common in the dorsal region for the processes are long and exposed to injury in falls on the back. Shovellers' fracture is a 'stress' fracture of spinous processes which occurs in men who use a shovel excessively, especially if they are undernourished. Localised pain and perhaps crepitus suggest the nature of the injury which is seldom shewn by radiography. Fracture of the transverse processes occurs most usually in the lumbar region, where these processes are long and comparatively unprotected; a corresponding kidney may be injured. Fracture of a lamina may be associated with depression of bone and injury to the underlying cord.

Compression fracture of a vertebral body may cause immediate hæmatomyelia and cord damage. Usually, however, only severe local pain is experienced necessitating X-ray examination, which may only reveal compression in the lateral view. It is probable that most cases of Kümmell's disease are due to compression of a vertebral body at the time of injury rather than the development of osteitis, as was formerly believed. Pain and deformity lead to an X-ray examination which reveals rarefaction and collapse of the body of a vertebra, usually in the lumbar region (fig. 465). Support to the spine is necessary for one year although Albee's bone-graft operation finds favour with some surgeons.

Traumatic intraspinal hæmorrhage may occur in association with fractured laminæ or pedicles, or compression fractures.

Hæmorrhage occurs either in the cord itself (hæmatomyelia) or as an extramedullary condition (hæmatorrachis); in the latter case the blood escapes either into the cerebrospinal fluid or the extradural space.

Intradural hæmorrhage produces symptoms of root irritation and is detected by finding old blood and an excess of lymphocytes in the cerebrospinal fluid at lumbar puncture.

Extradural hæmorrhage may fill the spinal canal gradually from below upwards causing progressive compression of the cord, followed by paraplegia (Thorburn's gravitation paraplegia).

Hermann Kümmell, 1852–1937. Professor of Surgery, Hamburg.
Fred Houdlett Albee, 1876–1945. Professor of Orthopædic Surgery, Post-graduate Medical School, New York.
Sir William Thorburn, 1861–1923. Professor of Clinical Surgery, University of Manchester.

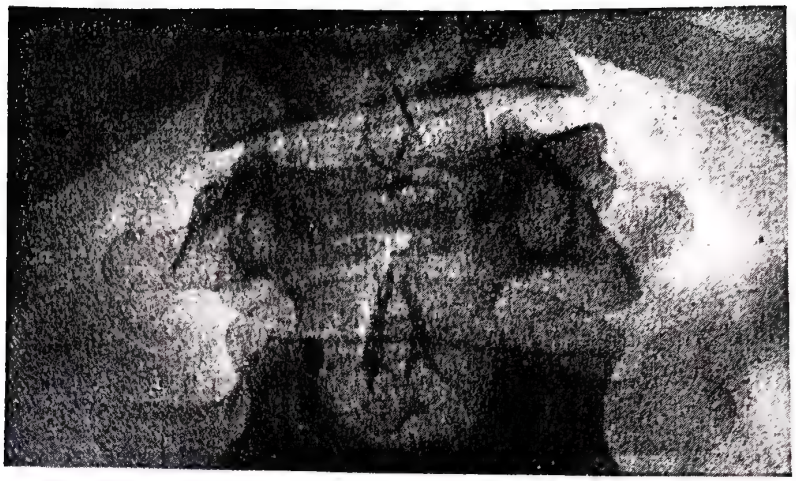

FIG. 465.—Kümmell's disease affecting the first lumbar vertebra.

Intramedullary Hæmorrhage.—Hæmatomyelia causes symptoms which follow the injury immediately. Destruction of the anterior horn cells causes a flaccid paralysis of the muscles concerned, while injury of the pyramidal tracts results in some spasticity of the legs. Pain and irritation are much less than in cases of extra-medullary hæmorrhage. Bruising of the cord against the bony bars produced by cervical spondylosis sometimes results from minor falls or whiplash injuries. In the early stages symptoms and signs are often vague. Subsequently, obvious neurological signs, e.g. muscular wasting, present themselves, and are usually permanent.

Complete fractures interrupt the continuity of the spinal column and consist of fracture-dislocations of the spine. These are usually produced by excessive flexion and occur at the sites of maximum mobility, C.5 to C.7 and L.3 to L.5, or at the junction of fixed and mobile portions of the spine. The prognosis is governed by the presence or absence of injury to the spinal cord and nerve roots.

SPINAL CORD INJURY

is produced by three factors:

(1) By long axis stretch occurring at the moment of acute flexion, causing concussion or rupture of nerve fibres and vessels within the cord.

(2) By nipping of the cord between the lamina of the vertebra above and the edge of the fractured body below, producing a local crush of the cord.

(3) By the protrusion of a disc at the moment of flexion leading to compression of the anterior aspect of the cord.

In the adult the spinal cord ends at the level of the lower border of the body of the first lumbar vertebra; hence fracture-dislocations below this level can only be associated with injury to the cauda equina. Anatomical factors govern the extent of the cord and nerve lesion at various levels.

In the cervical spine the horizontal line of the articular processes and the large intervertebral discs produce a high degree of mobility with little strength, hence dislocation or fracture-dislocation occurs readily as a result of relatively minor forces sustained in injuries at sport, such as falls on the head in riding, diving, cycling, or football. Since there is relatively little 'follow-through' produced by such forces and since the size of the neural canal in the cervical region is large in relation to the cord, cord injury may

be partial or absent. When greater forces are in action, as when the neck is struck by a falling bough, considerable displacement occurs. Cord injury is then complete and often fatal.

In the dorsal spine the vertical articular processes and low mobility, combined with great strength, account for the fact that the spine can only be broken by major forces, such as the collapse of a roof in a mine-working; displacement is therefore considerable, little space is available around the cord, and cord injury is invariably present and usually severe.

In the lumbar spine vertical articular processes and great strength are combined with mobility. Fracture-dislocations are produced by major forces, often combined with some degree of rotation which causes interlocking of the displaced articular facets. But since the roots of the cauda equina enjoy ample space in the lumbar theca, nerve injury may be absent or limited to a few roots of the cauda. The treatment of fracture-dislocations (p. 456) is of secondary importance to the treatment of the associated cord injury.

Injuries of the spinal cord occurring in association with fracture-dislocation and dislocation consist of (1) spinal concussion or (2) partial or complete spinal contusion.

Spinal concussion (**spinal shock**) is produced by long axis stretch on the spinal cord accompanying flexion. The grey matter of the cord consists of numerous nerve cells and synapses supported by a delicate tissue framework. A long axis stretch causes displacement of these structures with resulting disturbance of synaptic conduction. There is therefore an immediate loss of all functions which depend upon synaptic activity below the level of the lesion. Each anterior horn cell receives some hundreds of synapses, the stimuli passing through which maintain the central excitatory state in the nerve cell, by which the cell is maintained in a condition of readiness to respond and act as the final common path for voluntary movement, muscle tone, and reflex activity.

Cessation of the central excitatory state following synaptic disturbance therefore results in complete loss of voluntary movement, abolition of tone and reflex activity below the level of the lesion, producing a flaccid paralysis and retention of urine.

Pain and temperature sensation which cross a synapse in the inferior sensory decussation are also lost, but joint position sense which ascends the posterior columns is preserved. If the injury is merely spinal concussion, voluntary power and sensation will return within twenty-four to forty-eight hours. If concussion is superimposed upon an underlying partial or complete cord injury, the stage of spinal shock is prolonged. As time passes without improvement, recovery becomes increasingly improbable, and the appearance of a mass reflex at three to six weeks renders the outlook gloomy.

Partial or complete contusion of the cord is produced by nipping of the cord between the lamina of the displaced vertebra above and the edge of the fractured vertebra below; this causes a transverse zone of contusion and

bruising. Above and below this level minute petechial hæmorrhages may be seen, resulting from the rupture of cord vessels by the long-axis stretching force. Œdema developing around these hæmorrhages may lead to a rise in the level of paralysis and sensory loss in the early days after the injury. Massive hæmorrhage 'hæmatomyelia' is occasionally seen in the cord substance. Any damage inflicted on the cord is permanent and irreparable (p. 453).

Clinical Features.—The immediate effect of injury produces an initial picture of spinal shock resulting from the long axis stretch which masks the effects of the underlying organic rupture. There is, therefore, complete flaccid paralysis below the level of the lesion with retention of urine. The diagnosis of cord contusion can only be made with certainty in the early stage:

(1) If there is complete loss of all forms of sensation below the level of the lesion. This indicates interruption of the posterior columns (which escape the synaptic disturbance of concussion) by bruising on the back of the cord.

(2) If the level of sensory loss and paralysis rises after injury, indicating ascending œdema.

(3) If the stage of spinal shock persists for more than forty-eight hours. In general terms, the duration of the stage of flaccid paralysis is proportional to the severity of the contusion. This stage of spinal shock may last for weeks in severe cases.

The clinical course of cord contusion falls into three stages:

(1) The stage of spinal shock.
(2) The return of reflex activity.
(3) The stage of septic complications.

In the stage of spinal shock, suitable measures are taken to protect the cord from further damage, and await the return of reflex activity in order to judge from the character of the reflex changes observed the nature and extent of the cord lesion. During this period precautions are taken to prevent or combat the onset of septic complications, such as urinary infection, bedsores, and pneumonia, in order to bring the patient to the final phase of active rehabilitation.

The Management of Cord Injuries.—In the stage of spinal shock every care must be taken to avoid unnecessary movement or examination which might increase the cord damage.

First Aid Treatment.—Cervical injuries may be transported on the back with the head supported between sandbags *without* flexion. Dorsal and lumbar fractures should be transported with the patient face downward with the pelvis and shoulders raised on pillows to hyperextend the spine. The patient must be lifted and turned on to a blanket, placed on a stretcher, by three people (or more, if the patient is heavy), controlling the head, trunk, and pelvis, without bending or torsion of the unstable spine. Morphia or other available sedation should be given to relieve pain and anxiety.

Clinical Examination.—On arrival at hospital the patient should be left

lying on his stretcher until examination is completed and immobilisation is carried out. He should not be moved either for X-ray or clinical examination. Partial cord lesions may be rendered complete by excessive movement during clinical examination or over-zealous attempts to obtain a 'good' X-ray picture.

Evidence or history of an accident is usually obtainable. Neurogenic shock frequently accompanies the injury, but the patient may be able to state that he has severe pain in the back, girdle pains encircling the body, or that he 'feels dead' below a certain level.

The utmost gentleness must be exercised in order to prevent further injury to a cord which is only partially damaged or to avoid injury to an undamaged cord. Deformity of the vertebral column may be noticed. Paraplegia and anæsthesia extending from the level of the lesion are usually present, and are due either to spinal concussion, or crushing of the cord. The only examination required is to test the sensory level to pin-prick on the trunk, which will indicate the segmental level of the cord lesion, and to test whether the patient can recognise movement of the foot or knee. If he can appreciate these movements, the case may be one of concussion. If there is complete sensory loss the outlook is grave. Having determined the segmental level of the lesion, as good an X-ray as possible should be taken by the lateral view at the corresponding vertebral level without disturbing the patient. Fracture of the manubrium sterni may be associated with fractures in the dorsal region. If a fracture-dislocation is present the fracture is immobilised as soon as the patient's general condition permits, but it may be necessary before this to apply restorative measures to counteract shock.

Immobilisation.—*Cervical fractures* are treated by head traction with skull callipers, the patient lying on an inclined plane. After reduction is complete a plaster collar is applied from the crown of the head to the chest wall encasing brow, head, neck, and upper thorax but leaving the face exposed, producing an appearance reminiscent of an ancient casque and shoulder armour, from which the term Minerva[1] collar derives.

Dorsal and Lumbar Fractures.—Many cases of compression fracture in the dorsal region are treated by posture without plaster support. Dorsal and lumbar fractures produced by excessive flexion of the spine are immobilised in plaster with some extension to correct the deformity. The trunk is covered with a stockinette vest. The body is supported in canvas slings and plaster is applied from the pelvis below to the axilla above. A window is cut to compensate for abdominal distension. Excessive extension should be avoided, acute dilatation of the stomach is a rare complication of hyperextension as the third part of the duodenum may be thrust forward by the lumbar convexity. In the following conditions the spine is immobilised in a normal posture:

1. Comminuted fractures which involve the neural canal. The spine is immobilised in the normal position with head traction if necessary.
2. Fractures due to hyperextension associated with rupture of the anterior common ligament of the vertebræ.
3. Fracture dislocation with locking of articular processes in the lumbar region. The superior processes of the lower vertebræ must be excised at a later stage.

Methods of immobilisation only protect the cord from further injury, they do not relieve the existing damage to the cord which may well be increased by unwise operative intervention, e.g. plating.

[1] Minerva—Goddess of Wisdom and Arts.

Nursing.—Symptomatic treatment is now instituted. To prevent bedsore formation scrupulous drying and powdering of the skin is combined with regular turning of the patient every two hours to prevent local pressure, the patient being turned day and night in a Hey Groves bed or on banks of pillows. Since plaster immobilisation increases the risk of pressure sores, plasters should only be kept on in cases of incomplete cord lesion in which there is prospect of neurological recovery. Once there is evidence that the cord is hopelessly damaged the plaster case should be removed to diminish risk of pressure sores which delay the commencement of active rehabilitation. Attention to the bowels is necessary, and aperients or enemas are administered as required. If meteorism is allowed to occur upward displacement of the diaphragm causes pulmonary embarrassment. Hypostatic pneumonia is a grave danger, particularly if important accessory muscles of respiration, e.g., abdominal muscles, are paralysed, when coughing and expectoration are hampered. Contracture of muscles is prevented by frequent passive movements of the limbs.

Diet.—The patient should be given a high-protein diet to compensate for loss of serum from bedsores.

Care of the Bladder in Cord Injuries.—All cord injuries suffer from retention of urine in the initial stages. This may last for a few days to a year in recoverable lesions, or be permanent in complete lesions. Sixty per cent. of the mortality of spinal injury is attributable to ascending urinary infection producing pyelonephritis, and this infection results from instrumentation.

The Care of the Bladder is described in Chapter 55.

The Return of Reflex Activity.—Spinal shock should show some evidence of abatement at the end of 48 hours. If no sign of recovery is evident then the prognosis is gloomy for there is bound to be partial or complete contusion of the cord in such cases. The phase of spinal shock and flaccid paralysis persists for days or weeks according to the severity of the cord lesion. When it passes off it will be found that lower motor neurone paralysis persists in a few muscle groups corresponding to the level of the lesion, owing to the crushing of the anterior horns at this level.

Partial cord lesions show spastic paralysis in extension with exaggerated reflexes and extensor plantar responses, and sometimes with uninhibited flexor spasms. There may, however, be some return of sensation. Retention of urine may persist for up to one year.

Complete cord lesions are followed by spastic paralysis in flexion with gross flexor spasms and the appearance of mass flexor reflexes of spinal automatism, which indicates complete lack of inhibition of the spinal flexor reflex arcs. In this reflex the slightest touch on the foot will produce flexion of the ankle, knee, and hip on the side of stimulation followed by a similar contraction of the opposite leg, sometimes associated with evacuation of the bladder and rectum. The result of this reflex may be distressingly encouraging to the patient as it may be misinterpreted as evidence of recovering function, whereas it indicates that function can never recover. This 'mass

Ernest William Hey Groves, 1872–1944. Professor of Surgery, Bristol, England. Co-founder (with Moynihan) and first Editor, British Journal of Surgery.

reflex' and the position of flexion may lead to the production of deep sores on the front of the thigh where this is cut into by the plaster shell. Since the cord is irreparably damaged the plaster case should be discarded once the diagnosis is established in order to keep the patient in as good a condition as possible for rehabilitation.

Cervical.—In high cervical lesions all the respiratory muscles are paralysed, including the diaphragm, which receives its motor supply from the phrenic nerves, mainly the C.4 segment. If the fifth segment is injured, the arms, trunk, and legs are all paralysed, and the patient only breathes with his diaphragm.

In lesions of the sixth cervical segment the only movement remaining is abduction of the shoulder by the deltoid muscles, the biceps and triceps and small muscles of the hand being totally paralysed. At the seventh segment flexion of the elbow is retained by the action of biceps and brachioradialis but the triceps is paralysed. Lesions at the first thoracic level produce paralysis of the small muscles of the hand with a Horner's syndrome from paralysis of the cervical sympathetic fibres which leave the cord at the first thoracic root (fig. 149). At lower levels a band of hyperæsthesia is usually detected encircling the trunk, one segment above the site of injury.

Lumbar.—The lumbar enlargement corresponds to the twelfth dorsal and first lumbar vertebra. It contains the centre for the nervous control of the bladder. In complete cord lesions above the tenth dorsal segment, after an initial phase of retention due to spinal shock, since the bladder centres are intact and uninhibited, an automatic bladder eventually develops, evacuation occurring when the intravesical pressure rises, the patient having to wear a receptacle.

Complete lesions involving the bladder centre at the lumbar enlargement produces permanent retention with overflow incontinence from paralysis of the detrusor muscle innervated by the third and fourth sacral nerves. But since muscles of the upper abdominal wall can be contracted voluntarily by the seventh to tenth dorsal segments, patients can be taught to evacuate the bladder by straining and by pressing their hands supra-pubically during the day. This is made easier if the resistance of the bladder neck is diminished by a transuretheral ' V ' resection of the internal sphincter (Chapter 56), but he must wear a receptacle at night.

The centre for defæcation is also situated in the lumbar enlargement and damage to this is followed by a patulous anus and incontinence.

Cauda Equina.—Injuries to the cauda equina give rise to disabilities which correspond to the actual nerves involved. Usually the injuries are in the lower lumbar region and spare the lumbar roots so that contraction of the muscles on the front of thighs and legs are preserved. Involvement of the sacral roots however, produces anæsthesia in the back of the legs and saddle area of the peritoneum with urinary retention.

Rehabilitation.—If the patient has a partial or recoverable cord lesion, plaster immobilisation of the injured segment must be maintained for an adequate period of time of from four months, by which time stability is restored by the formation of massive areas of new bone in the anterior common ligament. If however, the cord is hopelessly destroyed, the plaster on the trunk should be discarded in order to minimise pressure sore formation. The work of Guttmann has revolutionised the prospects of the paraplegic patient, who can now be taught to work and earn a living, even with a complete lesion of the cord. The principles underlying Guttmann's methods are:

(1) To bring the patient into the best possible physical condition by the elimination of sepsis from bedsores and urinary tract.

(2) To over-develop the muscles above the site of the injury so that these may move the pelvis.

(3) To move the splinted legs by movement of the pelvis.

Johann Friedrich Horner, 1831–1886. Professor of Ophthalmology, Zurich, Switzerland.
Sir Ludwig Guttman, Formerly Director of Research, National Spinal Injuries Centre, Stoke Mandeville Hospital, Bucks, England.

Toxic absorption can depress recovering activity in the cord. Once pressure sores are established the plaster should be removed as soon as permissible in order to reduce pressure, the lesion then being treated by excision and skin grafting. The treatment of the established condition is described on p. 154.

Bladder training and the treatment of refractory cases or urinary infection is described in Chapter 55.

Rehabilitation of Muscular Activity and Locomotion.—Contractures are first relieved by physiotherapy, tenotomy, or partial neurectomy. If necessary, the lower portion of the completely divided cord is *destroyed* by intrathecal alcohol injection to abolish mass reflexes and flexor spasms which would prevent walking and which may be extremely painful if any sensory fibres persist. When the legs are straight, rope climbing and trapeze work is started to encourage enormous development of the muscles of the shoulder girdle. Lying in a sling, the patient then learns to swing the pelvis from the shoulder girdle using the long muscles, latissimus dorsæ, erector spinæ, and abdominal recti and obliques. Then, with his arms supported on parallel bars, he learns to move the pelvis like a hula-hula dancer, and when proficient in this art light aluminium splints with controllable knee-locks are fitted. Using sticks, the patient moves the pelvis from his shoulder and with the pelvis go the splinted legs, thus permitting the patient to walk slowly for short distances to a wheeled chair in which he may move about and engage in sport and training in specialised occupations, such as watch-making, lens-making, diamond-cutting, etc.

Complications.—Death may result from the following causes :

(1) Shock, which may be immediately fatal.

(2) Cessation of respiration from ascending cord œdema within hours or days, if the lesion is near the fifth cervical segment.

(3) Hypostatic pneumonia within days or weeks, especially if the lesion is sufficiently high to cause paralysis of abdominal and intercostal muscles.

(4) Infection is prone to spread to the kidneys, causing death from pyelonephritis (*syn.* surgical kidneys) within months or years. Necropsy reveals the renal cortex and pelvis studded with abscesses and areas of acute inflammation.

(5) Urinary calculi may occur as immobilisation leads to decalcification, with increased renal calcium excretion, also recumbency encourages stagnation of urine in the kidneys. Infection further increases the risk. Such calculi are usually painless, even though the kidney is both obstructed and infected, since the anæsthesia of spinal injury affects visceral as well as somatic structures.

(6) Bedsores, which hasten death owing to toxic absorption.

Indications for Operation

In the Acute Stage.—For the removal of a traumatic cervical disc protrusion causing cord compression without a fracture (p. 470) or for hæmatorrachis (p. 452). Apart from these rare conditions the indications for laminectomy are nil. The cord injury is irreversible and is made worse by meddling with indriven bone.

In the Late Stages.—1. Laminectomy is rarely required for the relief of cord compression produced by an arachnoid cyst which is impairing recovery of a partial lesion. Recovery occurs up to a point then deteriorates and lumbar puncture shows a block on Queckenstedt's test (p. 465).

2. Partial facetectomy may be required to reduce interlocked facets in the lumbar region.

3. Pain produced by root compression is treated by intrathecal phenol (p. 474).

Gunshot Wounds of Spine.—Portions of metal driven against the lamina or vertebral body and bouncing off away from the cord may nevertheless inflict an irreversible injury by exciting massive hæmorrhage in the cord substance. Direct penetration reduces the cord to a custard-like mass of diffluent cord and bone chips.

INFECTIVE CONDITIONS

Meningitis.—Acute infective meningitis is likely to follow a penetrating wound, or may be a complication of septicæmia. Severe constitutional disturbances follow with local and referred pain, hyperæsthesia, muscular spasms, and increased reflexes. Extension to the basal meninges is usual, and the only hope lies in an adequate course of penicillin and chemotherapy.

Hans Queckenstedt, 1876–1918, Chief of Medical Services, Hamburg, Germany, described the test in 1916. Killed by an army waggon on last day of 1914–18 War.

Spinal Epidural Abscess.—Pus may collect in the extradural space of the cervical mid-dorsal or lumbar regions, to which infection has extended through the intervertebral foramina from adjacent sepsis, particularly from a perinephric abscess in the lumbar region. This produces a syndrome of progressive cord compression and meningeal irritation. The pus is evacuated by laminectomy.

SPINA BIFIDA

Embryology.—During the second week of intrauterine life a longitudinal furrow appears on the dorsum of the embryo, this groove being formed by infolding of the epiblast. The margins of the neural groove unite, so that it becomes converted into a tube from which the nervous system is developed. This epiblastic tube becomes separated from the surface by mesoblast, which grows over it from either side, and from which are developed the vertebræ, spinal muscles, membranes, etc. (fig. 466). In each segment bars of cartilage appear on either side of the neural tube, and during the fourth month they fuse with each other to form the vertebral arches. Failure of fusion of these arches gives rise to spina bifida, with which is frequently associated mal-development of the spinal cord and membranes. The incidence of spina bifida, excluding spina bifida occulta, is 0·1 per cent.

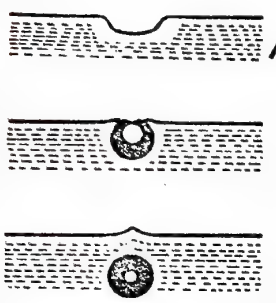

FIG. 466.—Development of the spinal cord. *E* = epiblast, *M* = mesoblast.

The types of spina bifida are as follows:

(1) *Spina bifida occulta* is due to failure of the neural arches to unite, but there is no protrusion of cord or membranes. Frequently only one vertebra is affected, most commonly in the lumbo-sacral region. A local patch of hair, a nævo-lipoma, or a depression in the skin are suggestive of underlying bony deficiency. A fibrous band, the *membrana reuniens*, connects the skin to the spina theca. Growth of the body causes the membrana to pull on the theca and nerve roots. Foot-drop, nocturnal enuresis, or backache occur when the child is older or in adult life. Many cases are symptomless and are undiagnosed unless an X-ray is taken for some other reason.

(2) *Meningocele.*—This is a protrusion of meninges through a defect in the spino-laminar segment (fig. 467). It contains only cerebrospinal fluid.

(3) *Meningo-myelocele.*—The normally developed spinal cord or cauda

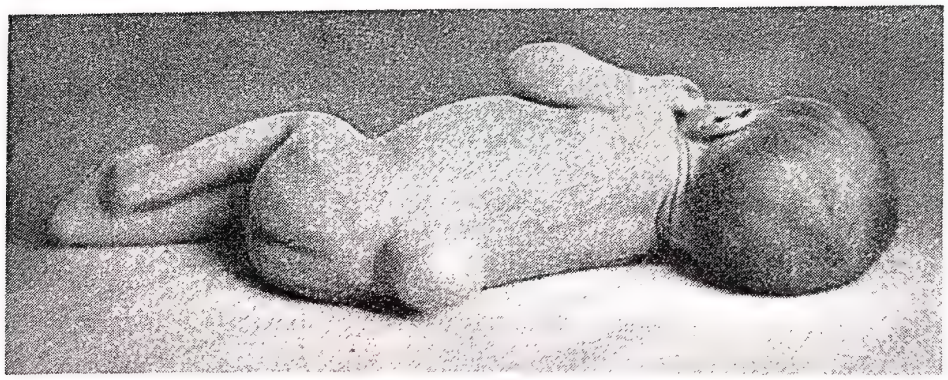

FIG. 467.—A typical meningocele which was excised successfully.

equina lies in the sac, and may be adherent to the posterior aspect. The cord or nerves can be seen as dark shadows on transillumination.

(4) *Syringo-myelocele.*—The rarest type of spina bifida, in which the central canal of the cord is dilated, and the cord lies within the sac together with the nerves arising from it.

(5) *Myelocele* results from arrest of development at the time of closure of the neural furrow. An elliptical raw surface is seen, which represents the ununited groove. At the upper end the central canal opens on the surface and discharges cerebrospinal fluid.

With the exception of spina bifida occulta, myelocele is the most common type of spina bifida, many cases are stillborn. If the child is born alive, death ensues within a few days from infection of the cord and meninges. Gross talipes is obvious.

Meningocele and meningo-myelocele are distinguishable on transillumination, a depression in the skin is sometimes produced by adherent cord or nerves in a meningo-myelocele. Interference with the spinal cord or nerves may occur in either condition but is more severe in meningo-myelocele, in which condition bilateral talipes with trophic changes are common, and in advanced cases extensive paralysis of the legs and incontinence occur. In serious cases no surgical intervention is indicated (see also p. 303).

FIG. 468.—Spina bifida occulta with a tuft of hair, and wasting of the right leg due to traction on nerves in the spinal canal. Also right-sided Sprendel's shoulder. *(R. L. Benison, F.R.C.S., Wolverhampton.)*

Treatment.—Operation for meningocele or meningo-myelocele is advisable as soon as the surgeon is of the opinion that the child's strength and condition warrant the procedure (often within a few days of birth), otherwise the sac is liable to grow out of proportion to the growth of the child, and the overlying skin will become atrophic and ulcerate.

Operation is performed under local anæsthesia with the child tied face downwards on a splint. The child is kept with the head low to minimise escape of fluid, and given a feeding-bottle during operation. The sac is opened and redundant membrane excised. If the cord or nerves are adherent, they are either freed by dissection, or separated with a strip of attached membrane and replaced in the vertebral canal. Membranes are sutured over the cord, spinal muscles are approximated and the wound is reinforced with flaps of sheath from the erector spinæ muscles. Some cases subsequently develop hydrocephalus from the effect of associated congenital abnormalities at a higher level (p. 443). Those cases which survive with gross paralysis of one or both lower limbs either after operation or without operation when the sac fails to rupture and develops some form of permanent coverage, may achieve some useful activity. Rehabilitation follows the lines of Guttman's rehabilitation of traumatic paraplegia (p. 458) the patient being provided with a suitable urinary receptacle and being taught to walk with the paralysed limbs supported with splints.

Operation for spina bifida occulta is required when neurological symptoms develop later in life. These symptoms are only rarely produced by traction from the membrana reuniens alone but are more likely to be due to compression of the cord by intra- or extradural lipomas or the effect of diastemato-myelia, a condition in which the cord is split in the mid-line by a bony spur which devides the neural canal beneath one laminæ into two lateral compartments. These abnormalities are almost always associated with the presence of a hairy tuft on the overlying skin, which is an important warning sign (fig. 468).

Myelography is required in all cases prior to operation.

At operation a tough fibrous band is encountered which leads down from the skin or deep fascia through a bony aperture to the dura mata. The dura is opened and the band excised together with any fibro-lipomatous tissue.

INFLAMMATORY DISEASES

Acute osteomyelitis occurs in the epiphysis of the body of a vertebra or, more rarely, one epiphysis of the neural arch. Severe consititutional disturbance is

associated with local pain and tenderness. Pain may also be referred along an adjacent spinal nerve. If the disease commences in a neural arch, some local evidence of inflammation is often detected. Acute osteomyelitis of a vertebral body has been mistaken for spinal meningitis, acute appendicitis, acute pancreatitis, and other abdominal conditions.

As soon as the disease is suspected, penicillin is administered, supplemented by chemotherapy. X-rays assist in determining the progress of the disease, and evacuation of pus or sequestrectomy is performed if necessary.

Tuberculous Disease—p. 213.
Spondylitis—p. 227.

TUMOURS OF THE VERTEBRAL COLUMN

Innocent tumours are extremely rare and include chondromas, osteomas, and fibromas. Many cases previously described as chondromas were in reality protrusions of an intervertebral disc. These tumours produce a syndrome of spinal compression affecting the anterior surface of the cord (p. 469) associated with characteristic X-ray appearances.

Malignant tumours of the spine are primary or secondary. Primary sarcoma is most frequent in children and young adults. The neural arches are usually affected, a palpable swelling may be detected in the paravertebral muscles, or invading tumour is discovered at this site during laminectomy performed for spinal-cord compression. Operative removal is always incomplete. Deep X-ray therapy is seldom effective.

Secondary deposits in the spine are common and far outnumber primary spinal or spinal-cord tumours. The majority are produced by bone metastasis chiefly derived from the breast or prostate. Deposits (from broncho-carcinoma) may rarely occur in epidural fat or in the cord itself. Malignant ganglion neuroblastomas of the sympathetic chain may invade through the intervertebral foramen.

Clinical Features.—Bone deposits produce severe local pain which may be the only symptom for a variable period. Later, as nerves become involved, the pain becomes girdle in type and increases in intensity. It is aggravated by movement, so that the patient may remain crouched in a chair or huddled up in bed for hours at a time. If diagnosis is established at this stage, deep X-ray therapy may prevent vertebral collapse and cord damage.

The sudden collapse of a vertebra in which a deposit has developed painlessly may lead to instantaneous paralysis and severe back pain as the first symptom. A similar disaster may occur if manipulation of the spine has been unwisely performed in an attempt to relieve the local pain produced by a vertebral deposit which has not been diagnosed. The diagnosis of secondary tumour should always be suspected when severe local pain is associated with a high erythrocyte sedimentation rate. Most commonly, a period of local pain is gradually followed by the onset of paraplegia and spasticity with increased reflexes, but once paraplegia is established it may become complete in a few weeks.

Treatment.—Secondary deposits from the prostate respond remarkably to treatment with stilbœstrol, and those from the breast may regress with hormone therapy, adrenalectomy or hypophysectomy. In other cases, treatment is limited to a support to the spine, analgesics, and deep X-ray therapy. Intrathecal phenol injections are a most satisfactory method of relieving agonising pain. Laminectomy is not advisable in the presence of vertebral collapse.

TUMOURS OF THE SPINAL CANAL

Tumours of the spinal cord and membranes are only one-tenth as common as cerebral tumours. On the other hand, at least 70 per cent. can be cured by operation.

Tumours of the spinal canal are extradural or intradural, the latter being either extramedullary or intramedullary.

Extradural tumours are relatively uncommon. Lipomas are described but are very rare. The majority consist of meningiomas or neurofibromas. Meningiomas form a plaque overlying several segments of the cord and compressing multiple nerve roots and the cord in the cervical and dorsal region.

Dumb-bell tumours are neurofibromas. Part of the tumour is extradural, and is connected with a larger paravertebral portion by a narrow isthmus which passes through an intervertebral foramen. Spinal cord compression eventually develops, necessitating laminectomy and excision. Erosion of an intervertebral foramen is a useful radiological aid to diagnosis.

Extramedullary tumours (75 per cent.) are neurofibromas and meningiomas.

Neurofibromas are commoner in males and usually arise from a posterior nerve root forming a fusiform tumour about 2·5 to 3·75 cm. long present on the postero-lateral aspect of the cord. Occasionally there is an extradural dumb-bell extension through an enlarged intervertebral foramen.

Meningiomas occur almost exclusively in women and usually form a small globular tumour the size of a grape attached to the dura and indenting the cord.

Carpet-like tumours corresponding to the meningioma *en plaque* spread widely over the inner aspect of the dura in the cervical and lumbar regions, where there is considerable available space, and engulf the cervical cord or lumbar nerve roots before producing any symptoms of compression. In the author's experience, one tumour extended from the tenth dorsal vertebra to the bottom of the sacrum and measured 27·5 cm. in length.

Of all extramedullary tumours 12 per cent. occur in the cervical region,
60 per cent. in the dorsal region, and
28 per cent. appear in the lumbar region.

In relation to the cord, three-quarters are on the postero-lateral aspect and only a quarter on the anterior aspect. They are very easily accessible at operation and all except a few diffuse meningiomas, or meningiomas invading bone, can be removed completely.

Intramedullary Tumours (25 per cent.).—Approximately half these growths are diffuse gliomas which cannot be removed. Others consist of ependymomas, a growth derived from the ependyma lining the central canal, forming either solid tumours like pencils which can be excised, or cysts which can be evacuated. Vascular malformations comprise 4 per cent., and for these little can be done. More than half the intramedullary tumours lie in the cervical cord.

Symptomatology

Spinal cord tumours produce symptoms:

1. By involvement of posterior nerve roots causing root pain and local sensory loss.
2. By involvement of anterior nerve roots and anterior horns causing lower motor neurone paralysis with wasting and loss of reflexes.
3. By involvement of long sensory tracts causing distant sensory loss below the level of the tumour.
4. By involvement of pyramidal tracts, causing upper motor neurone paralysis.
5. By involvement of both pyramidal tracts, causing disturbance of bladder function.

Extramedullary tumours are lesions of small size usually situated on the postero-lateral aspect of the cord in relation to posterior nerve roots, hence root pain is the earliest symptom which may precede any evidence of cord compression by a period of years. In the early stage it is often mis-diagnosed; when referred to the shoulders and arms, it may be regarded as arthritis or neuritis. In the thoracic

region it is regarded as angina pectoris or pleurodynia. In the abdomen it may be thought to originate from the gall-bladder, appendix, or pelvic organs.

The spinal origin should be suspected because the pain is *increased by coughing*, which raises the intraspinal pressure and forces the nerve root against the obstruction. Secondly, because pain follows the distribution of a spinal root and is often bilateral. Owing to the overlap of adjacent sensory areas, local sensory loss is absent or slight. Since most muscles receive a double nerve supply, the lower motor neurone paralysis is not recognisable unless extremely important roots are involved, such as the first thoracic.

The distant sensory loss is produced by pressure on the cord, which affects the longest sensory fibres first, hence whatever the level of the tumour the sensory loss starts in the legs and gradually spreads up the body as shorter and shorter fibres become affected. It seldom corresponds to the level of the tumour and is usually below the tumour level except in the latest stages. Pyramidal involvement occurs later, and the bladder symptoms last of all.

Examination shows bilateral spastic paralysis with a transverse sensory level on the trunk below the level of the tumour. The site of the tumour is reliably indicated by the level of the root pain.

Intramedullary Tumours.—Fifty per cent. of intramedullary tumours occur in the cervical region of the cord. These tumours occupy a length of the centre of the cord. Root pain occurs last when the tumour presses against the walls of the spinal canal. Involvement of many posterior and anterior horns causes a wide belt of local sensory loss and lower motor neurone paralysis, e.g. a dorsal tumour may

	Extramedullary	*Intramedullary*
Root Pain	Early	Late
Local Sensory Loss .	Nil or slight	Wide
L.M.N. Paralysis .	Absent except in C.8, T.1	Wide
Distant Sensory Loss	Ascending	Dissociated
U.M.N. Paralysis .	Late	Early
Bladder . . .	Late	Early

cause extensive paralysis of the abdominal muscles. Distant sensory loss may be disassociated in type, as in syringomyelia, from involvement of spinothalamic tracts. Spastic paralysis and bladder symptoms from pyramidal involvement occur first of all. Examination reveals a wide belt of local sensory loss and lower motor neurone paralysis associated with spastic paralysis in a patient who has only complained of increasing paralysis and bladder disturbance of a few weeks' duration.

Extramedullary Tumours of the Conus Medullaris and Cauda Equina.—All lumbar and sacral nerve roots leave the cord between the tenth thoracic and first lumbar vertebra. Tumours of the conus medullaris lie at the eleventh and twelfth dorsal and the first lumbar vertebræ, and press upon multiple lumbar nerve roots and the tip of the cord. The symptoms include root pain, sensory loss, and lower motor neurone paralysis in the distribution of the lumbar roots which supply the front of the thigh and legs. There is pain in the thighs, wasting of the quadriceps, foot-drop and reduction of the knee-jerks. Pressure on the cord produces spastic paralysis in the legs with increased ankle-jerk and extensor plantar response.

Reflexes : K.-J. − −
A.-J. +++ +++
P.-R. ↑ ↑

Tumours of the cauda equina occupy a central position among the sacral nerve roots below the conus, producing root pain, sensory loss, and lower motor neurone paralysis in the distribution of the sacral roots which supply the back of the legs. There is sciatic pain and wasting of the hamstrings and calves, and sensory loss in

the saddle area. The knee-jerks are increased owing to weakness of the opposing hamstrings; the ankle-jerks and plantar responses are absent owing to sensory disturbance:

K.-J.	+++	+++
A.-J.	—	—
P.-R.	—	—

Spinal arachnoiditis may produce simple cysts of the arachnoid, form cystic collections which compress the cord, or multiple diffuse adhesions which produce their effect by traction on blood-vessels. The cysts should be localised and removed in the same manner as spinal tumours.

FIG. 469.—Lateral X-ray showing marked hollowing out by pressure atrophy of the back of the bodies of the lumbar vertebra by a large tumour of the cauda equina extending throughout the lumbar theca. Similar appearances may also occur in the body of the sacrum.

Accessory Methods of Investigation

1. *X-ray of the spine* may indicate the level of the tumour by showing absorption of the pedicles of the vertebra, enlargement of an intervertebral foramen on the lateral view, or erosion of the posterior aspect of a vertebral body (fig. 469).

2. *Lumbar puncture* may be required in early cases to differentiate such conditions as disseminated sclerosis. The presence of a tumour is indicated by an obstruction in the cerebrospinal-fluid circulation demonstrated by Queckenstedt's test. This is performed by charting the rate of rise and fall of the lumbar cerebrospinal-fluid pressure occurring during compression and release of the internal jugular veins.

In normal circumstances, such compression causes a rapid rise in cerebrospinal-fluid pressure and a somewhat slower passive fall. The first effect of obstruction is to prolong the passive fall, later there is a slight rise and fall, and finally no response at all.

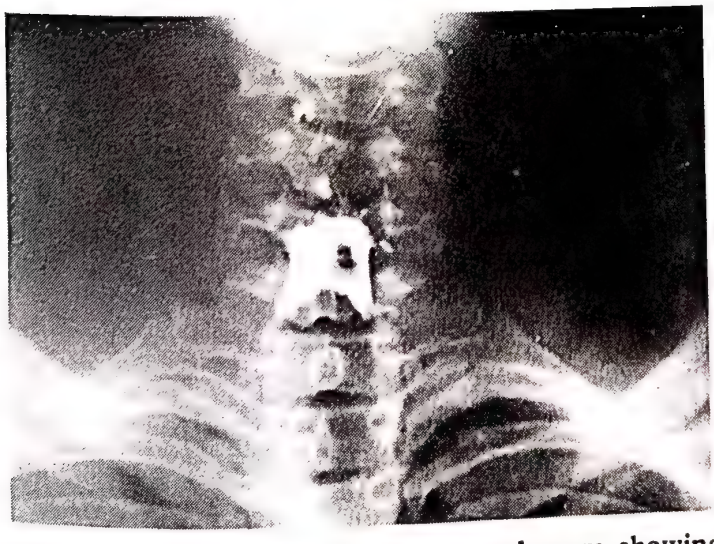

FIG. 470.—Descending cisternal myelogram showing complete obstruction of the down fall of myodil and the wavy outline produced by the upper border of a meningioma.

3. *Examination of the cerebrospinal fluid*, including protein content. In neurofibromas the cerebrospinal fluid protein is raised from

the normal 20 to 40 mg/100 ml (0·2–0·4 g/l) to figures of 200 to 400 mg/100 ml (2·0–4·0 g/l) without any evidence of block. When block becomes complete, the cerebrospinal fluid in the lower portion of the theca is encysted and transudation occurs between the blood vessels and the cerebrospinal fluid with diffusion of protein and pigments. The fluid becomes yellow and may clot spontaneously (Froin's syndrome) and may contain as much as 50 g/l.

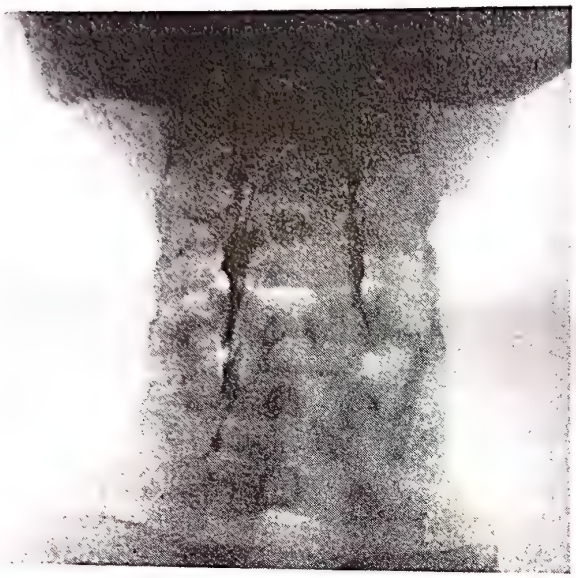

FIG. 471.—Ascending myelogram showing trouser leg appearance produced by columns of fluid ascending on each side of an expanded cord containing an intramedullary tumour.

Cisternal Myelography.—Cisternal myelography is essential in order to demonstrate the level of the upper border of the tumour before operation. The shape of the shadow produced at X-ray indicates the type of tumour. The upper border of a meningioma which is irregular produces a wavy outline in contrast to the smooth crescentic margin produced by the curved upper surface of a neurofibroma. An intramedullary tumour produces separation of columns of contrast medium passing on either side of the expanding cord with resulting candle grease or trouser leg appearances (figs. 470, 471 and 472).

Cisternal puncture is performed by inserting a lumbar-puncture needle in the mid-line at the level of the second cervical spine, the patient's head being flexed. The needle is advanced on a plane passing through the external auditory

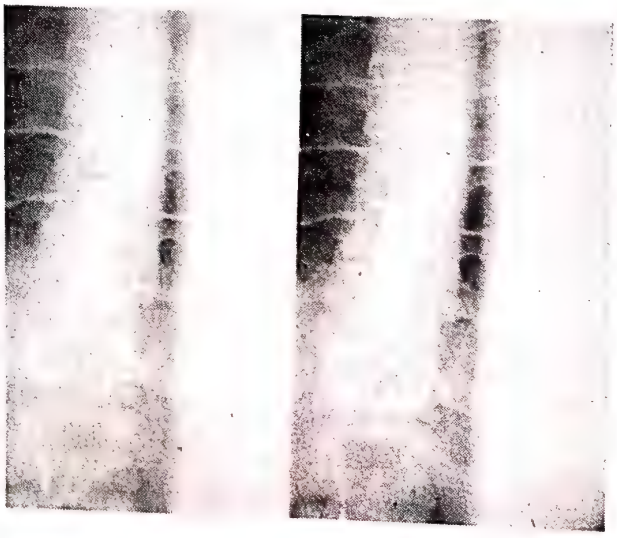

FIG. 472.—Descending myelogram showing candle grease appearance produced by myodil tracking down each side of a cervical intramedullary tumour. These appearances may sometimes be mimicked in severe cervical spondylosis where there is marked arachnoiditis and the cord is flattened by bony bars. The trouser leg appearance is perhaps more reliable in diagnosis.

meatus to the outer margin of the eye. At a depth of 3 cm the stylet is removed. The needle is further advanced to a depth of 5 cm, when it pierces the occipito-atlantoid ligament, which feels like a sheet of brown paper; the moment this is pierced the operator should wait for fluid to flow out. It may not do so although the needle

Georges Froin, 1874–1932. French Neurologist. Described this syndrome in 1903.

is in the cisterna magna, therefore the needle should be aspirated before it is advanced farther. If no fluid is obtained, it is put in a millimetre or two at a time until fluid escapes. Three ml. of Myodil is now injected and gravitates downwards until it is arrested by the tumour, the level of which is localised by examination on a tilting X-ray screen (fig. 473).

Treatment is by laminectomy when the upper level of the tumour has been accurately localised by cisternal myelography. A meningioma is excised together with a portion of the dura from which it arises.

A neurofibroma is removed with a portion of the nerve sheath to which it is attached.

Intramedullary solid ependymomas are excised after incision of the cord strictly in the mid-line between the posterior columns.

Intramedullary cysts are emptied.

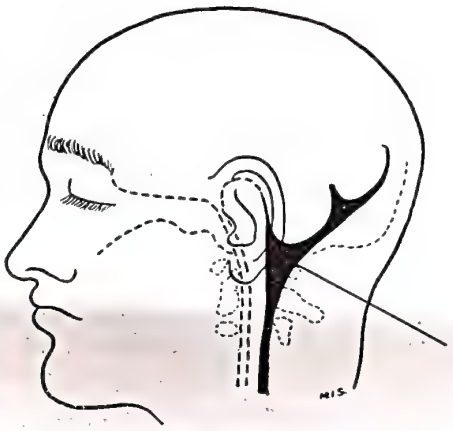

FIG. 473.—The technique of cisternal puncture.

LAMINECTOMY

In estimating the level of operation, the discrepancy between the level of the affected segment of the cord and that of the corresponding vertebra must be considered, owing to the disparity in the length of the spinal cord and vertebral column, a segment in the cervical region lies one vertebra above its corresponding vertebral body. In the upper dorsal region the tumour will be two vertebræ, and in the lower dorsal three vertebræ, above the corresponding vertebral body.

In estimating these levels by palpation of the spinous processes, in the dorsal region the processes overlap the vertebra below. Thus, presuming a tumour is localised to the ninth dorsal segment, it should be opposite the tip of the fifth spinous process, i.e. three vertebræ higher on account of the shortness of the cord as compared with the spinal column, and one vertebra higher because of the obliquity of the spinous process.

The patient is usually placed in the prone position with sandbags under the sternum and pelvis to leave the respiratory excursion of the diaphragm unimpaired in order to minimise back pressure on the epidural veins. The paravertebral muscles are injected with 1 : 100,000 of adrenalin in saline. A mid-line incision is made, the muscles are separated from the spinous processes by cutting diathermy, and raised from the neural arches with a raspatory after tendinous attachments have been cut through with curved scissors. Pressure from hot saline packs produces a dry field after any major vessels have been secured with coagulation. Self-retaining retractors are inserted and spines and interspinous ligaments are excised with bone-cutting forceps. The exposed raw edges of bone at the bases of the spines are now drilled through with a Hudson's burr to the level of the dura on each lamina, and finally the laminæ are removed with bone-biting forceps, thus exposing the dura and the ligamenta subflava beneath the site of each lamina. The ligamenta subflava and epidural fat are now incised in the mid-line and the ligaments removed. The dura is then inspected for evidence of the tumour, usually shown by a slight bulge at the tumour site or a zone in which pulsation is absent. If any doubt exists as to the correct level, the dura is picked up on a fine hook and a small mid-line incision is made, and stay sutures of fine silk are inserted into the dural edge. A No. 3 fine rubber catheter is passed up or down inside the theca to estimate the site of obstruction. If the exposure is correct and no further bone removal is required, the dura is opened fully in the midline by extending the original small incision by slitting the dura with guarded scissors.

Several fine silk stay sutures are inserted into the dural edge to hold the dura back against the bone and prevent bleeding from the epidural veins. Strips of fine lintine cotton tissue are inserted against the muscle to absorb any minor oozing in order to keep the field dry and free from cerebrospinal fluid. The tumour is now removed in the manner previously described, following which the dura is sutured completely with

William Henry Hudson, 1862–1917. Surgeon, Atlanta, Georgia, U.S.A.

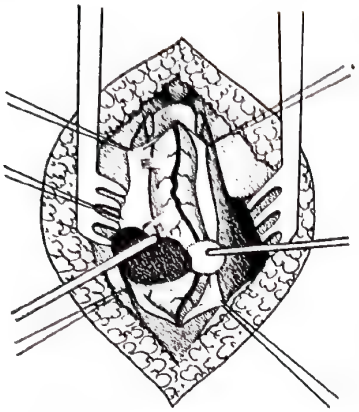

FIG. 474.—Removal of a meningioma indenting the dorsal cord.

fine silk, the muscles approximated with strong silk in layers, and the wound closed (fig. 474).

Additional Indications for Laminectomy include:

1. Traumatic. These are considered on p. 459.
2. Inflammatory paraplegia complicating Pott's disease (p. 214).
3. Division of posterior roots to relieve chronic pain resulting from (*a*) malignant metastasis in lymph nodes or post-irradiation fibrosis in the high cervical region following malignant disease of the tongue and jaw; (*b*) from post-herpetic neuralgia following herpes zoster in the thorax and abdomen. Owing to the sensory overlap of adjacent spinal segments, more than one nerve root must always be divided. To relieve pain in three thoracic root areas, five must be cut to include those above and below the affected zone. This renders the operation of posterior rhizotomy inapplicable to the relief of pain in the arms or legs, as extensive denervation will abolish position sense and thus result in a severe ataxia.
4. Cordotomy. Division of the spinothalamic tracts for the relief of pain due to such conditions as an irremovable new-growth or arthritis, *vide infra*.
5. The tremor of Parkinson's disease is relieved by division of the whole of the lateral tract at the second cervical segment on the side affected (Leslie Oliver). Most surgeons now prefer stereotaxic operations on the basal ganglia (p. 450).
6. Division of the anterior roots of C.2, 3 and 4, to paralyse the posterior rotator muscles in cases of spasmodic torticollis, this operation being combined with division of the contralateral spinal accessory nerve in the neck to paralyse the opposite sternomastoid.

SPINOTHALAMIC TRACTOTOMY

Intraspinal division of the spinothalamic tracts will produce loss of pain sensation with preservation of touch on the opposite side of the body. This operation can be employed unilaterally or bilaterally for the relief of chronic long-lasting pain resulting from arthritis, spondylitis, or intermittent claudication, and also be employed to relieve severe pain from incurable new-growths, but only if the general condition of the patient is good and survival is likely to be prolonged. In the terminal stages of cancer, however, cordotomy carries a higher risk of mortality from bronchopneumonia.

If pain is unilateral and not of visceral origin, the tract on the opposite side of the body only needs to be divided. For visceral pain bilateral divisions are required. If bilateral sections are to be made, they must be placed at levels two segments apart in the cord in order to avoid the risk of transverse degeneration and paraplegia.

In choosing the site of operation, allowance is made for the oblique crossing of the spinothalamic tracts. In the dorsal region the incision must be three segments above the level of the pain; in the cervical region, two segments. In the dorsal region the tract lies between the dentate ligaments and anterior roots. but fibres from the lower limbs may be displaced in front of the anterior root. Pelvic fibres will lie deep near the anterior horn. In the cervical region, recently entered arm fibres lie 2 mm. behind the dentate ligaments. Section may be carried out as high as the fourth cervical segment by ' open ' operation, or the tract interrupted at a higher level by the insertion of radioactive seeds under stereotactic control anterior to the spinothalamic tract in the front face of the cord. Seeds of yttrium ^{90}Y which have limited range of emanation destroy the anterior column to the appropriate depth without causing damage to other important areas.

The cord is exposed at the required level, the dentate ligament is identified, and divided and grasped with mosquito forceps, which are used to rotate the cord and thus expose the anterolateral aspect to view. An incision 4 mm. deep is now made from the line of the dentate ligament to the anterior root and carried into the anterior horn and beyond, if pelvic fibres are to be divided.

Stereotactic surgery on the spinal cord is performed through the atlanto-occipital space. The cord is outlined with positive contrast injected by cisternal tapping.

James Parkinson, 1755–1824. English general practitioner who practised in Shoreditch, London.
Leslie Claremont Oliver, Contemporary. Neurosurgeon, Charing Cross Hospital, London.

The head is flexed and supported in a stereotactic frame and holder. Trigeminal tractotomy and spinothalamic tractotomy produced by accurate radio frequency lesions have succeeded in relieving intractable pain.

PROLAPSE OF INTERVERTEBRAL DISC

Intervertebral discs are interposed between the vertebral bodies, and serve not only as shock absorbers for the column but also provide the normal mobility between the adjacent vertebræ. Each disc consists of a soft central portion of spongy material, the nucleus pulposus, containing a remnant of the notochord, which is surrounded by a tough fibrous ring, the annulus fibrosus, which is attached to the adjacent vertebral bodies, the whole being enclosed between fibrocartilaginous plates above and below.

During normal flexion of the spine the disc is deformed and the annulus fibrosus and nucleus bulges backwards slightly into the neural canal.

Intervertebral disc protrusion is produced by the effect of flexion-forces acting upon the most mobile portions of the spine. A sudden strain with the spine in an unguarded position will rupture the tough annulus, allowing portions of the torn annulus and soft nucleus to escape into the spinal canal and form either a central protrusion in the midline under the posterior common ligament of the vertebræ, or a lateral protrusion at the side of the posterior common ligament adjacent to the intervertebral foramen (fig. 475).

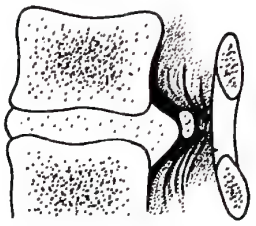

FIG. 475.—Intervertebral disc protrusion passing towards the intervertebral foramen, the posterior margin of which, at A, is constituted by the anterior edge of the subflavian ligament.

In 80 per cent. of cases the protrusion is traumatic in origin and there is either a history of sudden severe strain, or the patient's occupation is one in which flexion strain must be resisted, such as a packer, fireman, porter, etc. The condition is therefore more common in males.

In 20 per cent. of cases the condition is degenerative in origin. There is no history of injury. A small portion of the nucleus pulposus herniates through a weak area in the annulus without tearing that structure.

Since the mechanism demands the combination of stress and mobility, protrusions are most common in the most mobile portions of the spine which are subject to the greatest stress, hence approximately :

19 per cent. occur in the cervical region at the mobile C.5/6 and C.6/7 levels.

1 to 2 per cent. occur in the immobile dorsal spine.

80 per cent. occur in the lumbar regions, particularly at the mobile L.4/5 and L.5/S1. levels.

Escape of disc material leads to:

1. The narrowing of the invertebral joint space visible in X-ray in 50 per cent. of cases.

2. Slackening of the anterior common ligament of the vertebræ producing abnormal mobility between the vertebræ with local joint pain, and ultimately the development of intervertebral arthritis. Traction osteophytes form on the anterior aspect of the vertebræ and are visible in X-ray. Compensatory thickening of the ligamenta flava occurs in an attempt to check the abnormal mobility.

Massive protrusions may occur as a result of major cervical injuries (p. 471). Alternatively when the spinal ligaments are softened at the end of pregnancy the strain of labour may force out a massive protrusion in the lumbar region, giving rise to one form of obstetric paralysis.

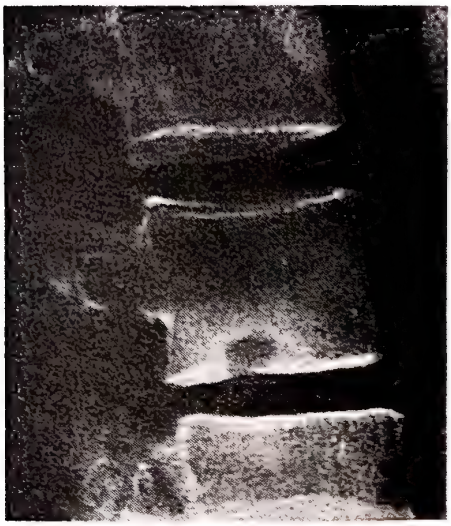

FIG. 476.—Schmorl's node in a lumbar vertebra (see text). Note also the narrowed disc space.

A Schmorl's Node (fig. 476) is a radiological manifestation of an extrusion of the nucleus pulposus into the body of a vertebra. In itself, it has no clinical significance. As time goes by, the new bone activity which surrounds it condenses into a shell.

Christian G. Schmorl, 1861–1932. Professor of Pathology, Dresden, Germany.

Lumbar Disc Protrusion.—In the lumbar region the roots of the cauda equina run obliquely over a number of intervertebral joint spaces, hence a lateral protrusion may press on two roots. The nerve root that issues from the corresponding intervertebral foramen may be compressed against the lateral margin of the disc, whilst the nerve root going to the intervertebral foramen next below is caught against its inner margin.

Clinical Features.—In all cases there is an initial period of low back pain resulting from injury to the disc. Later the pain will radiate to the leg when nerve roots become compressed. There is then root pain, accentuated by coughing, in the distribution of the affected nerve, paræsthesiæ and pins and needles in the peripheral portion of that area, cramps, and tenderness in muscles supplied by the nerve, and a

FIG. 477.—Anteroposterior myelogram showing characteristic lateral filling defect produced by lumbar-disc protrusion.

FIG. 478.—Lumbar myelogram, lateral view, showing characteristic anterior pyramidal defect crossing to the joint space produced by disc protrusion. Myelography is not completely reliable as it fails to detect the small lesion.

variable degree of sensory loss and motor weakness. Since the commonest roots to be involved are the first sacral and fifth lumbar, pain is usually in the back and side of the leg radiating to the sole of the foot and the big toe, and is called sciatica. Sensory loss is found on the sole and side of the foot and the ankle-jerk is lost. But in higher disc lesions the pain may be referred to the front of the thigh or leg.

In an endeavour to reduce pressure on the nerve root, the patient adopts a position of scoliosis and walks with a limping gait. Attempts to touch the toes or at straight-leg raising, or neck flexion with the legs raised, increases pain by pulling the nerve root against the protrusion.

Physical Signs.—Pain is produced by friction of the nerve against the protrusion. Small protrusions only compress the nerve root slightly and the nerve is free to rub against the protrusion. *Small protrusions* thus cause very severe pain because there is maximum friction without much loss of conduction in the nerve. Since there is little impairment of conduction, physical signs are slight and limited to a small patch of sensory loss in the periphery of the skin area involved where long sensory fibres have been affected. *Larger protrusions* cause less pain because they lock the root more firmly so that there is less friction, while the conduction of the nerve is diminished. Since conduction is diminished, the physical signs are more marked and sensory loss is extensive owing to involvement of short sensory fibres. *Massive protrusions* completely fix the root and cause no pain whatsoever, but produce the maximum sensory loss and motor paralysis (obstetric paralysis).

Treatment consists of confinement to bed until symptoms abate, which is usually a matter of two to four weeks. A plaster jacket is applied for two to three months, after which a spinal brace is worn for a further period. The majority of cases are cured by this routine. Operation is indicated if symptoms persist, if severe pain recurs, or if motor weakness is developing.

Root Involved	*Pain and Sensory Loss*	*Motor Weakness*	*Reflex Change*
1st sacral root	Back of leg. Sole and side of foot.	Gastrocnemius, weak plantar flexion.	Absent A.-J.
5th lumbar	Back of thigh. Most of lateral aspect of leg. Dorsum of foot to big toe.	Anterior tibials. Weak dorsiflexion.	Nil.
4th ,,	Side of thigh. Front of inner aspect of leg.	Quadriceps and anterior tibial, weak dorsiflexion and extension of knee.	Diminished K.-J.
3rd ,,	Front of lower thigh.	Quadriceps.	Diminished K.-J.
2nd ,,	Front of mid-thigh.	Quadriceps.	Diminished K.-J.
1st ,,	Groin.	Nil.	Nil.

Often combined in L.4/5 disc.

Often combined in L.5/S.1 disc.

The disc is removed by hemilaminectomy, removing the adjacent margins of two laminæ and the subflavian ligament which obscures the view of the nerve root and disc protrusion until it has been excised (fig. 479). After removal of the subflavian ligament, the swollen root is seen overlying the protrusion by which it is displaced inwards. Loose disc material (looking like crab meat) is then grasped with forceps and extracted.

A full laminectomy is contraindicated as it encourages further weakness of the spine. Even after satisfactory removal of a prolapsed disc, symptoms or physical signs are not always alleviated. Two conditions may persist. Prolonged compression of the nerve may have resulted in interstitial neuritis producing sensory loss or motor weakness, or the intervertebral joint may be unstable or become affected by osteoarthritis. Intervertebral arthritis or instability is to be suspected when pain is not relieved by rest, but persists at night and wakes the patient when he turns over in bed. If this condition is present, spinal fusion should be performed when the disc is removed so as to afford complete rest to the affected segment of the spine.

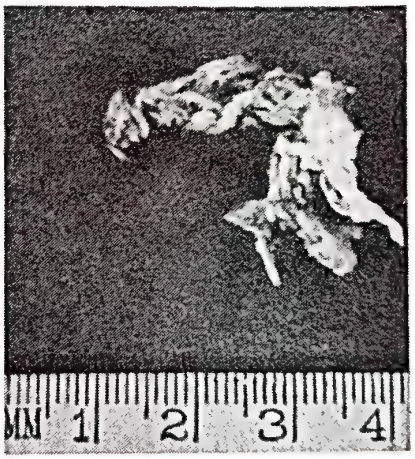

FIG. 479.—A typical portion of protruded disc removed at operation.

Cervical disc protrusions are relatively uncommon. In many cases a diagnosis of cervical disc lesion is mistakenly applied in patients who are really suffering from referred pain arising from a cervical strain which has affected the interspinous ligaments, or lateral articulations following a flexion strain, or who are suffering from cervical spondylosis. As true cervical disc protrusions are uncommon, this diagnosis must only be accepted when there is definite evidence of compression of the spinal cord or nerve roots, and when the presence of a disc protrusion has been confirmed by demonstrating a lateral filling defect at myelography. In the cervical region the nerve roots run transversely and come into relation with one intervertebral disc only. Each nerve issues above the level of the corresponding vertebra.

Lateral protrusions press on the corresponding nerve and half the spinal cord, producing cervical rhizalgia with half-cord compression, a Brown-Séquard syndrome. They are never situated sufficiently far laterally to press upon the nerve root alone. Symptoms of brachial rhizalgia without cord compression are produced by intraforaminal osteophytes occurring in association with cervical spondylosis, which may,

Charles Edouard Brown-Séquard, 1817–1894. Physician, National Hospital for Nervous Diseases, London (1860–1864), Professor of Medicine, Harvard University, Boston, Mass. (1864–1878) and College de France, Paris (1878–1894). Described this syndrome in 1851. He was a native of Mauritius.

unlike a disc, affect multiple nerve roots. Each spinal root emerges above the corresponding vertebra, hence C.5/6 protrusion compresses the C.6 nerve root and half the cord (see Table below).

Root	*Pain, Sensory Loss*	*Sensory Loss*	*Muscle Weakness and Reflex Change*
C.6	Trapezius. Shoulder tip, outer border of upper arm. Dorsum of forearm.	Lateral border of upper arm. Dorsum of forearm and thumb.	Weakness of biceps, diminished biceps and supinator jerk.
C.7	Trapezius. Shoulder tip, back of upper arm, and dorsum of forearm.	Dorsum of forearm and all fingers except thumb.	Weakness of trapezius and extensors of the fingers. Diminished triceps jerk.

Mid-line protrusions compress the anterior part of the cord and affect the anterior spinal artery and the anterior spinal veins. Compression of the anterior spinal artery may affect the pyramidal and spinothalamic tracts and anterior horns. Compression of the veins which ascend on the front face of the cord produces stasis in the anterior horns below the level of the lesion.

The symptomatology varies on repeated examination as pressure on the vessels varies, and may simulate syringomyelia, disseminated sclerosis or primary lateral sclerosis. In time secondary atrophic changes produce an atrophy of the cord substance with permanent spastic paresis.

Acute midline protrusions occurring in cervical injuries may produce symptoms of a partial or complete cord lesion without bone displacement. High protrusions at the 4th cervical level may cause serious respiratory embarrassment.

Treatment.—If neurological symptoms and signs do not improve as the result of conservative treatment by support and immobilisation operation is required. Lateral protrusions are exposed by hemilaminectomy and removed by an extradural approach. Midline protrusions are treated by a full laminectomy of sufficient length to permit one to open the dura and divide the dentate ligaments for several segments above and below the protrusion in order to allow the cord to fall back and thus relieve pressure on the arteries and veins. Attempts to remove a midline protrusion may damage the anterior spinal artery and cause permanent paralysis.

Cervical Spondylosis is a degenerative condition characterised by (1) degeneration of the intervertebral discs with the formation of bony ridges running across the anterior surface of the neural canal and (2) the formation of osteophytes from the neurocentral joints of Leschka which project backwards into the intervertebral foramen (fig. 480). The condition may be quite symptomless or may cause neurological symptoms.

(*a*) Sudden strains inflicted on the affected joints as, for example, in the violent forward lurch sustained in road traffic accidents, so called ' whip-lash ' injuries, may give rise to referred pain in the occipital or post-auricular regions and in the upper portion of the trapezius, and between the shoulder blades. Persistent occipital and posterior auricular pain can be relieved by excision of the corresponding nerves. Since referred pain and muscle spasm in the lower cervical region is the result of movement in the painful joints, these symptoms are often relieved by wearing a collar, but if they become chronic they may be permanently relieved by the insertion of a paraspinal inlay to immobilise the affected joints or by anterior spinal fusion in which the vertebrae are approached anteriorly internal to the carotid sheath. A portion of the

Hubert von Luschka, 1820–1875. Professor of Anatomy, Tübingen, Germany.

upper and lower surfaces of adjacent vertebrae are channelled out to form a prepared bed into which a small bone graft is inserted from in front. Great care is required to avoid penetration of the dura and damage to the closely

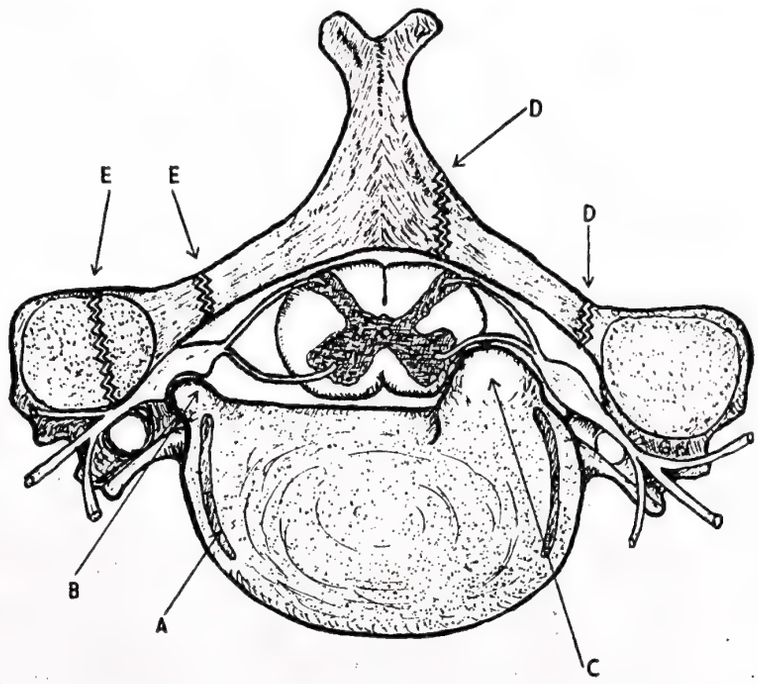

FIG. 480. — Diagrammatic cross-section of the cervical spine and cord showing the position of (A) the neuro-central joint of Luschka, (B) an intraforaminal osteophyte developing from that joint compressing the nerve root within the foramen, (C) a lateral disc protrusion compressing the cord and nerve root. Projection into the intervertebral foramen is prevented by the position of the joint of Luschka. (D–D) the section of bone removed in hemi-laminectomy giving access to a lateral disc protrusion. (E–E) The section of bone removed in hemi-facetectomy giving access to an intraforaminal osteophyte. *(G. B. Northcroft, F.R.C.S., London.)*

adjacent spinal cord. (*b*) Bony ridges on the anterior surface of the cord may compress arteries and veins with consequent neurological symptoms and spasticity and ultimate cord atrophy simulating a mid-line disc lesion. This should be treated by division of the dentate ligaments. (*c*) intraforaminal compression by osteophytes may affect multiple nerve roots. The nerve roots may be decompressed by excision of the back of the intervertebral foramina by hemifacetectomy.

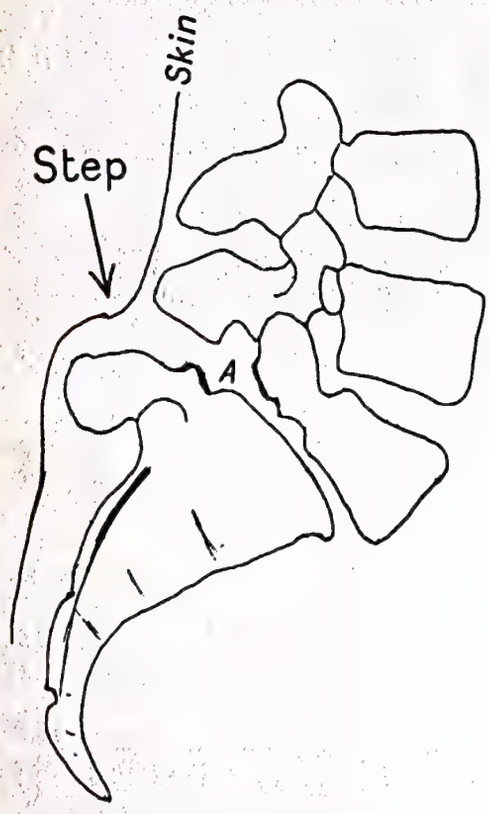

FIG. 481.—Spondylolisthesis at the level of L5 – S1 disc. Note the defect at A and the step over S1 spine.

Spondylolisthesis.—This is a condition in which a lower lumbar vertebra, usually the fifth, slips forward through the plane of the intervertebral disc below it and so carries with it the whole of the upper portion of the spine. The essential lesion is a separation of the body of the vertebra from the posterior articulation, lamina, and spinous process as a result of a defect in the pedicles which hold these two parts of the vertebræ together (fig. 481). Because the lamina is left behind in its normal position, the forward displacement of the vertebral body does not narrow the spinal canal. The deformity can, however, cause root pressure which may manifest itself as sciatica.

In general, the main symptoms are usually those of long-standing low-back pain. On examination, in a mild case nothing will be found other than some excessive prominence of the first sacral spinous process. In a severe case, where the lumbar vertebra has become dislocated in front of the sacrum, there will be a severe lordosis and a rather characteristic shortening of the trunk, so that the lower ribs seem to rest on the brim of the pelvis.

Though trauma was frequently regarded in the past as a common cause of spondylolisthesis, accurate X-ray studies now show that a congenital defect in the development of the pedicles is much the commonest explanation. X-ray studies often reveal a condition sometimes known as ' prespondylolisthesis ', or ' spondylolysis ', where slipping of the vertebræ is absent, or minimal, in the presence of defects in the pedicles.

The majority of these cases never require any special treatment other than simple placebos for backache, such as local heat and rest from time to time. A stiff lumbosacral corset will give relief to the majority, but a few will require lumbosacral fusion to abolish pain. As in the management of any case of ' low-back pain ', it is unwise to alarm the patient with injudicious reports about the X-ray appearance. Many cases of severe spondylolisthesis go through life with nothing more than an occasional attack of ' lumbago '. Injudicious remarks can convert a mild case into a complete invalid!

LUMBAR PUNCTURE

This procedure is adopted for the following reasons:

1. **Diagnostic,** e.g. meningitis, Wassermann reaction or gold test for syphilis; and to disclose intradural hæmorrhage. Also for the injection of pantopaque, or to assess the protein content, if a tumour is suspected. Manometric readings are essential to assess the intradural pressure (p. 475).

2. **Therapeutic,** in order to introduce some drug, e.g. penicillin for meningitis, or, the relief of pain.

Relief of Pain.—The intrathecal injection of phenol has now largely replaced the use of absolute alcohol, which was far more likely to produce undesirable sequelæ such as paralysis or retention of urine. Intrathecal alcohol injections are now given chiefly to destroy the severed lower portion of the spinal cord in complete and irrecoverable cord injuries, to obliterate flexor spasms and rigidity and facilitate rehabilitation (p. 458). The pain-conducting fibres passing from the posterior root ganglia to enter the spinal cord are either non-myelinated, or possess a much thinner myelin sheath than fibres conducting other forms of sensation. Since phenol acts upon the non-myelinated fibres, it will relieve certain forms of pain without affecting normal sensation or motor power. Slow pain travelling at a speed of approximately six metres a second is conducted by the finest non-medullated fibres of less than 10μm. Fast pain travelling at approximately sixty metres a second is conducted in larger medullated fibres of over 10μm. Since phenol affects the non-medullated fibres, it therefore abolishes the slow pain and is most effective in relieving the deep aching pain of cancer and secondary deposits, but is far less effective in the sharp pain of neuritic origin.

The injection of intrathecal phenol has now superseded the use of intrathecal alcohol which often produced rectal and urinary incontinence. A solution of 1 per cent. phenol in glycerine has proved to be unreliable and liable to produce incontinence, and a solution of 7·5 per cent. phenol in myodil is far safer. It appears that the phenol is in some way fixed in this solution. When used with radio-opaque myodil the phenol can be guided under X-ray control to the appropriate level. The myodil solution is

heavy and therefore drops to a low level in the theca. To relieve pain from the bladder and pelvis the injection is made with the patient sitting up; at other levels, the patient lies on the affected side on a tilting X-ray couch, between 1 and 3 ml. of 7·5 per cent. phenol in myodil are injected by lumbar puncture, and the radio-opaque substance is then guided to the affected level by tilting the X-ray couch and checking the level of the myodil by observation on a fluorescent screen.

3. **Anæsthesia.**—Nupercaine, Novocaine, and Spinocaine; each has its individual supporters.

Nupercaine is used in a 1:1,500 solution in 0·5 per cent. saline. The specific gravity of this solution is 1003, which is lighter than cerebrospinal fluid (sp. gr. 1006). The average dose is 14 ml., which gives complete abdominal anæsthesia, but 10 ml. is usually sufficient for operations below the umbilicus. After injection the patient lies on his face for five minutes so that the posterior roots are chiefly affected. He is then turned on his back, and slight tilting downwards of the head of the table will help to fix the Nupercaine caudalwards and counteract any fall of blood pressure.

Spinocaine is composed of Novocaine (100 mg. in each ml.) and strychnine. The dose varies from 1 ml. for children under six years of age to 3 ml. for adults. A pressor substance, such as ephedrine 30 to 45 mg. is usually given intramuscularly in order to maintain the blood pressure.

Catastrophes, such as incontinence of urine or damage to spinal nerves, occasionally occur. These calamities are possibly due to an invisible crack in a phial, which, if submerged in spirit or other antiseptic, may allow some of the fluid to percolate into the interior. *Phials should always be submerged in coloured fluid*, and any phial which contains coloured contents is rejected. Otherwise autoclave all ampoules.

Some premedication, such as omnopon and scopolamine, is safe and humane, but if the intercostal muscles are paralysed, depression of the respiratory centre is dangerous.

Technique.—At birth the cord extends to the third lumbar vertebra. In the adult it terminates opposite the lower border of the body of the first lumbar vertebra, below this level the dural sac can be safely punctured. A space of 2·5 mm. in width exists between the caudal equina nerve roots on either side and hence, if the lumbar puncture needle is kept strictly in the mid-line, it will avoid contact with the roots. The patient lies on his side with the spine well flexed in order to open up the spaces between the neural arches. Scrupulous asepsis is required. The skin must be fully prepared and isolated with sterile towels, gloves and gown being worn in order to perform the puncture. A line connecting the highest parts of the iliac crests passes over the fourth lumbar spine (fig. 482). The interspace above or below this spine is selected, and this area is infiltrated deeply by injecting local anæsthetic into the interspinous ligaments. The depth to which the needle will need to pass varies according to the build of the patient, from a few cm in a small child to 10 cm in a fat adult. In the case of some nervous children or patients afflicted with tetanus, general anæsthesia is necessary. The needle used should be of medium bore (about 18 to 20 gauge) as the aperture resulting from puncture with a wide needle will allow continuing escape of cerebrospinal fluid from the dura, with consequent persistent headache, produced by intracranial hypotension. The bevel of the needle must be short. As the puncture is commenced, the position of the needle should be checked, making sure that it is introduced at right angles to the skin and is not sloping to one side. This is best judged by looking along the skin of the patient's back; it should also be slanted slightly towards the patient's head so that it will enter obliquely beneath the lumbar spines. As the needle and stylet are introduced, the resistance of the tough ligamentum flavum is encountered, a little extra pressure perforates this structure, and on withdrawal of the stylet cerebrospinal fluid should flow from the needle. If only a few drops of blood escape, in all probability the point of the needle is lying in the spinal canal outside the dural sheath and the

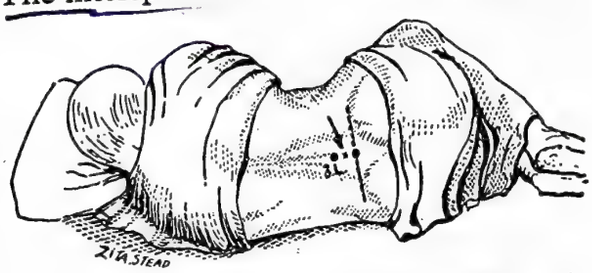

FIG. 482.—Lumbar puncture. (The site of puncture is usually between the third and fourth lumbar spines.)

blood is escaping from a spinal vein, in which case the needle should be advanced slightly further. When the theca is entered, a manometer is attached to the needle in order to estimate the cerebrospinal fluid pressure, the normal being 120 mm of water in the recumbent position. In cases of raised pressure only a small quantity of fluid must be removed for investigation, and the pressure should not be reduced, even as low as the normal 120 mm, owing to the risk of causing midbrain pressure cone, or a medullary cone in the foramen magnum with fatal consequence.

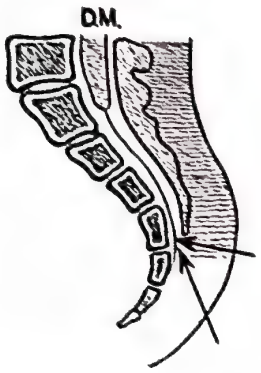

FIG. 483. — Indicating direction of needle.

SACRAL PUNCTURE (EPIDURAL)

The sacral epidural space may be entered through the large triangular opening on the dorsum of the bone, and sacral anæsthesia obtained by the injection into the space of 20 ml. of 1 per cent. Novocaine. Operations on the lower bowel and anal region can then be performed painlessly, and some obstetricians practise this method in order to relieve the pains of child-birth, an additional advantage being that the infant is unaffected.

To perform sacral puncture the median crest of the sacrum is palpated until the depression caused by the sacral opening is recognised. A lumbar-puncture needle is introduced directly forwards until the ligaments covering the opening are pierced, after which the direction of the needle is changed so that it passes vertically upwards within the sacral canal (fig. 483). In order to ensure that the point of the needle is within the epidural space, it is wise to inject a few millilitres of normal saline; if the needle has not penetrated the canal, infiltration of the subcutaneous tissues will be evident, in which case it is withdrawn and a fresh attempt is made.

CHAPTER 26

NERVES

CRANIAL NERVES

THE **Olfactory Nerve** may be injured by fractures of the cribriform plate, resulting in partial loss of smell (hyposmia) or anosmia on the corresponding side. Olfactory filaments may be ruptured as a result of anterior displacement following blows on the back of the head (*contre-coup*, p. 402).

The **Optic Nerve** may be damaged by fractures involving the optic foramen or by contusion against the margin of the foramen. Involvement by tumours or aneurysms is not uncommon. Primary optic atrophy with partial or complete blindness results in the affected eye, but contraction of the pupil will occur if the opposite retina is stimulated. The optic nerve is an outgrowth of the brain and gliomas arise in its substance, particularly in young children.

The **Third Nerve** is involved by tumours, trauma, or aneurysm in the skull, sphenoidal fissure, or orbit. Pressure on the nerve above the tentorium occurs in the early stages of midbrain pressure cone formation causing a dilated pupil. Partial lesions may only produce a dilated pupil, but in complete lesions the following features are noted.

(*a*) Ptosis of the upper eyelid, owing to paralysis of the levator palpebræ superioris.

(*b*) Proptosis, owing to paralysis of the majority of the ocular muscles, which normally exercise traction on the eyeball ; this will be increased if an intraorbital tumour is also present.

(*c*) Mydriasis, as the sympathetic fibres are unopposed, and cause unhampered dilatation of the pupil.

(*d*) Loss of accommodation, owing to paralysis of the ciliary muscle.

(*e*) Diplopia and external strabismus, with a slight downward inclination of the eye-ball due to unopposed action of the external rectus and superior oblique muscles. Owing to their proximity, other nerves passing to the orbit are often affected.

The **Fourth Nerve** supplies the superior oblique muscle, and is rarely involved alone. Diplopia and deficient movement of the eye in a downward and outward direction may be observed.

The **Fifth Nerve** or its branches are sometimes injured, and sensory disturbances follow.

Trigeminal neuralgia or *tic douloureux* occurs most commonly in females. The cause is unknown but may be related to infection of the nerve by the virus of herpes simplex. Pain commences in the third or second division and extends in time to the adjacent division, the ophthalmic division

usually escaping. The pain is characteristically intermittent and extremely severe, but of brief duration, often described as being like red-hot needles searing the flesh. Spasms of pain are precipitated by external stimuli such as cold draughts, brushing the teeth, washing, speaking, eating, or drinking hot or cold substances. The patient often indicates 'trigger zones', stimulation of which produces an attack. Pain occurs in bouts of several weeks' duration with long periods of remission. The periods of remission, however, gradually become shorter and the attacks last longer, until eventually the patient is in almost continuous pain and may become suicidal. Pain may also be experienced in the trigeminal areas as a result of partial lesions either dental, nasal, or ocular, or from involvement of the trigeminal pathways, in disseminated sclerosis, eighth nerve tumours, or aneurysms but in such cases the pain is more continuous and occurs in association with physical signs of the causative lesion. Trigeminal neuralgia is to be distinguished by the fact that it is an intermittent pain of great severity which occurs in the absence of physical signs.

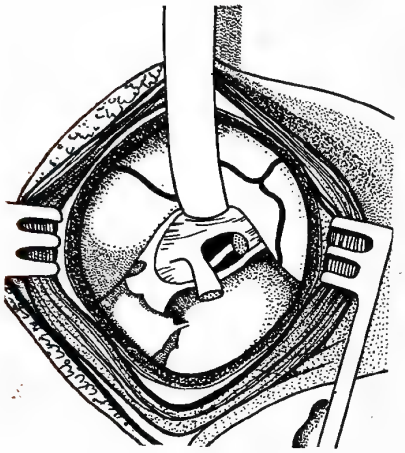

FIG. 484.—Fractional section of the lower and outer two-thirds of the sensory root at the apex of the petrous. The motor root is visible behind the cut portion of the sensory root.

Treatment consists of a thorough search for any source of symptomatic pain, and the use of analgesics. Tegretal (Geigy) may control pain in certain patients. If the condition persists, injection or operation is indicated.

Alcohol injection is made into the Gasserian ganglion. The needle is inserted 1 cm below the zygomatic notch and passed upwards, backwards, and inwards to make contact with the third division at a depth of 5 to 6 cm. The needle is then advanced into the nerve, causing severe pain; a drop of local anæsthetic is immediately injected. Before alcohol is injected, the syringe is aspirated to make sure that no cerebrospinal fluid escapes. If the needle is well into the nerve, considerable resistance is offered to injection of local anæsthetic. The anæsthesia produced indicates the position of the needle point, which is now advanced into the ganglion, and further anæsthetic is injected until the requisite area of the face is rendered numb. 4 or 5 millilitres of absolute alcohol are now injected. Relief from pain may last from six months to two years, following which sensation usually returns and pain with it. Repeated injections are then necessary and are made with increasing difficulty owing to fibrosis in, and around, the nerve. If further injections are required in a young subject, it is better to proceed to the safe operation of sensory root section in the middle fossa.

Phenol Injection.—Recent experiments indicate that the injection of 7·5 per cent. phenol in myodil, introduced by injection into the ganglia under X-ray control, will produce relief of pain without loss of sensation.

Division of the Sensory Root.—Sensory root section is greatly facilitated by operation in the sitting-up position. This reduces pressure in the venous sinuses, minimises bleeding, and facilitates exposure, since any effused blood collects in the floor of the skull and is easily sucked away without obstructing the view.

The temporal muscle is exposed by a curved-hook incision and divided. An opening is made at the base of the skull in order to minimise the elevation of the dura. The dura mater is separated from the floor of the middle fossa until the middle meningeal artery is seen emerging from the foramen spinosum. A blunt hook is inserted into the foramen, the artery is coagulated with diathermy, and then divided with cutting current. The mandibular nerve is then identified as it passes back from the

Johann Ludwig Gasser, died 1765. Professor of Anatomy, Vienna. His pupil, Raymund Balthasar Hirsch, discovered the ganglion and named it after his teacher.

foramen ovale to the cave of Meckel. The dural sheath is now stripped up by blunt dissection with the point of the sucker, opening Meckel's cave in order to expose first the ganglion and then the sensory root which lies in a sheath of arachnoid farther backward on the apex of the petrous bone. A retractor is inserted into Meckel's cave and the sensory root is exposed and the sheath around it is opened. Cerebrospinal fluid escapes in considerable volume and is removed by suction. The sensory root is then distinguished by its loose texture and parallel fibres. The root is now divided on a blunt hook, avoiding the motor root which lies deep to the sensory fibres and crosses behind them at an angle of some 60 degrees. Fractional division of the lower and outer two-thirds of the root preserves sensation in the first division, the fibres of which lie in the upper and inner one-third of the root (fig. 462).

Temporary facial paralysis rarely follows operation as a result of traction on the great superficial petrosal nerve being transmitted to the geniculate ganglion of the facial nerve. This can be avoided by keeping the third division of the nerve and the ganglion between any dissection and the great superficial petrosal which passes under the ganglion.

Neuropathic keratitis also results from damage to the great superficial petrosal, which is the secreto-motor nerve to the lacrimal gland. In all cases tear secretion is reduced to 50 per cent. of normal for the first six weeks, the eye must therefore be kept covered for this length of time.

Sensory root division has an operative mortality of less than 0·5 per cent. The operation has been successfully performed in patients of up to eighty-four years of age.

Sjöqvist intramedullary tractotomy.—The descending root to the fifth nerve conveying pain fibres is divided by an incision 4 mm wide and 4 mm deep opposite the lowest vagal fibres in the medulla. This produces analgesia without loss of touch in the face, but is less satisfactory and more dangerous to the patient than sensory root section, see also Stereotactic Trigeminal Tractotomy p. 468.

The **Sixth Nerve** is slender and has a long intracranial course. It may be affected by fractures of the base of the skull or displacement of intracranial structures, or it may be involved in association with other ocular motor nerves by lesions in the cavernous sinus, sphenoid fissure, or orbit. The external rectus muscle is paralysed, and internal strabismus results.

The **Seventh Nerve** is involved by a variety of causes.

1. *Intracranial.*—Lesions within the brain are supranuclear, nuclear, or infranuclear. Supranuclear lesions involve only the lower half of the face, as the occipito-frontalis and orbicularis palpebrarum muscles enjoy bilateral innervation. In nuclear lesions the whole face and the sixth nerve on the same side are affected and also the opposite arm and leg, as the motor decussation takes place at a lower level. An infranuclear lesion occasionally results from pressure of a tumour, e.g. of the cerebello-pontine angle, in which case involvement of the auditory nerve is also evident.

2. *Cranial.*—The intraosseous portion of the facial nerve may be affected by fractures of the base (fig. 485) and middle ear disease. Following fracture paralysis may appear immediately as a result of direct injury to the nerve or within hours or days from hæmorrhage within the nerve sheath, in which latter case recovery is possible. Paralysis occurring after some weeks is produced by the pressure of callus and is unlikely to recover. Facial paralysis is a complication of middle ear disease and may follow injury at operation on the mastoid antrum. Compression within the aqueduct of Fallopius occasionally follows chronic inflammation.

3. *Extracranial.*—The facial nerve or its branches may be injured outside the skull. The nerve is commonly involved by Bell's palsy, which is due to herpetic neuritis and follows exposure to cold or draught. Swelling within the

Johann Friedrich Meckel (the elder) 1724–1774. Professor of Anatomy, Botany and Gynæcology, Berlin.

Gabriel Fallopio, 1523–1563. Professor of Anatomy and Surgery, Padua, Italy.

sheath of the nerve extends into stylomastoid foramen, and the nerve is compressed within the bony canal. Absorption of exudate usually occurs before the pressure has damaged the nerve permanently, but in about 3 per cent. of cases complete paralysis remains, and in 5 to 10 per cent. some degree of paralysis persists. Tetanus arising from a wound in the distribution of the facial nerve sometimes causes paralysis, the cause being similar to that described above. Malignant tumours of the parotid gland involve the facial nerve, and paralysis is an important diagnostic sign distinguishing simple from malignant tumours.

FIG. 485.—Right-sided facial paralysis following fracture through the middle fossa.

Branches of the facial nerve are injured either accidentally, e.g. by broken windscreens, or by ill-placed operation incisions. For operating on the parotid, the main trunk of the nerve must first be located and then branches followed forward (p. 557).

The paralysed face is flat and expressionless. The eye cannot be closed, and attempts to do so result in the eyeball being turned upwards and outwards (fig. 485). Corneal ulceration may follow from exposure. Epiphora occurs owing to drooping of the lower eyelids. Whistling is impossible, as the cheek merely flaps, and food collects between the gums and cheek.

Treatment is directed to the cause. To promote recovery the angle of the mouth is supported by a malleable rod covered with rubber tubing, which is bent like an 'S' so that the upper curve will hook around the ear and the lower will elevate the angle of the mouth. Small strips of adhesive strapping applied under tension also form a very convenient method of preventing-overstretching of the facial muscles. If considered advisable, an intra-oral splint can be fashioned from plastic material. Electrical treatment and massage are prescribed, and during recovery the patient should practise facial movements with the aid of a mirror. Hypoglossal anastomosis may be considered in hopeless cases (p. 488). Repeated facial tic with spasmodic contracture of the facial muscles may be relieved by fractional division of the branches of the facial nerves which supply the affected muscles, these branches being exposed through a curved incision anterior to the lobe of the ear.

In cases of Bell's palsy early decompression of the nerve may be achieved by cortisone (60 mg. daily for 3 days, then 20 mg. for 3 days).

Facial tic.—An embarrassing condition in which repeated spasm of the facial muscles produces repeated winking or twitching of the face according to the muscles affected; may be relieved by partial section of branches of the facial nerve supplying the affected areas.

The **Eighth Nerve** may be involved in fractures of the middle fossa, or compressed by a tumour, e.g. of the auditory nerve sheath, causing unilateral deafness (p. 538). Vestibular functions are sometimes impaired.

Sir Charles Bell, 1774–1842. Surgeon, Middlesex Hospital, London (1812–1835). Professor of Surgery, Edinburgh (1836–1842).

Menière's disease (p. 538) is a paroxysmal disturbance associated with giddiness, deafness, and vomiting. If medical measures fail, the vestibular portion of the nerve is exposed through the posterior fossa and divided as it enters the internal auditory meatus (fig. 486).

The **Ninth Nerve** is occasionally injured by a fractured base. Some dysphagia may occur from paresis of the constrictor muscles.

Glosso-pharyngeal neuralgia is characterised by severe explosions of pain either in the region of the tonsil or deeply in the ear. The ' trigger ' zone is in the tonsillar area, and the diagnosis is clinched by the fact that cocainisation of the zone temporarily relieves the condition. In genuine cases the nerve must be divided. It is approached either through the posterior fossa and severed as it enters the jugular foramen, or as it crosses the tonsillar fossa after tonsillectomy.

The **Tenth Nerve** may be damaged in association with a fractured base, or crushed by a ligature which includes it as well as the internal jugular vein or common carotid artery. Injury to one vagus nerve is unlikely to cause more than a temporary tachycardia. In doubtful cases examination of the laryngeal muscles will reveal recurrent laryngeal nerve involvement.

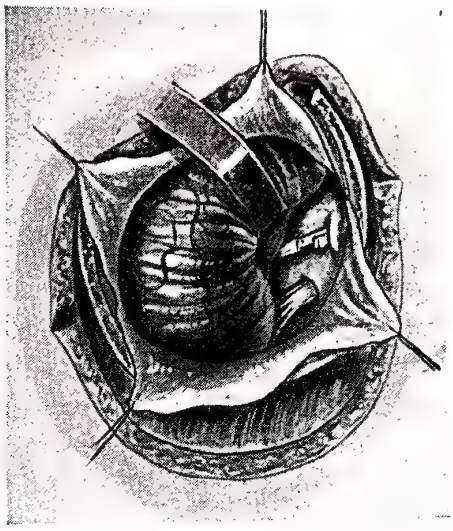

FIG. 486.—Unilateral cerebellar exposure. The cerebellum is drawn inwards and exposes the ninth, tenth, and eleventh nerves at the jugular foramen. Above this the eighth nerve has been divided as it lies behind the seventh at the internal auditory meatus.

The recurrent laryngeal nerve may be damaged in operations on the thyroid gland (p. 682) or ductus-arteriosus by traction or post-operative extravasation. Complete paralysis may follow division or inclusion by a ligature at operation, infiltration by neoplasm of the thyroid gland or secondary lymph nodes from carcinoma of the lung, and on the left side by pressure of an aneurysm of the aortic arch. Partial involvement affects the abduction fibres, which are more susceptible than those which supply the adductor muscles, and thus if partial involvement is bilateral, stridor results, and tracheostomy may be required. Complete involvement results in paralysis of both abductors and adductors, and consequent paralysis of the corresponding vocal cord in the half-way or ' cadaveric ' position. The opposite vocal cord increases its range of mobility, so that it reaches across the mid-line and closes the glottis. The voice is adequate but somewhat monotonous.

Hysterical aphonia is emotional in origin and is distinguished from true paralysis by the fact that, although the patient can only whisper, coughing is readily performed on request.

The **Eleventh Nerve** is rarely damaged by fractures but is more commonly injured during high cervical dissections, particularly in the removal of tuberculous lymph nodes which often entirely surround it. The nerve passes downwards and backwards at right angles to the centre of a line connecting

the angle of the jaw and the mastoid process, and emerges from the posterior border of the sternomastoid muscle at the junction of the upper third and lower two-thirds; it then passes across the posterior triangle, and disappears under cover of the trapezius muscle. Division of the nerve in the anterior triangle usually produces complete paralysis of the sternomastoid muscle, but the motor supply contributed from the second and third cervical roots is sufficient in a third of the cases to prevent a complete paralysis of the sternomastoid. Division will result in only a partial paralysis of the trapezius as the trapezius receives a sufficient additional supply from the third and fourth cervical nerves. If injury occurs in the posterior triangle, the trapezius alone is affected. On inspection, drooping of the shoulder is seen, and wasting of the trapezius is obvious (fig. 487). Contraction of the sternomastoid muscle is tested by asking the patient to turn his head to the side opposite to the muscle. Palpation detects the rigid band of muscle if contraction is normal. Injury of the nerves to the trapezius results in inability to continue elevation of the arm after it is abducted to a right angle by the deltoid muscle. If the branches to the muscle from the third and fourth cervical nerves are intact, about 20 degrees elevation from the right-angled position is possible.

FIG. 487.—Drooping of the left shoulder and wasting of the trapezius muscle following division of the spinal accessory nerve. The swellings on forehead and face are soft fibromas—a common condition after middle age.

If division of the spinal accessory nerve is recognised at operation, primary suture should be performed. Secondary suture is not successful on account of retraction of the ends and difficulty in identifying them in scar tissue.

The **Twelfth Nerve** escapes in fractures of the base of the skull, as the anterior condyloid foramen is protected by a bony ridge which diverts a fissure towards the foramen magnum. It may be injured in submental operations, e.g. for removal of tuberculous lymph nodes. Hemiatrophy of the tongue occurs, the corresponding side of the tongue being shrivelled and wrinkled, the tongue being pushed towards the paralysed side on protrusion (fig. 488).

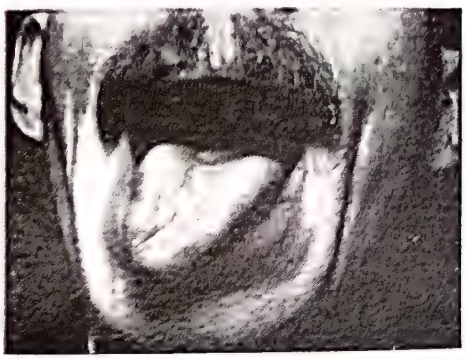

FIG. 488.—Hemiatrophy of the right side of the tongue following involvement of the hypoglossal nerve by syphilitic basal meningitis.

PERIPHERAL NERVES

Injuries of nerves are classified according to the extent of the damage to the nerve fibres and sheath, as neurapraxia, axonotmesis, and neurotmesis.

NEURAPRAXIA

is the equivalent of concussion. There is physiological paralysis of conduction in the intact nerve fibres as the result of stretching or distortion without any

organic rupture. Neurapraxia is produced by minor stretch injuries, or by the concussion and vibratory effect of a high-velocity missile passing near a nerve without contacting it. Fibres remain intact within the intact sheath. It produces sensory loss, paraesthesiæ, and weakness of muscle groups lasting for days. During this time there is no reaction of degeneration in the muscles. There is no degeneration of the axons. When the power of conduction returns, all functions, motor and sensory, return together, sensation recovering in the whole limb within a period of hours. Recovery is complete.

Treatment consists of splinting the limb in a position of relaxation of the paralysed muscle groups until spontaneous recovery occurs.

AXONOTMESIS

consists of the intrathecal rupture of nerve fibres within an intact sheath. According to the cause, the nerve fibres are damaged to a variable degree (see below). Wallerian degeneration occurs in the distal portion of the broken axons, leaving an empty tubule. Intraneural fibrosis occurs at the sites of axonal rupture and minute intraneural hæmorrhages. Recovery takes place slowly by the proliferation and down-growth of axons into the distal tubules, the combined bulk of the proliferating axons and intraneural fibrosis producing a fusiform neuroma on the course of the nerve. There is some loss of nerve fibres owing to the blockage of the down-growing axons by the intraneural fibrosis, but since the relative position of axon and distal tubule is preserved by the intact sheath there is little maldistribution, hence the quality of regeneration is often good except in the case of progressive fibrosis. Recovery is delayed until the down-growing fibres reach their appropriate endings, and occurs first in the muscle groups nearest to the site of division and lastly in the peripheral skin areas, where the anæsthetic area begins to decrease steadily from the margin inwards. The length of time required for the recovery depends upon the level of the lesion. After an initial delay of approximately ten days, down-growing axons proceed distally at a rate of approximately 1 mm. a day, and on arrival at their endings there is a further delay of three weeks before the end organs become activated. Partial or complete intrathecal rupture of fibres may complicate a single stress occurring in association with fractures or dislocations, or excessive vigour during attempted reduction of such injuries; it also accompanies traction injuries at birth and may be produced by clutching for support when falling, as in brachial plexus lesions. It may follow contusion of a nerve with extensive hæmorrhage into its sheath or be the result of severe and acute compression by tourniquets, splints, or incorrect posture on the operating table.

Gradually increasing lesions are produced by progressive compression from crutches, splints, callus, and scar tissue or by repeated minor stretching of a nerve which becomes fixed near a mobile joint. The latter is seen when a nerve such as the external popliteal becomes fixed at the head of the fibula, or the ulnar nerve becomes fixed behind an arthritic elbow or stretched by cubitus valgus; in such cases movements of the joint pulling on the

Augustus Volney Waller, 1816–1870. General Practitioner, Kensington, London (1842–1851). Subsequently worked as a physiologist at Bonn, Paris, Birmingham and Geneva.

fixed nerve produce repeated minor ruptures at different levels, each of which is succeeded by a small degree of fibrosis, which gradually induces a progressive fibrosis and loss of function within the nerve.

Clinical Features.—Following a severe stretch, there is an initial picture of neurapraxia with widespread loss of sensation, tone, power, and reflex activity in the limb; this is followed by an incomplete recovery. The resolution of concussion will restore sensation and movement to certain areas of the limb to which the nerve fibres remain intact. The numbness and paralysis will persist in those areas to which the fibres have actually ruptured. Usually the total area affected is less than the known anatomical distribution of the nerve as a proportion of fibres have escaped.

Treatment of closed injuries of nerves consists in maintaining the nutrition of the limb and combating, by suitable means, the secondary pathological changes which would otherwise follow nerve injury, in order to maintain the muscles and joints in good working order pending the arrival of down-growing axons.

Secondary pathological changes accompanying nerve injury affect the skin, muscles, and joints. Impaired circulation consequent on disuse renders the part blue and cold. The skin becomes thin, the nails brittle, and so-called trophic changes occur as a consequence of minor unrecognised trauma. Those muscles which are paralysed and flaccid will be overstretched by unopposed action of antagonist groups. Within three weeks the reaction of degeneration appears. The muscle fibres no longer respond to the rapid make-and-break of faradic stimulation owing to an increase in the duration of chronaxie which accompanies paralysis, but they will still respond to the slow make-and-break of galvanism. The polarity also changes so that A.C.C.[1] becomes greater than K.C.C.[2] If the muscle nutrition is not maintained by galvanic stimulation, muscle fibres degenerate and progressive fibrosis replaces inert fibres. Recovery is then impossible. Periarticular adhesions eventually form around the immobile joints and fix them in a contracted position. To combat these effects the part must be protected by warm padding to prevent injury, and splinted in a position of relaxation of the paralysed groups. The electrical reactions of the muscles are recorded and muscle movement is maintained by regular galvanic stimulation of all paralysed groups. All joints are put through full passive movements daily to prevent contraction. In the case of the hands, joint movements and exercise of the paralysed muscles are best maintained by the use of elastic splints in which strands of catapult elastic are attached to leather thimbles, which are inserted over the finger-tips and mounted on wire frames in positions corresponding to the paralysed tendons, so as to provide an elastic counter-pull to replace the normal contraction of the paralysed muscles against which the opponents can act. This not only ensures full normal movement of all joints, but will also permit partial use of the hand during recovery.

Considerable encouragement must be given to the patient during the long

[1] A.C.C. = Anodal Closing Contraction. [2] K.C.C. = Kathodal Closing Contraction.

period of time required for restoration of function. Progress is carefully checked by taking regular records of the electrical reactions and skin sensitivity. Electrical reactions change back to normal in the proximal groups as the downgrowth of fibres proceeds. These changes must be recorded, together with diagrams of the skin sensation, in order to determine whether normal recovery is taking place. Failure to recover, or regression after the initial recovery, is an indication for the local exploration of the injured site. It is occasionally necessary to deal with a perineural scar or remove an intraneural fibroma.

Movements produced by unaffected muscles must not mislead the observer. Thus, in a case of radial paralysis, the fingers can be extended by the interosseous and lumbrical muscles, provided that the hand is supported. Also vicarious movements may be performed by adjacent muscles, e.g. in the case of division of the median nerve, the adductors of the thumb, acting in conjunction with the extensor ossis metacarpi pollicis, can produce opposition of the thumb.

H. J. Seddon *et al.* have endeavoured to calculate the rates of nerve regeneration, basing their results on the following clinical data:

(1) Tinel's sign—the course of the nerve is lightly percussed with a patella hammer, from below upwards. A tingling sensation is experienced when the level of regeneration is reached.

(2) Measurement of the rate at which pain and touch sensibility return.

(3) Observation of the times at which the function of muscles returns at different levels from the injury.

It appears that regeneration occurs initially at about 2 mm. a day, but the rate diminishes as time passes, so that after about three months it has slowed down to about 1 mm. a day. (Other factors which influence the results of suture are discussed on p. 488.)

Compression of a nerve.—The first symptoms usually consist of paræsthesiæ, numbness, and tingling along the distribution of the nerve, associated with neuralgic pain. Complete paralysis and wasting of muscles are uncommon unless the initial compression has been prolonged and severe, but when the compressing cause is progressive, paralysis can occur later and may then necessitate operative measures.

Treatment is by removal of the cause, usually a tight splint or plaster, but may necessitate exploration of the nerve and the excision of perineural scar tissue, or mobilisation of the nerve from callus, following which a new bed is prepared for the nerve in adjacent muscles, the nerve itself being wrapped in a layer of tantalum foil.

Sensory symptoms are satisfactorily relieved by these steps, but if intervention is delayed too long intraneural fibrosis may lead to persistent motor disability.

Progressive fibrosis produced by fixation of the nerve has to be treated by nerve transplantation (p. 495); recovery may be complete or incomplete, according to the degree of fibrosis.

NEUROTMESIS

is usually produced by penetrating wounds and results in partial or complete division of the nerve sheath and fibres. Very rarely, complete rupture of

Sir Herbert John Seddon, Contemporary. *Formerly Professor of Orthopædic Surgery, Royal National Orthopædic Hospital, London.*
Jules Tinel, 1879–1952. *Physician, Hôpital Beaujon, Paris.*

nerves may occur in major brachial plexus injuries. In war and severe industrial injuries extensive soft tissue damage to muscle and skin, and associated fractures, greatly complicate the problems of repair.

Partial lesions produce a lateral neuroma of the nerve. Complete division produces a terminal neuroma on the end of the proximal segment. In the proximal portion of the divided axons, retrograde degeneration occurs as high as the first node of Ranvier. After an interval of ten days the axons begin to subdivide to produce an excess of end bulbs, which then commence to grow downwards. By this time, however, the gap between the divided nerve ends, which was at first filled with blood, has now been replaced by organising clot and fibrous tissue, which presents an almost impenetrable barrier to the down-growing axons. In the distal segment of the divided nerve, Wallerian degeneration of the axons occurs, but the cells of the sheaths of Schwann proliferate, forming a slight bulb at the commencement of the distal end from which sprouts of Schwann cells grow proximally into the plane of division, being drawn by chemotaxis towards the down-growing axons. A few axons may by this means succeed in entering the distal segment, producing there a deceptively encouraging Tinel's sign, but any spontaneous healing is minimal.

Even after accurate nerve suture the quality of regeneration is less perfect than in cases of axonotmesis owing to the wastage of axons in the scar tissue at the suture line, and mal-distribution of those fibres which reach the distal segment. The density of scar tissue at the suture line is increased by local sepsis and inflammation, and by tension at the suture site.

Mal-distribution of fibres is greatest in the case of mixed motor and sensory nerves, for motor fibres may then unite with sensory endings. It is also greatest in those motor nerves which supply a large number of small muscles; hence the quality of recovery is best in the case of a pure motor nerve, such as the radial, which supplies a few groups of large muscles concerned in coarse movement, and is worst in mixed sensory and motor nerves supplying a large number of small muscles concerned in fine movement, such as the ulnar or median nerves at the wrist.

Treatment is by suture under suitable conditions, in the absence of sepsis and in the absence of tension, when the nerve can be placed in a suitable bed. In war injuries where there has been considerable loss of surface tissue, preliminary plastic operations such as pedicle grafting must precede attempted repair of the nerve in order to provide a suitable covering and bed at the suture site.

Open wounds (p. 4). In tidy clean incised wounds immediate primary suture is the ideal treatment for a divided nerve. In untidy contaminated wounds, the nerve suture should be postponed until three or four weeks after the injury. If a divided nerve is encountered during excision of such a wound, the ends are approximated by one stitch of fine silk, which prevents retraction during the period of delay. On no account should an attempt be made to identify or scrutinise a nerve in the vicinity. If only one end of a nerve is seen, then a suture should be inserted so as to fix it to adjacent

Louis Antoine Ranvier, 1835–1922. French histologist and pathologist.
Theodor Schwann, 1810–1882. Professor of Anatomy, Louvain, 1839–48, and, thereafter at Liège. Original researches before the age of twenty-seven laid the foundation of Physiology of Nerve and Muscle. The first to deal with problems related to living matter on a purely physical and chemical basis, and to recognise the cell as the unit of living matter. Discoverer of pepsin, and rôle of living organisms in fermentation.

muscle or fascia. The advantages of early secondary suture over immediate primary suture in untidy wounds are as follows :

(i) Primary suture usually requires enlargement of the wound by further incisions, so as to mobilise the nerve in order to allow approximation of the ends without tension. As the wound is potentially infected, exposure of previously uncontaminated tissues should be avoided.

(ii) The normal nerve sheath is a delicate structure, which is easily torn by the slightest tension, and accurate suturing is essential for the success of the operation. In addition, the sheath is often further weakened by longitudinal slits or tears. After about three weeks of the injury, epineural fibrosis occurs and the sheath becomes thicker and tougher, consequently the insertion of sutures and accurate coaptation of the nerve ends are greatly facilitated.

NERVE SUTURE

The two ends of the nerve are identified, the incision being prolonged sufficiently to expose the nerve well above and below the seat of injury, in such a position that its normal anatomical relations are not obscured by scar tissue. The two ends of the nerve are freed and ' freshened ' by means of a scalpel or a Bard-Parker knife. Scissors should not be used, as the nerve is crushed thereby. Slices are removed from the ends of the nerve until the projecting fibres are seen, and blood freely oozes from the cut surface. Apposition of the two ends is accomplished as follows:

(*a*) *Mobilisation.*—The two ends are dissected from surrounding structures, care being taken to preserve important motor branches. Branches can often be stripped from the parent nerve in order to facilitate mobilisation.

(*b*) *Posture.*—The limb being held in a relaxed position.

(*c*) *Transposition.*—The radial nerve is brought in front of the humerus, or the ulnar nerve in front of the internal condyle (p. 495).

(*d*) *Nerve Anchoring.*—If it is obvious that the two ends of a divided nerve cannot be brought together, on account of excessive loss of tissue or retraction, then the two untrimmed ends are approximated as closely as possibly by tension stitches, the position of the limb being such that approximation is facilitated. Subsequently the nerve is stretched by gradually straightening the limb, and at a second operation the two ends are brought together. In some cases adequate suture can be performed while the limb is flexed, and extension is gradually regained.

(*e*) *Resection of Bone.*—This extensive procedure may be justifiable if nerve injury is associated with an ununited fracture, which also needs operative measures, e.g. in the case of the radial nerve and a fractured humerus.

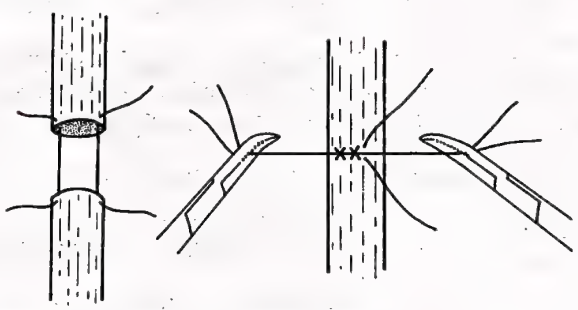

FIG. 489.—Primary nerve suture. Two sutures are passed through the sheath of the nerve in order to approximate the cut ends. The sheath is then sutured.

Approximation having been obtained by one of the above procedures, sutures are introduced through the nerve sheath (fig. 489). Non-irritating material is used, such as fine black silk or tantalum wire. Catgut encourages fibrosis of the nerve. The suture line can be further supported by painting with fibrin glue. Torsion of the nerve ends must be avoided, so that, as far as possible, proximal nerve fibres will join with their corresponding distal fibres. ' Shunting ' is thus avoided, and delay due to re-education of groups of muscles is obviated. If adjacent tissues are fibrosed, a new path can be constructed for the sutured nerve by opening a muscle sheath, and embedding the nerve among the muscle fibres. Finally, a layer of tantalum foil is always wrapped round the nerve to prevent epineural fibrosis and the out-sprouting of axons

Bard-Parker Inc., Danbury, Connecticut, U.S.A.

from the suture line, which may produce a painful local lesion. The limb is placed in a suitable position to prevent any strain on the sutured nerve, and a plaster cast may be advisable for a few weeks to immobilise the limb.

RESULTS OF NERVE SUTURE (see also Chapter 19)

This depends on many factors:

1. **Pre-operative.**—(*a*) *The Nerve Affected.*—Mixed motor and sensory nerves, e.g. ulnar and median, are subject to a greater degree of mal-distribution of down-growing fibres than purely motor nerves supplying a small number of large muscles, e.g. radial.

(*b*) *Infection* may cause delay in performing suture at the appropriate time and increases scar tissue formation following suture.

(*c*) *Time.*—Early secondary suture (p. 487) yields the best results, and further delay is detrimental.

(*d*) *Pre-operative Management.*—If muscles and tendons have been allowed to stretch or if the tone of the muscles has not been maintained, then the chances of recovery are correspondingly diminished.

2. **Operative.**—This consists of attention to the details already mentioned, e.g. hæmostasis, prevention of torsion and tension, preparation of suitable bed, and the use of non-irritating suture material.

3. **Post-operative.**—(*a*) *Absence of Infection.*—If the wound is already infected, or if infection supervenes, then little improvement is likely.

(*b*) *After-treatment* consists in continuance of the relaxation of paralysed muscles, massage, electrical treatment, and muscular effort gradually increased as muscles recover their power.

(*c*) *Co-operation of the patient.*—This important factor must receive due consideration and the patient given every encouragement during his rehabilitation.

(*d*) *Vicarious Movements.*—Although the physiological results of nerve suture may be poor, yet adjacent muscles often take upon themselves some of the functions of those which are paralysed, e.g. if the hamstrings are paralysed and flexion of the knee thereby affected, the sartorious and gracilis muscles hypertrophy, and partially compensate for this deficiency. Thus the functional result of a nerve injury is often more satisfactory than the physiological recovery would suggest.

Irremediable Injury.—If suture is impossible on account of loss of tissue or wide separation of the ends of a divided nerve, the following procedures may be considered:

(*a*) *Nerve anastomosis,* e.g. part of the hypoglossal nerve is united to the distal end of the facial nerve. This method often results in improvement, but 'successful' cases are sometimes associated with uncontrolled grimaces on movement of the tongue.

(*b*) *Nerve grafting* has produced encouraging results in selected cases, e.g. a gap in the facial nerve within its body channel may be bridged by insertion of an auto-graft from the external cutaneous nerve of the thigh. Grafting of peripheral nerves is disappointing.

(*c*) *Tendon transplantation,* e.g. in the case of radial paralysis, tendons and muscles of the forearm may be transplanted into the extensor group. However, if proper relaxation of the extensor muscles has been consistently maintained, drop wrist should not occur, as the extensor tendons will not be over-stretched.

(*d*) *Arthrodesis,* e.g. in the case of injury to the sciatic nerve, arthrodesis of the flail ankle joint will render it stable and rigid.

(*e*) *Amputation,* for persistent sores and ulcers on the foot, particularly if growth is impaired. Sympathetic ganglionectomy might first be tried (p. 153).

Incomplete division of a nerve gives rise to a central or lateral neuroma. Effects vary according to the extent of the injury. Fibres supplying certain muscles are often constant in position, and hence are more liable to injury if their position exposes them to trauma. Thus partial division of the great sciatic nerve affects the lateral popliteal portion nine times more commonly than the medial popliteal, which passes down on the inner and deeper aspect of the great sciatic nerve.

Partial lesion of the median or medial popliteal nerves, or injury to their branches, may give rise to the distressing condition of *causalgia* (p. 498).

Injection lesions are due to accidental injection of therapeutic agents. They are more common in tropical countries where amœbiasis, schistosomiasis, and malaria are treated by intramuscular injections. The sciatic and radial nerves are usually involved. Injections in the buttock should always be given into the upper and outer quadrant (fig. 19) and in the case of the arm into the upper half of the deltoid muscle

SPINAL NERVES

Injuries of the **Cervical Plexus** are uncommon, although muscular branches, e.g. to the trapezius and sternomastoid muscles, are occasionally damaged (p. 482).

The **Phrenic Nerve,** which arises from the third, fourth, and fifth cervical nerves, may be crushed in order to cause a temporary diaphragmatic paralysis and so reduce the size of the pleural cavity in such conditions as bronchiectasis or tuberculosis, and also to diminish movement after repair of the diaphragm for a hernia. Should the temporary paralysis produced by crushing prove to be insufficient, it is not difficult to recrush the nerve.

Paralysis of the diaphragm secondary to malignant disease in the thorax is equally frequent on the right and left sides and is often due to direct invasion of the phrenic nerve by adjacent growth. When phrenic paralysis is due to lymph node metastases, it is almost always due to involvement of a node which lies alongside the phrenic nerve at the level of the pulmonary artery at the upper region of the hilum.

Brachial plexus lesions are either complete or partial (fig. 490).

Complete lesions are rare, as an injury of sufficient severity to damage all the roots of the plexus will probably inflict fatal injuries on adjacent important structures.

In the event of a complete lesion, anæsthesia of the upper limb occurs except over areas supplied by the supra-acromial branches of the cervical plexus and the intercosto-humeral nerve. Complete paralysis of arm and scapular muscles occurs, except that in the case of tears of the plexus the lesion is usually distal to the site at which the nerve of Bell and the nerve to the rhomboids arise, and consequently the serratus magnus and rhomboid mucles escape.

Incomplete lesions, if due to stabs or cuts, are liable to affect any of the roots, the clinical features depending on the nerves divided. The commonest type of injury is due to traction or pressure, and affects either the upper or lower portions of the plexus.

Although the segmental innervation of the arm muscles is somewhat inconsistent, the following table summarises a distribution which is commonly accepted :

Nerve	*Muscles*
C.v	Rhomboids, spinati, deltoid, teres minor, biceps, brachialis, brachioradialis, supinator brevis.
C.vi	Pectoralis major (clavicular head) and minor, subscapularis, coracobrachialis, latissimus dorsi, teres major, serratus anterior, triceps, pronator teres, pronator quadratus.
C.vii	The extensors of the fingers, extensor carpi ulnaris, and sternal part of the pectoralis major.
C.viii	The flexors of the wrist and fingers.
D.i	The small muscles of the hand.

Upper Brachial Plexus Lesion (Erb-Duchenne, fig. 490 (1)). This injury is due to excessive displacement of the head, depression of the shoulder, or a combination of these two conditions. It affects infants after a difficult

Wilhelm Erb, 1840–1921. Professor of Medicine, Heidelberg, Germany.
Guillaume Benjamin Amand Duchenne (Duchenne de Boulogne), 1806–1875. Neurologist, successively in Boulogne and Paris, but never held a hospital appointment.

confinement or adults following blows or falls on the shoulder. The fifth and sometimes the sixth cervical roots are involved. In the former case the muscles affected are the biceps, brachialis, brachio-radialis, supinator brevis, spinati and deltoid, and thus the limb, internally rotated by the unopposed subscapularis, hangs by the side with the forearm pronated, in the well known 'tip' position (fig. 491). Sensory changes are absent if the fifth nerve only is involved, but if the sixth nerve also suffers, an area of anæsthesia is present over the outer side of the arm. Since the innervation of the hand is preserved, functional improvement is obtained by arthrodesis of the shoulder and elbow joints in suitable cases, together with transplantation of muscles from the pectoral groups to the humerus or scapula.

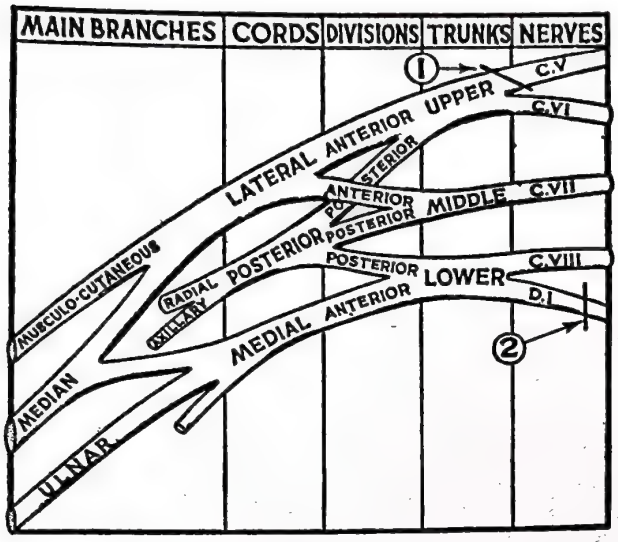

FIG. 490.—The brachial plexus, showing two classical sites for injury—see text.

Lower Brachial Plexus Lesion (Klumpke, fig. 490 (2)).—The lower nerve trunk or the inner cord are injured either above the clavicle, classically by inclusion with the subclavian artery in a ligature, or in the axilla, as by an unreduced dislocation of the humerus. In either case, the inner portion of the plexus is involved, and wasting of all the small muscles of the hand occurs, together with sensory loss along the inner side of the forearm and the inner three and a half fingers, owing to involvement of fibres passing to the ulnar and inner head of the median nerves.

FIG. 491.—Erb's paralysis.

Nerve roots may be avulsed from the spinal cord, as in the case of a falling person clutching at an object and hyper-abducting his arm, e.g. failing to obtain a foothold on a passing bus. The first dorsal root is usually affected. Paralysis of the intrinsic muscles of the hand results, with anæsthesia of the inner three and a half fingers in front, and inner one and a half behind. In addition, the oculopupillary fibres, which pass along the first dorsal nerve to the rami communicantes, and so to the cervical sympathetic, are also affected, and Horner's syndrome follows (fig. 149). Hæmorrhage sometimes occurs in the spinal cord following avulsion of the nerve root, and results in damage to the pyramidal tract and consequent spasticity of the leg on the same side.

Treatment.—Subcutaneous injuries are at first treated on expectant lines, paralysed muscles being relaxed. Thus, in the case of an Erb's paralysis, the arm should be fixed in a position of right-angled abduction and eversion, to

Madame Augusta Marie Dejerine-Klumpke, 1859–1927. Neurologist, Paris.
Friedrich Horner, 1831–1886, Professor of Ophthalmology, Zürich, described his syndrome in 1869.

relax the deltoid and spinati, the forearm being flexed and supinated in order to relax the biceps, brachialis, and supinators. In serious brachial plexus lesions, physiotherapy must be continued for two years before recovery is assessed.

Some minor improvement usually occurs during this time, especially if the initial loss of function has been due to neurapraxia and stretching rather than rupture of nerve fibres. When fibres have been ruptured, a great deal of mal-distribution of down-growing fibres among the complex plexus branches is bound to result in considerable reduction of functional efficiency. Where the nerve tracts are torn across (neurotmesis) little recovery is to be expected, and such cases are rarely improved by exploration of the brachial plexus.

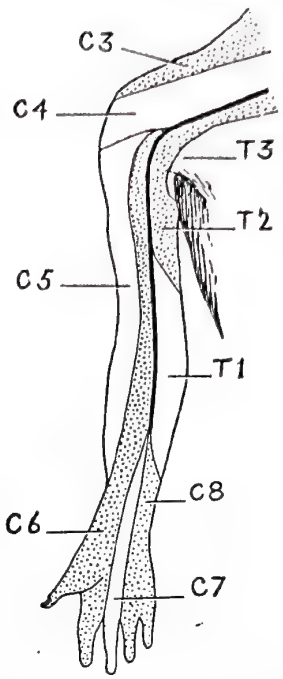

FIG. 492.—The dermatomes of the upper limb.

BRACHIAL NEURALGIA

This condition (*syn.* brachial neuritis) is comparable to sciatica in the leg. The cutaneous distribution of the cervical nerves is illustrated in fig. 492, and the muscular innervation is summarised on p. 489. Some of the more important causes of brachial neuralgia are as follows:

Spinal Tumour (p. 482).—Evidence of pressure on the cord is usually present, and Queckenstedt's test is commonly positive.

Prolapsed intervertebral disc (p. 469) is often difficult to distinguish from osteoarthritis, but localised pain in the neck, which often appears suddenly and which is aggravated by coughing, suggests a disc lesion.

Osteoarthritis of the cervical spine (*syn.* spondylitis) causes neuralgia either as a result of pressure on a spinal nerve by an osteophyte or from absorption of the disc and consequent compression of the spinal roots. The onset is gradual and symptoms intermittent, and radiography usually establishes the diagnosis.

Costo-clavicular syndromes are due to many conditions. Sagging of the shoulder girdle, especially in middle-aged females, is a common cause, quite apart from cervical rib. Exercises and physiotherapy directed to improving the tone of muscles which elevate the shoulder may relieve the symptoms in such cases.

FIG. 493.—Wasting of the left deltoid muscle and area of anæsthesia due to bruising of the circumflex nerve.

The **Circumflex Nerve** passes through the quadrilateral space, and winds around the shaft of the humerus about one finger's-breadth below the centre of the deltoid muscle. It is sometimes injured by a direct blow, or involved by a fracture or dislocation of the humerus.

The deltoid muscle is paralysed and wastes rapidly, and a patch of anæsthesia over the outer side of the arm distinguishes this condition from a partial lesion of the fifth cervical nerve (fig. 493). Paralysis of the teres minor is unrecognisable clinically.

Hans Queckenstedt, 1876–1918. (*See footnote p. 459.*)

Recovery commences in a few weeks if the cause of the compression is removed, provided that the arm has been supported in right-angled abduction.

The **Nerve of Bell**, or external respiratory nerve, arises from the fifth, sixth, and seventh cervical nerve roots and supplies the serratus anterior muscle. It may be injured by blows or carrying a heavy object on the shoulder, or during operations on the breast or chest wall, as it lies on the inner wall of the axilla. Paralysis of the serratus anterior allows 'winging' of the scapula, i.e. the vertebral border and inferior angle are unduly prominent (fig. 494). The 'lunge' stroke of fencing is dependent on the serratus anterior, and this and similar movements, such as pushing forward with the arm, are deficient. Owing to inability to rotate the scapula on the chest wall, difficulty is experienced in raising the arm above a right angle from a position in front of the body.

FIG. 494.—Winging of the scapula; the patient is pushing against a wall.

Suture of the nerve is sometimes possible. Otherwise, if disability warrants such a procedure, the scapula is steadied by a slip of pectoralis major muscle, which is detached from the humerus and fixed to the inferior angle of the scapula.

The **Radial** or musculospiral nerve is commonly injured. The classical sites are the axilla and the radial groove.

1. **Injury** in the **axilla** follows: (i) Crutch palsy: all crutches should have hand-grips, and their length should be carefully adjusted, especially if use is likely to be prolonged. Paresis has occurred after only four hours' use of crutches unsupplied with hand-grips.

(ii) Fractures and dislocations of the upper end of the humerus, or by attempts at their reduction.

(iii) Rarely by pressure of an aneurysm or new-growth.

Clinical Features.—(*a*) *Motor.*—The triceps and extensors of the wrist and fingers are paralysed, and consequently inability to extend the elbow, wrist, and fingers results, and wrist drop is present. If the hand is supported, as by supporting it upon the table, extension of the fingers can be produced by the action of the lumbricals and interossei, which are inserted into the extensor expansions. The supinator and brachio-radialis are also paralysed, but supination is ably performed by the biceps. The brachio-radialis muscle is tested readily by endeavouring to flex the semi-prone forearm against resistance. If the muscle is active, the contraction is visible, and the rigid muscle is easily palpable.

(*b*) *Sensory.*—Anæsthesia is present over the dorsum of the forearm and back of the hand where anæsthesia is reduced to a patch over the base of the thumb and first interosseous space owing to overlap of the musculocutaneous and other adjacent nerves (fig. 495). In peripheral nerve injury when sensory function is not restored, the final sensory loss is less extensive than the ana-

Sir Charles Bell, 1774–1842. *See footnote p. 480.*

tomical distribution of the nerve owing to the overlap of adjacent sensory areas.

(*c*) *Trophic.*—These are usually trivial.

2. **Injury** in the **radial groove** is due to:

(i) Pressure, e.g. of the arm on the edge of the operating table, especially in Trendelenburg's position, or as in 'Saturday night' paralysis, due to the enjoyment of a heavy sleep with the arm over the sharp back of a kitchen chair. Prolonged application of a tourniquet is especially liable to compress the radial nerve, as it lies close to the bone, and possibly the median and ulnar nerves as well. For this reason a sphygmomanometer should always be used on the arm.

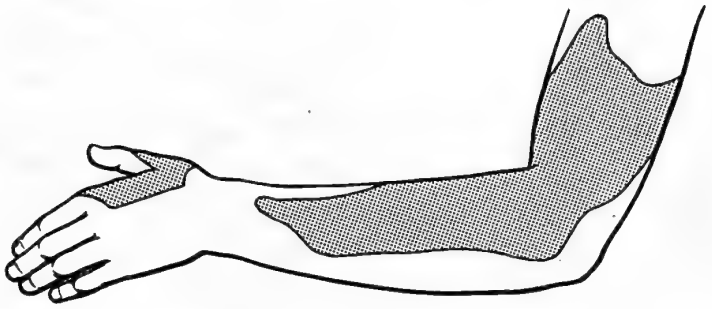

FIG. 495.—Areas of anæsthesia and anhidrosis following complete division of the radial nerve above the dorsal cutaneous nerve of the forearm and lower lateral cutaneous nerve of the arm. In lesions below the origin of the dorsal cutaneous nerve of the forearm the sensory loss is limited to the lower segment depicted over the dorsum of the base of the thumb and first interosseous space.

(ii) Fracture of the shaft of the humerus when immediate injury of the nerve occurs in about 8 per cent. of cases. It is often overlooked owing to the more obvious fracture overshadowing the nerve injury, in which case involvement in callus is usually blamed, rather than oversight on the part of the surgeon.

(iii) The nerve being overstretched during operations on the humerus, e.g. in dealing with an ununited fracture.

(iv) 'Intramuscular' injections of drugs being given into the radial nerve.

Clinical Features.—(*a*) *Motor.*—These are similar to those following injury in the axilla, except that the triceps and anconeus muscles escape.

(*b*) *Sensory.*—If the external cutaneous branch escapes, anæsthesia will be limited to a patch over the ball of the thumb. Division of the radial nerve in the upper third of the forearm is symptomless. Below this position the musculo-cutaneous nerve joins the radial, and division then causes anæsthesia over the ball of the thumb.

(*c*) *Trophic.*—These are slight.

The *posterior interosseous nerve* may be injured as a result of fracture or dislocation of the upper end of the radius, or in operations performed to deal with these conditions. Paralysis of the extensors of the wrist and fingers results. The upper end of the nerve has been sutured with excellent results. If nerve repair is impracticable, good results are obtained by a tendon and muscle transplant, e.g. the radial carpal flexor is transplanted to the extensor tendons of the thumb and fingers, and the pronator teres into the extensors carpi radialis longus and brevis (p. 303).

The **Median Nerve** is classically injured at the elbow or wrist.

1. Injuries at the **elbow** are due to fractures of the lower end of the humerus or dislocations of the elbow joint. A tourniquet endangers the

Friedrich Trendelenburg, 1844–1924. See footnote p. 71. Described this position for pelvic operations in 1890.

nerve at any level in the arm, in which case other nerves, particularly the radial, will also be involved.

Clinical Features.—(*a*) *Motor.*—The pronators of the forearm and flexors of the wrist and fingers, with the exception of the flexor carpi ulnaris and the inner part of the flexor profundus digitorum, will be paralysed. As a result of paralysis of the flexor carpi radialis, the hand deviates to the ulnar side when flexed against resistance. The index fingers cannot be flexed at the phalangeal joints—the 'pointing index'—but flexion of the other fingers is performed by that portion of the flexor profundus digitorum which is supplied by the ulnar nerve. Flexion of the terminal phalanx of the thumb is impossible, owing to paralysis of the flexor longus pollicis. The muscles of the thenar eminence are wasted and paralysed, and on inspection the eminence is flattened, so that the metacarpal bone of the thumb is apparently on the same plane as the other metacarpal bones—the so-called 'simian' or 'ape-like' hand. Paralysis of the two outer lumbricals is unrecognisable.

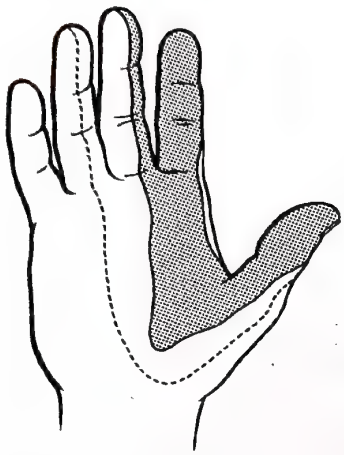

FIG. 496.—Area of persistent sensory loss in a complete median nerve injury above the wrist showing, in broken line, the distribution of the median nerve and, in stipple, the reduced area of anæsthesia, anhidrosis and analgesia finally persisting after injury owing to overlap of adjacent nerves. The ulnar nerve overlaps the ulnar side of the third finger.

(*b*) *Sensory.*—Appreciation of touch is at first lost over the thumb and radial two and a half fingers in front, and posteriorly as far proximally as the middle of the proximal phalanges. Loss of response to pin-prick affects the terminal phalanges of the index and middle fingers, but sometimes a larger area is involved. Deep sensibility is lost over the terminal phalanges of the index and middle fingers. Later this area is reduced by overlap from adjacent nerves.

(*c*) *Trophic.*—Obvious trophic changes are usually seen in the hand and affected fingers, particularly the index finger. Causalgia may complicate partial injuries (p. 498).

2. Injuries at the **wrist** are comparatively common, and are due to cuts from a variety of causes. Fractures of the lower end of the radius or dislocation of the semilunar bone sometimes cause injury to the median nerve.

Clinical Features.—(*a*) *Motor.*—The muscles of the thenar eminence are paralysed and wasted. The hand is 'simian', and abduction and opposition of the thumb are lost. Attempts to oppose the tip of the thumb to the tip of the little finger result in flexion and adduction of the thumb, as the patient is unable to swing it across the palm.

(*b*) *Sensory.*—Sensory losses resemble those following an injury at the elbow. Muscular sense is not impaired if tendons are not severed. Thus, as no striking muscular deficiency occurs, and as no part of the hand is completely anæsthetic, a divided median nerve at the wrist is readily overlooked, particularly in those who use refinements of sensation but little, e.g. a horny-handed labourer.

(*c*) *Trophic.*—These occur, as with an injury at the elbow.

The poor prognosis of a divided median nerve is rendered even more gloomy if tendons are also severed.

Median compression occasionally occurs as the nerve passes through the carpal tunnel (*entrapment neuropathy*). Paræsthesia, followed by wasting of the thenar muscles, suggests the diagnosis. A description to be found on p. 295.

The **Ulnar Nerve** is also classically injured at the elbow and wrist.

1. Injuries at the **elbow** are due to the following causes :

(i) Fractures in the region of the internal condyle.

(ii) Excision of the elbow joint.

(iii) Cubitus valgus, due to old injury of the humerus and increase of the 'carrying angle'. Hence the nerve is unduly stretched, and friction occurs as the groove on the internal condyle becomes a pulley, and this continuous friction results in interstitial neuritis. This condition may occur many years after the original injury, and transposition of the nerve is required.

(iv) Fixation of the nerve in the groove due to adhesions complicating osteoarthritis may lead to traction with resulting rupture of axons and progressive interstitial neuritis requiring transposition of the nerve (*entrapment neuropathy*).

Anterior transposition of the ulnar nerve is sometimes required for friction (axonotmesis), following fracture of the internal condyle, pressure by an osteophyte, recurrent dislocation of the nerve, or injury which results in loss of substance, so that approximation is thus rendered possible. The nerve is exposed by a curved incision with the concavity forwards, and the humeral head of the flexor carpi ulnaris is divided. Careful dissection is necessary so as to avoid injury to motor branches, and the internal intermuscular septum should be divided or excised, otherwise the nerve may be kinked by this structure when it is displaced forwards. A bed is then prepared in the flexor group of muscles and the nerve buried therein.

Clinical Features.—(*a*) *Motor.*—The flexor carpi ulnaris and inner portion of the flexor profundus digitorum are paralysed. Normally, on flexion of the wrist, the tendon of the flexor carpi ulnaris is readily palpable just above its insertion into the pisiform bone, but when the muscle is paralysed the tendon is impalpable, and wasting causes flattening of the inner border of the forearm. Weakness of the flexor profundus digitorum results in hyperextension of the little, ring, and slightly of the middle fingers at the metacarpophalangeal joints.

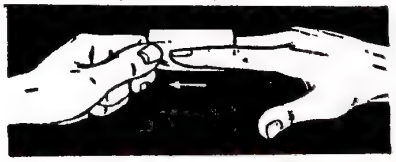

FIG. 497.—Test for weakness of the interosseous muscles.

Paralysis of the small muscles of the hand also results, with the exception of the thenar muscles and outer two lumbricals. Inability to abduct and adduct the fingers results, and the patient cannot grip a piece of paper placed between the fingers (fig. 497). If the patient pinches a piece of paper between his thumb and fingers the terminal phalanx of the thumb assumes a flexed position, as weakness of the adductor pollicis permits overaction of the long flexor of the thumb (Froment's sign) (fig. 498). Considerable wasting occurs, which is obvious in the interosseous spaces and along the inner border of the hand, the normal curve being lost (fig. 499).

Jules Froment, 1878–1946. Professor of Clinical Medicine, Lyons, France.

(*b*) *Sensory.*—The appreciation of light touch is at first lost over the inner one and a half fingers in front and behind. Response to pin-prick is lost over the little finger and ulnar border of the palm (fig. 500). Later this area will be reduced by overlap from adjacent nerves.

(*c*) *Trophic.*—These changes are usually well marked.

2. Injury at the **wrist** is due to the same causes as those enumerated in connection with the median nerve.

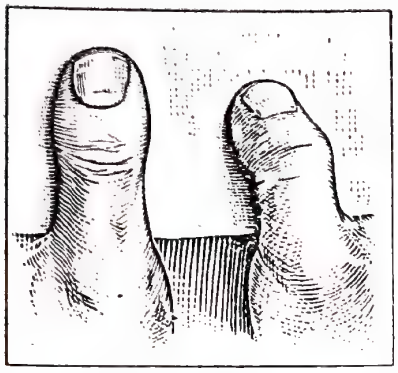

FIG. 498.—Froment's sign for right ulnar paresis.

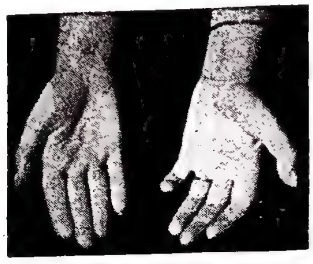

FIG. 499. — Wasting of the hypothenar eminence following injury to the left ulnar nerve.

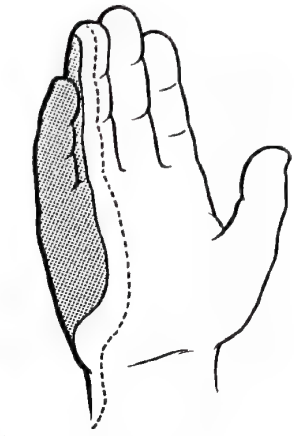

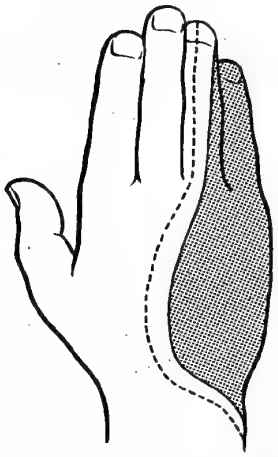

FIG. 500. — Persistent sensory loss in a complete ulnar nerve injury showing, in broken line, the anatomical distribution of the ulnar and, in stipple, the reduced area of persistent anæsthesia finally resulting.

The ulnar nerve passes in front of the anterior annular ligament, and is damaged by more superficial injuries.

Clinical Features.—(*a*) *Motor.*—Paralysis and wasting of small muscles of the hand, as described above.

(*b*) *Sensory.*—The dorsal cutaneous branch of the ulnar nerve leaves the main trunk about 6·3 cm. above the styloid process of the ulna. Sensation is therefore lost only on the anterior aspect of the inner one and a half fingers.

(*c*) *Trophic.*—Correspond to the area of sensory loss.

FIG. 501.—An inguinal hernia which followed appendicectomy with drainage through a gridiron incision one year previously.

The **Twelfth Dorsal Nerve,** as in the case of the intercostal nerves, is sometimes implicated by severe neuralgia, which may be associated with herpes zoster. More commonly the nerve is implicated by a suture during a kidney operation, or by subsequent scar tissue. Resulting pain is occasionally sufficiently severe to necessitate exposure and excision of part of the nerve.

The **Ilio-inguinal Nerve** may be damaged on the right side in a gridiron incision for appendicectomy, although with care the nerve should be avoided. If drainage tubes are inserted through this incision, the resulting scare tissue may implicate the nerve. On the left side, injury to the nerve may follow iliac colostomy. Weakness of the conjoined tendon results, with consequent predisposition to the formation of an inguinal hernia (fig. 501).

The **External Cutaneous Nerve** is occasionally compressed as it passes through the deep fascia of the thigh, especially in muscular subjects, e.g. oarsmen. The condition is termed *meralgia paræsthetica*, and resection of part of the nerve is sometimes necessary to rid the patient of pain or paræsthesia.

The **Sciatic Nerve** is occasionally injured by wounds, fractures, or 'intramuscular' injection of drugs. The component nerves in the pelvis may be involved by fracture, tumour, or aneurysm. Injury in the upper part of the thigh sometimes complicates deep wounds or posterior dislocation of the hip joint. If the lesion is above the origin of branches to the hamstrings, the following features will be present:

(*a*) *Motor.*—The flexors of the knee are paralysed, but some degree of flexion is possible owing to the action of the sartorius and gracilis muscles. Complete paralysis exists below the knee, and the pull of gravity therefore causes foot drop.

(*b*) *Sensory.*—Complete loss below the knee, with the exception of the skin supplied by the long saphenous nerve, i.e. a strip along the inner side of the leg extending along the inner border of the foot to the ball of the big toe.

(*c*) *Trophic.*—Especially on the sole of the foot and toes.

(*d*) Causalgia may complicate partial lesions (p. 498).

Partial involvement of the sciatic nerve affects the lateral popliteal portion nine times as commonly as the medial popliteal.

The **Lateral Popliteal Nerve** is injured as follows:

(i) Fracture or excision of the upper end of the fibula.

(ii) Pressure from plasters or splinters.

(iii) In operations for multiple ligation of varicose veins.

(iv) Pressure within the origin of the peroneus longus from the fibula (*entrapment neuropathy*).

(v) Subcutaneous tenotomy of the biceps tendon.

Clinical Features.—Complete lesions will cause:

(*a*) *Motor.*—Complete paralysis of the extensor and peroneal groups of muscles, with resulting talipes equino-varus.

(*b*) *Sensory.*—Anæsthesia of the outer side of the leg in its lower two-thirds, and of the dorsal aspects of all the toes, with the exception of the outer side of the little toe, which is supplied by the external saphenous (sural) nerve, as one contributory branch—the sural communicating from the medial popliteal nerve—escapes.

(*c*) *Trophic.*—Corresponding to the sensory loss. Moderate degrees of pressure will cause ill defined pain and variable degree of weakness or sensory loss.

The **Medial Popliteal Nerve** is but rarely injured on account of its protected position. The calf muscles and muscles of the sole are paralysed, and talipes calcaneo-valgus may result. The sole is anæsthetic, and trophic changes are usually severe. Causalgia (see p. 498) occasionally follows a partial injury of the nerve or injury to one of its branches.

AUTONOMIC NERVOUS SYSTEM

Indications for Operations.

1. **To Improve Circulation** (Sympathectomy, pp. 131, 134 and 153).
2. **To Relieve Secretory Disturbances.**

Hyperhidrosis (excessive sweating) can be very distressing both at work and socially. Sweating of the hands responds promptly to preganglionic cervico-dorsal sympathectomy below the third dorsal ganglion (p. 153). Sodden, offensive feet, the skin of which is cracked and painful, may be a genuine disability for which lumbar sympathectomy is justified. If the axilla is troublesome, relief follows the excision of that area of axillary skin which contains apocrine sweat glands. The area can be mapped out by applying a sweat-sensitive starch and iodine dusting powder. Alternatively these glands can be destroyed by curettage, inverting the skin through an axillary incision.

A parotid fistula (p. 563), may be encouraged to heal by avulsion if the auriculo-temporal nerve, which is exposed in front of the ear in relation to the superficial temporal artery.

Vagotomy to decrease gastric secretion is described in Chapter 41.

3. To Relieve Painful Conditions

Causalgia is a condition in which paroxysmal attacks of pain follow an incomplete nerve injury, especially of the brachial plexus, sciatic or median nerves. In more than half the cases symptoms supervene immediately after the injury, in the remainder symptoms are deferred for any length of time up to two or three months. The incomplete lesion on the nerve, usually a lateral neuroma, gives rise to antidromic impulses which pass peripherally to the sensory nerve endings where stimuli give rise to the production of histamine-like substance (H substance) similar to that liberated by the posterior nerve root vasodilators. The accumulation of H substance causes vasodilation and renders the part red and engorged, the affected area also sweats profusely and is exquisitely painful and hyperæsthetic owing to the increased pressure. It is noticeable that the patient tends to keep the limb elevated and usually prefers to have the affected area out of bed at night in order to diminish vascular engorgement. The skin is often thin as the result of trophic changes. The pain is alleviated by cold (e.g. a wet sock or glove). Sooner or later the patient loses his morale and becomes introspective and unco-operative. Some cases of causalgia tend to recover gradually, but the condition is often so distressing that surgical alleviation is desirable.

Treatment.—Paravertebral block (either D.2 and 3, or L.1, 2 and 3) relieves the pain for a short time, and confirms the necessity for operation (p. 131). Thoracic sympathetic trunk section or lumbar sympathectomy is the treatment of choice. Sometimes the relief is incomplete although the area of pain involvement is reduced in superficial extent.

Visceral Pain.—*Pancreas.*—The wearying pain from recurring pancreatitis and carcinoma may respond to injection (see paravertebral injection p. 131) of the cœliac and related sympathetic ganglia.

Uterus.—Certain cases of spasmodic dysmenorrhœa can be relieved by presacral neurectomy. No untoward effects on uterine (including parturition) or bladder function have been recorded.

Presacral Neurectomy.—The bifurcation of the aorta is exposed by an incision through the overlying peritoneum, which is easily lifted from the vessel. The presacral nerves are usually represented by a plexus, and in order to ensure complete removal, all the nervous, fatty, and areolar tissues lying over the lower inch of the aorta and the sacral promontory are excised.

CHAPTER 27

EYE AND ORBIT

PERIORBITAL AND ORBITAL SWELLINGS

A NUMBER of conditions present as swellings that arise from around or within the orbit. Periorbital and lid swellings are readily accessible to examination, while those arising from within the orbit cause displacement of the eyeball, resulting in proptosis.

A. Swellings Related to the Supraorbital Margin

External angular dermoid cyst.—The commonest situation for a dermoid cyst (fig. 502), and a swelling in this position is almost pathognomonic. The cyst often lies within a bony depression, caused by the constant pressure.

FIG. 502.—External angular dermoid.

FIG. 503. — Dermoid cyst at the root of the nose.

FIG. 504.—A mucocele of the lachrymal sac. (*Dr. Peter Hansell, London.*)

Some dermoid cysts may have a dumb-bell extension into the orbit, and may erode the orbital plate of the frontal bone to become attached to dura. X-ray is therefore important before excision.

Midline subcutaneous cyst.—If this does not vary on pressure, then it is almost certainly a dermoid cyst (fig. 503), but if it can be emptied on pressure, a meningocele or a communication with a dural venous sinus must be considered.

B. Swellings of the Lids or Lachrymal Drainage Apparatus

Meibomian cyst (chalazion) is a retention cyst of a tarsal gland, and is visible as a swelling on both skin and conjunctival surfaces of the lid; it may become secondarily infected. Treatment is by a vertical incision on the conjunctival surface, and curettage of the contents. This condition must be distinguished from a *Hordeolum* (stye), which is a pyogenic infection of an eyelash follicle and is self-limiting (p. 102).

Mucocele of the lachrymal sac is due to obstruction of the nasolachry-

mal duct, and gives rise to a swelling just below and medial to the inner canthus of the eyelid (fig. 504). Pressure on the swelling may cause mucous regurgitation back into the conjunctival sac. It is common in infants from delayed canalisation, and spontaneous resolution may be expected by one year, but in adults surgical drainage into the nose is necessary; unless this is performed, infection may result in acute abscess formation requiring preliminary surgical drainage via a vertical skin incision.

C. Swellings Arising from within the Orbit: Proptosis

A localised or diffuse swelling arising within the orbit causes space-occupation, resulting in displacement of the eyeball. This is usually associated with some limitation of ocular movement, causing double vision. The commonest cause of proptosis is not however due to *neoplasia*, but due to *hyperthyroidism*, *vascular* and *inflammatory* conditions.

Hyperthyroidism.—Chapter 33.

Vascular causes of proptosis.—Characteristically these present with proptosis of abrupt onset. There are two conditions of the cavernous sinus which present with abrupt proptosis due to intense venous congestion of the orbital tissues. Firstly, an *arteriovenous fistula* may develop between the cavernous sinus and the internal carotid artery, either spontaneously or following a head injury, associated with a pulsating noise in the head. Vision may be jeopardised in both eyes from poor intraocular perfusion, but unless blindness threatens, conservative treatment is the safest procedure. Secondly, a *cavernous sinus thrombosis* presents with abrupt proptosis, visual impairment and oculomotor pareses; the patient is extremely ill. This condition may arise by septic emboli from a focus of infection in the territory of the facial vein, or may complicate meningitis. Intensive parenteral antibiotic therapy is required, but the prognosis is grave.

FIG. 505.—Orbital cellulitis.

Hæmorrhage into the orbit may follow blunt trauma, but the history and associated lid bruising makes the diagnosis obvious.

Inflammatory causes of proptosis.—Acute infection, resulting in *orbital cellulitis*, is a common complication of acute sinusitis; this is accompanied by severe pain, discharge and lid swelling, and proptosis and double vision develop; marked constitutional symptoms are present (fig. 505). Initially the cellulitis must be controlled by intensive parenteral antibiotic therapy, but subsequently the underlying sinusitis may require surgical drainage. In more chronic sinus infections, a localised abscess or mucocele may extend into the orbit, causing displacement of the eyeball. Surgical drainage is required. In *granulomatous* disease, such as sarcoidosis or Wegener's granulomatosis, involvement of the lachrymal gland may cause proptosis, associated with other general manifestations.

Tumours of the Orbit.—These present with slowly developing proptosis, and the direction of the displacement of the eyeball gives some indication of the origin of the tumour.

Commonly, the orbit is secondarily invaded by *tumours arising from adjacent structures*, such as antral or ethmoidal carcinomas, sphenoidal ridge meningiomas, or invasive rodent ulcers from the skin. Orbital metastases are rare, the commonest being from a neuroblastoma of the adrenal gland. Proptosis may be the presenting feature of leukæmia in children. *Primary orbital tumours* are rare; in children, the principal tumours are a *glioma* of the optic nerve (fig. 506), or an *osteogenic sarcoma* (fig. 507); the latter may follow irradiation to this region. In adults, a *mixed tumour* may arise in the lachrymal gland (fig. 508), resembling its counterpart in the parotid gland.

Treatment.—In all conditions presenting with proptosis, treatment is directed not only to the cause, but also to prevent damage to the cornea from

FIG. 506.—Glioma of the optic chiasma. (*J. Minton F.R.C.S., London.*)

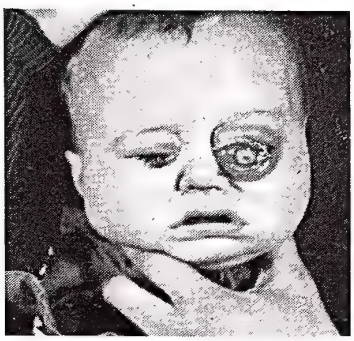

FIG. 507.—Sarcoma of the orbit. (*Professor A. A. McConnell. Dublin.*)

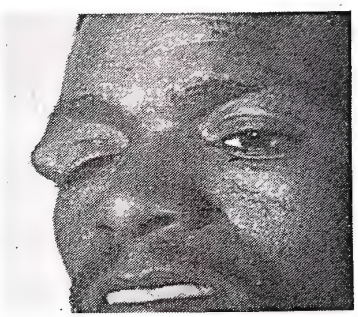

FIG. 508.—Mixed tumour of the lachrymal gland. (*Professor Charles Saint, Cape Town.*)

exposure, by liberal application of antibiotic ointment or artificial tear drops.

The treatment of orbital tumours is by excision where feasible, followed by irradiation for malignant lesions.

INTRA-OCULAR TUMOURS
- **Occurring in Children = Retinoblastoma**
- **Occurring in Adults = Melanoma**

Retinoblastoma.—This is a highly malignant undifferentiated tumour arising in the retina; the growth fills the eye, and becomes visible as a white pupil. It may spread by invasion of the optic nerve and meninges, or by bloodborne metastases. Most retinoblastomas are unilateral and sporadic, but in the less common hereditary form, both eyes are affected. Treatment is by enucleation or by radiotherapy.

Malignant melanoma.—This tumour commonly originates in the choroid, but it may arise from the ciliary body or iris; it presents as an elevated pigmented growth. Although initially intraocular, direct extension through the sclera may occur, or it may metastasise through the veins. However, growth of these metastases may be extremely variable, and can be delayed

many years, hence the adage 'beware the patient with a large liver and a glass eye'. (fig. 509). The prognosis for an intraocular melanoma is more benign in the elderly, and for the more anteriorly sited lesion. In most patients, however, an intraocular melanoma is an indication for enucleation.

FIG. 509.—Patient with a greatly enlarged liver, who for many years had worn a glass eye after excision of the eyeball for melanoma.

INJURIES INVOLVING THE EYE AND ADJACENT STRUCTURES

Burns.—The commonest ocular burn is *radiational*, after an arc-welding flash; symptoms of intense pain and photophobia develop in both eyes some hours after exposure to the ultraviolet radiation, but healing rapidly occurs.

In *thermal* burns, rapid lid closure usually protects the eye itself, but full-thickness burns involving the eyelids will lead to scarring and deformity, resulting in corneal exposure, and early reconstructive surgery is indicated. A direct thermal burn of the eye follows a splash of molten metal, causing intense localised necrosis. Treatment consists of prevention of infection with antibiotic ointment, combined with atropine drops, and prevention of adhesions developing between the burnt eye and conjunctiva by daily separation with a glass rod. Scarring of the cornea may permanently impair vision.

Chemical burns are the most serious, particularly alkali burns, which can penetrate deeply into the eye and cause ischæmic necrosis. The most important treatment is immediate irrigation, which should be continued for 30 minutes before seeking expert advice. In lime burns, particulate matter may be trapped under the lids, requiring manual removal, followed by irrigation with a chelating solution. Subsequent treatment of chemical burns is along the lines indicated for molten metal burns, but the prognosis is worse.

FIG. 510.—Facial lacerations from windscreen injury: beware of a perforating eye injury.

Blunt Injuries.—A blunt injury may either cause hæmorrhage into the orbit, or the force may be transmitted to the orbital floor, resulting in a *blowout fracture* (fig. 510). Orbital contents may be trapped in the fracture, causing double vision. Crepitus of the eyelids

from surgical emphysema confirms the communication of the orbit with the maxillary antrum, and X-rays may demonstrate blood and other structures trapped in the fracture. Spontaneous improvement may occur, but if double vision persists, the floor of the orbit requires exploration via a subperiosteal approach along the infra orbital margin.

Direct contusion of the eye may follow blunt injury, and the commonest manifestation of this is an *hyphaema*, blood in the anterior chamber (fig. 511). There is a risk of serious secondary bleeding within the first four days after injury, and complete bedrest for this period is mandatory. More serious damage to the intraocular structures may permanently affect vision.

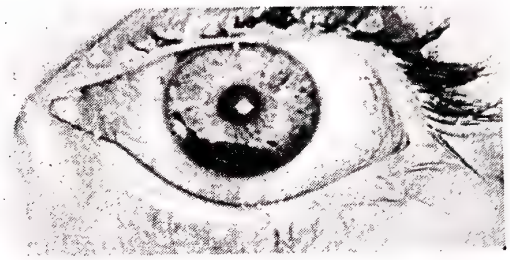

FIG. 511.—Hyphæma—blood in anterior chamber after blunt injury.

Lacerations.—It is important in any laceration involving the eyelids to exclude an underlying perforation of the globe: this is particularly true of multiple facial lacerations following an injury from broken glass, and any bleeding from beneath the lids should suggest the possibility of a perforating eye injury. In such an injury, prolapse of intraocular contents occurs through the wound, resulting in distortion of the pupil, loss of the anterior chamber, and intraocular hæmorrhage; damage to other structures may be present. This requires expert repair, and there is a risk of developing an autoimmune reaction in the uninjured eye that may lead to blindness; this is known as **Sympathetic Ophthalmia**. Prevention of this complication is by enucleating any injured eye that fails to improve rapidly after surgical repair, and this should be performed within two weeks of injury. Danger signs in the injured eye are failing vision, increasing irritability, and loss of intraocular pressure.

Note.—A commonly missed serious injury involves falling on a sharp object, such as a stick; the entry wound may not be very obvious, and the point may bypass the eyeball, and penetrate the orbital roof or superior orbital fissure, with ensuing brain damage, abscess formation or meningitis. Any such injury should be X-rayed and carefully observed. Similarly, a patient presenting with a history of a foreign body in the eye after using a hammer and chisel, or after an explosion, should always be X-rayed, as a minute steel or copper foreign body may penetrate into the eye without obvious external signs, and may lead to blindness if not removed.

EXCISION OF AN EYEBALL

Indications include a painful blind eye, intraocular neoplasms, and the risk of Sympathetic Ophthalmia.

The Operation.—The speculum is introduced between the lids, and opened. The conjunctiva is picked up with toothed forceps and divided completely all round as near as possible to the cornea. Tenon's capsule is entered, and each of the rectus tendons is hooked up on a strabismus hook and divided close to the sclera (fig. 512). The speculum is now pressed backwards and the eyeball projects forward. Blunt scissors, curved on the flat, are insinuated on the inner side of the globe, and these are used to

Jacques René Tenon, 1724–1816. Surgeon, La Salpêtrière, Paris.

sever the optic nerve. The eyeball can now be drawn forward with the forceps, and the oblique muscles, together with any other strands of tissue which are still attaching the globe to the orbit, are divided. A swab moistened with hot water and pressed into the orbit will control the hæmorrhage.

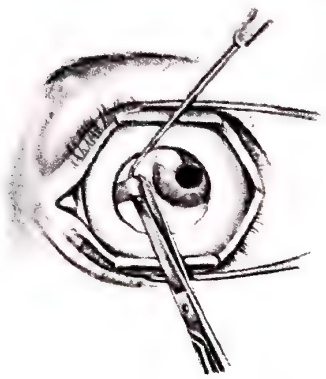

FIG. 512.—Excision of an eyeball. Medial rectus tendon being divided, aided by a strabismus hook.

Evisceration of the Eyeball.—Owing to the danger of opening up lymphatic spaces at the back of the globe and thus favouring meningitis, evisceration is to be preferred to excision in panophthalmitis. The sclera is transfixed with a pointed knife a little behind the corneo-sclerotic junction, and the cornea is removed entirely by completing the encircling incision in the sclera. The contents of the globe are then removed with a curette, care being exercised to remove all the uveal tract. At the end of the operation the interior must appear perfectly white.

DIFFERENTIAL DIAGNOSIS OF THE ACUTE RED EYE

The importance of this is in the recognition and treatment of minor ocular complaints, and those requiring expert attention, particularly acute glaucoma.

There are four conditions presenting as an acute red eye:

— conjunctivitis
— keratitis (corneal ulceration)
— uveitis (inflammation within the eye)
— acute glaucoma (acutely raised intraocular pressure)

Conjunctivitis.—Only conjunctivitis is not painful and does not affect vision; the symptoms are grittiness and discharge, and the conjunctiva is diffusely infected. It is serious in the newborn, when gonococcal infection may be present, but otherwise it is usually self-limiting, and will respond to antibiotic drops.

The following other conditions are all painful and may affect vision; both pain and visual loss is most severe in acute glaucoma, which should be suspected in an elderly patient. All are characterised by circumcorneal injection.

Keratitis.—In keratitis, minor conditions, such as inturned eyelashes or a subtarsal or corneal foreign body may be dealt with by removing the offending cause and applying antibiotic ointment, but *corneal ulceration*, which may be demonstrated by staining with a drop of fluorescein, is serious. Steroid drops should never be used, as a virus keratitis may be induced and aggravated.

Uveitis.—Uveitis may be recognised by the presence of an exudate in the anterior chamber and by irregularity of the pupil.

Acute Glaucoma.—In acute glaucoma, the cornea becomes hazy, and the eye feels rock-hard. The severe pain may be accompanied by such vomiting and prostration as to be mistaken for an acute abdominal emergency.

Corneal ulceration, uveitis and acute glaucoma require immediate referral for expert treatment.

CHAPTER 28

FACE, LIPS, PALATE, FACIO-MAXILLARY INJURIES

EMBRYOLOGY OF THE FACE

About the sixth week of fœtal life a depression appears at the front of the head. Around this depression, called the stomodæum or primitive mouth, five processes appear: a single one at the cephalic end, the frontonasal process, and on each side a maxillary and a mandibular process (fig. 513). Soon the frontonasal process becomes subdivided, by the appearance of the olfactory pits, into a solitary median nasal process and two lateral nasal processes. The median nasal process becomes bluntly bifurcated, forming the processus globularis. Maxillary mesoderm extensions grow medially beneath the olfactory pits to join in the mid-line, thereby forming the primitive palate and excluding the placodes (future nostrils) from the upper lip. Every congenital deformity of the face has existed from the ninth week of foetal life. The pinna is developed from six tubercles situated around the posterior end of the first branchial cleft.

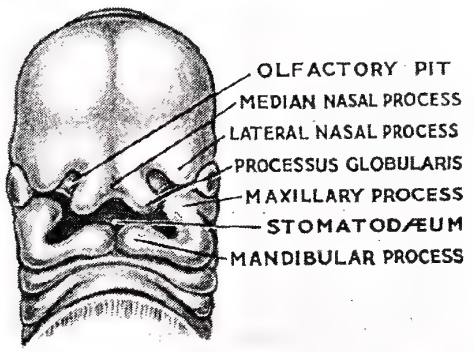

Fig. 513.—The head of an eight-week embryo.

CONGENITAL ABNORMALITIES

Cleft-lip and Cleft-palate[1]

Classification.—Cleft-lip and cleft-palate are variations of one and the same congenital defect. Failure of coalescence of the developing processes (fig. 513) results in either (*a*) a cleft of the lip alone, (*b*) a cleft of the lip and

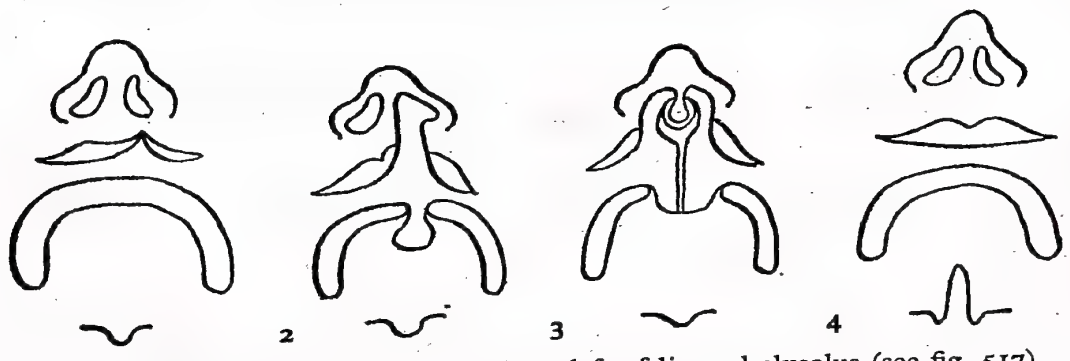

Fig. 514.—1. Partial cleft-lip. 2. Complete cleft of lip and alveolus (see fig. 517). 3. Double cleft of lip and alveolus. 4. Cleft soft palate. (*After Kernahan and Starke.*)

the alveolus, (*c*) a cleft of the lip, alveolus, and palate, or (*d*) cleft-palate alone (figs. 514 and 515).

[1] Cleft-lip is also commonly known as hare-lip.

Normal union commences at the incisive foramen. (*a*) The extreme anterior portion of the Primary Palate and the alveolus and lip are formed in one process. Failed formation may result in a cleft which involves part or all of the lip and may extend as far back as the incisive foramen. (*b*) The palate behind the incisive foramen—the Secondary Palate—is formed by the fusion of two shelves which grow medially from the maxillary arches. Failure of these to join results in a cleft-palate which may involve either the soft palate alone, or as far forward as the incisive foramen.

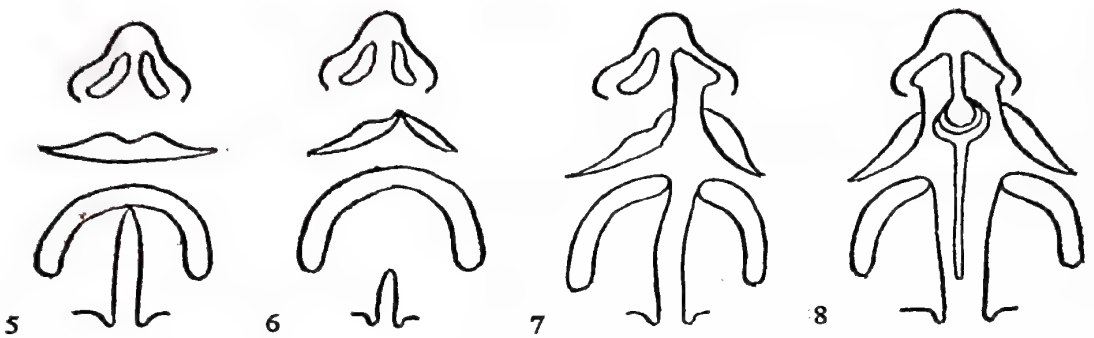

FIG. 515.—5. Cleft soft and hard palate. 6. Partial cleft of palate and lip. 7. Complete cleft of lip, alveolus, and palate. 8. Double complete cleft of lip, alveolus, and palate (see fig. 521). (*After Kernahan and Starke.*)

Possible causative factors.—Exposure to X-rays, cortisone intoxication, vitamin deficiency, and certain virus infections (e.g. rubella) during the first trimester of pregnancy, are all associated with an increased incidence of these abnormalities in the fœtus. In about 12% of cases the condition is familial. In 10% of cases other abnormalities are present, such as hydrocephalus, congenital blindness and mental deficiency. For a reason that has never been explained, clefts on the left side greatly outnumber those on the right side and bilateral clefts.

Relative Distributions of the Various Types of Cleft.—Based on a study of the records of 703 Danish patients operated upon for one or other of these anomalies, P. Fogh-Andersen found that the incidence was as follows:

Cleft-lip alone	25 per cent. (60% males)
Cleft-palate alone	25 per cent. (59% females)
Cleft-lip and cleft-palate combined . .	50 per cent. (70% males)

In 75 per cent. of the patients the cleft was unilateral.

Effects on Function.—Swallowing, speech, dentition, nose development, and even hearing are affected.

Ability to Suck.—Cleft lip does *not* interfere with feeding. A special teat may be required for bottle feeding but, with breast feeding, a mother invariably acquires a technique to feed the baby adequately.

With cleft palate, however, the infant may be unable to suck properly as negative pressure cannot be established. In this case feeding may be assisted with special bottles and teats, or alternatively spoon feeding may be employed. In some cases an obturator is needed which facilitates sucking.

Speech.—A person with a cleft-palate is unable to make consonants and has a typical cleft-palate voice. To make consonants (e.g. B, D, K, P, T, and the hard G) air must not escape into the nose via the naso-pharyngeal sphincter (the levator sling pulls the soft palate backwards and into contact with the posterior wall of the pharynx).

Poul Fogh-Andersen. Plastic Surgeon, Deaconesss Hospital, Copenhagen, Denmark.

Eighty per cent. of patients may develop favourable speech, but usually require extensive speech therapy to achieve this.

Orthodontics.—The child will require very careful supervision of the growth of the alveolus and teeth, and corrective splinting where indicated.

The nose may remain misshapen (fig. 518), particularly if the upper lip does not develop to its full width and dimensions, and lack of development of the alveolar arch results in malpositioning of the teeth. Much depends upon the reconstitution of, and therefore the moulding action from a properly functioning orbicularis oris muscle.

Hearing.—About 50 per cent. of children with cleft-palate have an audiometrically detectable hearing loss of about ten decibels, due largely to œdema of the orifice of the Eustachian tube consequent upon pharyngeal inflammation from regurgitated food.

Treatment

Aims of Treatment.—*Cleft-lip*—the aim is solely to improve appearances. (Cleft-lip does not interfere with feeding—see above.)

Cleft-palate—the aim is to achieve adequate speech and dentition. The length of the palate is not important, but mobility and muscularity are.

Timing of Treatment.—*Cleft-lip*—repair is usually undertaken at an age of three months or when the infant weighs 5–6 kg.

Cleft-palate—repair is undertaken at the age of 1–1½ years.

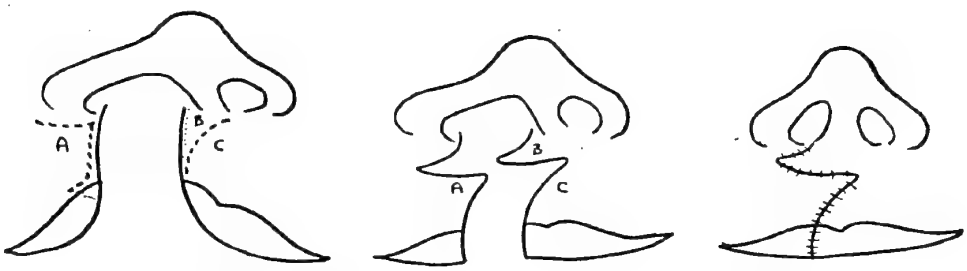

FIG. 516.—Repair of cleft-lip (after Millard).

Methods of Repair.—*Unilateral Cleft-lip:* There are several different operations described for repair of the unilateral cleft-lip. Fig. 516 illustrates the method of repair described by Millard. Fig. 517 shows a cleft-lip before operation and fig. 518 the child at the age of four. Note the residual nasal defect.

Cleft-palate: The aim of repair of cleft-palate is to achieve adequate speech and dentition.

FIG. 517.—Cleft lip.

FIG. 518.—Same case as fig. 517 four years after repair.

Operation.—Endotracheal anæsthesia is employed and the head is well extended. The principle of the repair is to achieve firm union of the muscle of the palate in the mid-line. In order to achieve this, incisions are made laterally and the soft tissues extensively dissected to mobilise the palate. (This may involve fracturing of the hamulus). This repair is known as the V-Y repair (fig. 519). The repair is effected by suturing the cleft in the mid-line in two layers (nasal and pharyngeal), leaving a raw area laterally which re-epithelialises.

Bartolommeo Eustachi (Eustachius), ?1520–1574. Professor of Anatomy, Rome.
David Ralph Millard, Jr. Contemporary. Plastic Surgeon, Miami, Florida, U.S.A.

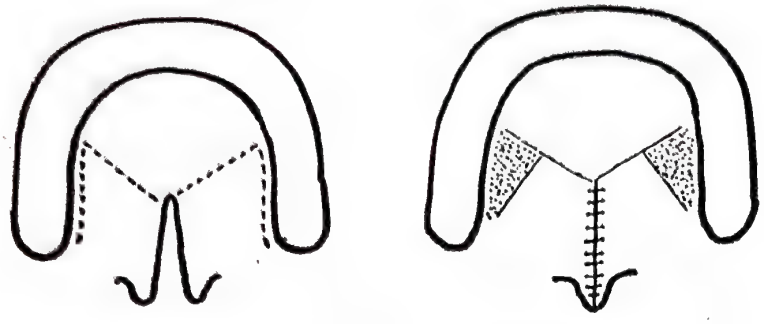

FIG. 519.—V-Y Repair of cleft-palate.

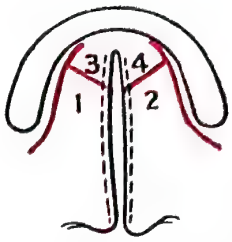

FIG. 520.—Four-flap method.

With clefts extending as far forward as the alveolar arch, the ' four-flap ' repair is used (fig. 520).

When severe alveolar defects exist, bone-grafting is used after corrective orthodontic alignment.

Double Cleft-lip with an Unfused Premaxilla (fig. 521).—The premaxilla must not on any account be removed, for the subsequent concavity is most difficult to remedy with a prosthesis. The best method of treatment of these difficult cases is still open to question, but if the premaxilla juts out considerably the second of the following two procedures should be chosen.

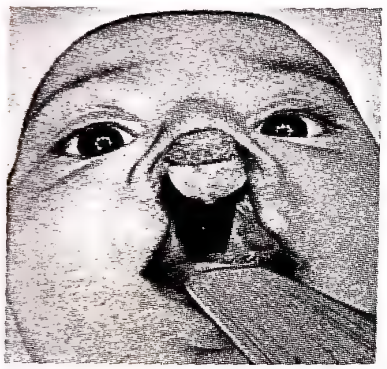

FIG. 521.—Bilateral cleft-lip associated with an unfused premaxilla and cleft-palate.

(*a*) The cleft on each side is united to the prolabium in one or two stages, and as a result of the continuous pull exerted by the reconstructed orbicularis oris, the premaxilla retreats between the halves of the maxilla.

(*b*) First the lip on one side is repaired, in order to ensure an adequate blood-supply to the adjacent bone. With this established, a few weeks later prevomerine bone can be resected safely and (at the same operation) the repair of the other side of the lip is performed (R. J. V. Battle). Again the reconstructed orbicularis oris proves an admirable agent for retaining the replaced premaxilla.

Other Congenital Abnormalities of the Face and Lips

Preauricular Sinus.—Imperfect fusion of the six tubercles that form the pinna results in a preauricular sinus, the opening of which is usually found at the root of the helix or on the tragus. The track run downwards, and ends blindly. A preauricular sinus gives rise to no symptoms unless the tiny opening becomes occluded, when a cyst is prone to develop. If the cyst becomes infected and it bursts or is incised, a cutaneous preauricular ulcer may follow. This ulcer refuses to heal, for infection is maintained from the sinus (Stammers). Often the condition is mistaken for a tuberculous sinus associated with a preauricular or parotid lymph node. The only curative treatment is complete excision of the sinus.

Periauricular dermoid cyst is due to inclusion of epithelium during fusion of two contiguous embryological aural tubercles. Usually the cyst is posterior to the pinna (fig. 522).

Congenital Short Frænum[1] of the Upper Lip.—Both lips have a frænum, that of the upper lip being better developed. Sometimes it is congenitally short and is

[1] Frænum—Latin = a bridle.

Richard John Vulliamy Battle, Contemporary. Formerly Plastic Surgeon, St. Thomas's Hospital, London.
Francis Alan Roland Stammers, Contemporary. Emeritus Professor of Surgery, Birmingham, England.

then associated with a wide gap between the permanent incisor teeth (fig. 523). If dental malposition, and a sibilant lisp in the speech are to be prevented, early in life the frænum must be incised transversely, the mucosa on each side of the incision mobilised by undercutting, after which the cut edges are sutured longitudinally.

FIG. 522.—Peri-auricular dermoid cyst.

Congenital fistulæ of the lower lip, unexplained by embryology, occur in certain families. There are two blind pits, one on either side of the mid-line. They are, apparently, wide-open mucus secreting labial glands which are also found in certain quadrupeds. The treatment is excision.

FIG. 523.—Congenitally short frænum labii. (*The late Patrick Clarkson, F.R.C.S., London.*)

Prolapse of the Mucous Membrane of the Lip (Bichelia).—The mucous membrane of the lip protrudes as an unsightly fold below the vermilion border. Usually congenital, it can be acquired by repeatedly sucking the lining of the lip through a gap between the natural teeth or an ill-fitting denture, in which case the prolapse is unilateral and mostly affects the lower lip. *Treatment* consists of excision of redundant mucosa. In acquired cases orthodontic corrections must also be made.

Micrognathia (fig. 524).—This is often associated with cleft palate. The infant is born with a mandible the horizontal ramus of which is foreshortened. This renders the tongue unduly mobile, and results in tongue-swallowing with frequent attacks of dyspnœa, cyanosis, and feeding difficulties, especially if a cleft-palate is present as well. *Treatment*—is conservative with attention to nursing (face down), the maintenance of an airway, and feeding. In young adulthood, cosmetic bone-grafting may vastly improve the patient's appearance.

FIG. 524.—Micrognathia. An endotracheal tube has been passed. (*The late Sir Alan Moncrieff, London.*)

FIG. 525.—Mandibular prognathism. (*J. H. Hovell, F.D.S., R.C.S., London.*)

Mandibular Prognathism (fig. 525).—This occurs as a developmental abnormality and may be genetically determined. The unopposed incisor teeth suffer early periodontal disease as a result of disuse. Faulty speech occurs on account of incorrect relationship of the tongue to the incisor teeth, and temporo-mandibular joint dysfunction is favoured. *Treatment.*—After freeing the periosteum from the bone, an open sliding osteotomy of the ascending ramus or the body, with preservation of nerves, and wire fixation of the fragments, gives satisfactory correction of the deformity. If the periosteum is not freed from the bone, muscle pull on the original attachment causes recurrence of the deformity.

LESIONS OF THE PALATE

Swellings of the Palate.—(*a*) A tumour of the palatal mucosa or bone: (*b*) carcinoma of the maxillary antrum extending downwards (p. 529); (*c*) an alveolar abscess of the incisors (p. 520); (*d*) chronic infections, e.g. gumma.

Ectopic salivary tumour is a special problem (fig. 614).

Perforation of the Palate.—A hole in the *mid-line* of the hard palate may be due to friction from a malfitting dental plate. Rarely nowadays is it the result of a gumma. A hole *to one side of the mid-line* is due to the bursting of an empyema through the floor of the antrum, or a palatal antrostomy. *Treatment.*—A well-fitting dental plate is all that is required.

LESIONS OF THE LIPS

Pigmented Lips and Buccal Mucous Membrane.—Brown pigmented spots on the lips, inside the cheeks, and on the palate occur in familial intestinal polyposis (Peutz-Jeghers syndrome (fig. 1112)). Addison's disease must be excluded.

Macrocheilia.—True macrocheilia is due to a lymphangioma, akin to lymphangiomatous macroglossia (p. 545). Treatment is similar. Chronic inflammation also causes enlargement.

Cracked Lip.—Chapping is common, and a definite crack in the middle of the lower lip, which bleeds readily, is a frequent complaint in cold weather. *Treatment* includes the local application of glycerin. . In chronic cases simple excision may be indicated.

Cracks at the corners of the mouth (p. 542).

Chancre of the Lip.—Unlike a similar lesion on the genitals, the neighbouring lymph nodes become *greatly* enlarged.

NEOPLASMS OF THE LIP

Lymphangioma (macrocheilia), and cavernous hæmangioma are innocent neoplasms (p. 108).

Ectopic Salivary Tumour.—Usually it is the upper lip of a young adult male which is affected, the tumour commencing on one or other side at the site of the right or left fusion lines (Kuber Dhar Sharma).

Carcinoma of the lip is usually seen in men between sixty and seventy years of age who have followed an outdoor occupation, and it has been known colloquially as 'countryman's lip'. Only comparatively recently has the importance of exposure to sunlight, wind and driving rain been stressed in the ætiology of this neoplasm. In particular, bright sunlight causes exfoliation of the lips—more especially the lower lip. Actinic cheilitis should be considered as a precarcinomatous condition, and 40 per cent. of patients with carcinoma of the lip give a history of recurrent blistering cheilitis.

This is a squamous-celled carcinoma (known for short as an 'S.C.C.' or an 'epithelioma') which presents as a shallow ulcer (fig. 67) with or without the typical everted edge. Thus, any ulcer of the lip which does not readily heal should be viewed with suspicion and a biopsy obtained. With small lesions, diagnosis and treatment can be combined as an excision-biopsy. The lower lip is affected in 93 per cent. of cases, the upper lip in 5 per cent., and 2 per cent. occur at one of the angles of the mouth. Rutherford Morison was the first to point out that a carcinoma occurring at the angle of the mouth and

John Law Augustine Peutz, 1886–1957. Chief Specialist for Internal Medicine, St. John's Hospital, The Hague, Holland.
Harold Jos Jeghers. Professor of Internal Medicine, New Jersey College of Medicine and Dentistry, Jersey City, U.S.A.
Thomas Addison, 1793–1860. Physician, Guy's Hospital, London.
Kuber Dhar Sharma, Contemporary. Professor of Pathology and Bacteriology, Medical College, Aurangabad, India.
ames Rutherford Morison, 1853–1939. Professor of Surgery, University of Durham, Newcastle-upon-Tyne.

involving *both* lips, however slightly, is far more malignant than the more usual varieties. The reason for this is that the angle of the mouth has a double lymphatic drainage.

Carcinoma of the lip must be distinguished from Molluscum sebaceum (Kerato-acanthoma), described on p. 105.

Treatment.—In its typical form (fig. 526) the carcinoma is comparatively slow-growing and it is eminently curable by surgery or radiotherapy, the five-year survival being 70 per cent. If the lesion is advanced, or has recurred after radiotherapy, adequate surgical treatment necessitates plastic reconstruction.

FIG. 526.—Carcinoma of the lower lip.

Radiotherapy.—After confirmatory biopsy, conventional deep therapy voltage (250 kV) is used. Ten doses are given over a period of two weeks to a total dose of 5,000 rad, the mouth, alveolus, and tongue being protected by lead backing. Radium needles or a mould may be used for buccal or commissural lesions (7,000 rad in seven days).

Treatment of Lymph Nodes.—Involvement of the lymph nodes (submental or deep cervical) is relatively late. If the nodes are mobile, the present practice is to perform a classical block dissection (p. 584). If the nodes are fixed, or the patient is elderly and feeble, operation is contra-indicated. Telecobalt therapy may be of use in these circumstances.

Careful follow-up of cases is essential.

FACIAL INJURIES

Injuries to the face are extremely common. Minor injuries such as black-eyes and small lacerations form a large number of casualty attendances especially at weekends. These are inevitably due to accidents, sport injuries or fights. In more severe trauma such as that resulting from motor accidents, the face and underlying bones are involved in at least 30% of the cases. The victims are usually motor car passengers who are thrown forward against the windscreen or dashboard. The nature and severity of the injuries vary enormously with the force and striking surface involved. The wearing of safety harness, now compulsory equipment in new cars, reduces the incidence of this mutilation.

First Aid.—The immediate danger to patients with severe injuries of the face is respiratory obstruction due either to inhaled blood, or of the tongue falling back as a result of a bilateral fracture of the jaw. The patient should therefore be immediately placed in a horizontal and lateral (tonsil) position (p. 666) or right over on to his face with his forehead supported on his hands. If he has to be transported by ambulance he should remain in this position and not be turned on to his back. Local firm pressure with pads will help to control bleeding (p. 70).

Examination of the injury.—These wounds often appear to be more horrifying than they really are (fig. 3) especially as bleeding is so profuse.

No examination is complete until carried out in the operating theatre with the patient appropriately anaesthetised. The wound may then be cleaned with any of the recognised antiseptics such as Hibitane 1:500–1:200 soln., (Chlorhexidene), but not with a spirit base. Devitalised tissues and divided structures can then be recognised, and glass or other foreign bodies removed

N.B. If the patient is suffering from shock, one should always look for other injuries. The shock is seldom due to facial injuries alone.

Soft Tissue Injuries.—Because of the good blood supply, wounds of the face heal well. Excision of dead tissue can be reduced to a minimum, and nearly all wounds can be treated by primary suture even when treatment has been delayed for as long as 24 hours. The procedure for operation on facial wounds is similar to that for wounds in general (p. 4). If the laceration follows a car accident in which the victim has been thrown against the windscreen, the wound is very likely to contain pieces of glass. These and any dirt must be carefully searched for and removed. Dirt may be removed by persistent gentle scrubbing, any left behind may cause permanent tattooing. If deeper layers of the face are involved all layers must be carefully reconstituted, mucosa and muscle with 4/o chromic catgut sutures and skin with 4/o or 6/o silk or nylon sutures. Numerous small sutures are stronger than a few widely spaced thick sutures. The skin sutures are removed on the 5th-7th post-operative day. On the nose, sutures remaining for more than 5 days may leave a permanent mark. After 24 hours skin wounds need no dressing at all and should be left open (fig. 4).

FIG. 527.—Method of avoiding inversion of the skin edges. *(After T. P. Kilner, F.R.C.S., Oxford.)*

Special Soft Tissue Injuries

Facial Nerve.—Primary repair may be indicated (depending on other injuries and the state of the overlying skin etc.), but this can be a major task. Secondary repair is not usually very satisfactory. Re-innervation after trauma occurs in a sufficient percentage of cases to warrant waiting 12 months.

Parotid Duct.—Suturing is often easier than expected and should be done where ever possible. It is advisable to anastomose the duct over a fine ' polythene ' catheter or a broad nylon thread which remains *in situ* for 2-3 weeks. Parotid fistulae often close spontaneously but may take many months to do so (p. 563).

Lachrymal Apparatus.—Suture of the lid is performed in layers after cannulating both ends of the injured canniliculus with a fine nylon thread, the distal end of which is passed into the lachrymal sac. This thread is kept in as long as possible (up to 3 months). Secondary procedures for scarred duct systems are best referred to plastic or ophthalmic surgeons.

Bone Injuries of the Face and Jaws

Fractured Nose.—This is the simplest type of ' facio-maxillary ' fracture, most often missed and often the most difficult to treat. The 2 nasal bones, plus their lateral cartilages, form a tent over the vertical midline septum. The injuries may be (i) *lateral* (fig. 533) resulting in impaction of one lateral bone under the other. Reduction cannot be effected until the side away from the impact is elevated first, thus freeing the bone on the side of the blow,

(ii) *frontal*—this results in telescoping of the nasal structures, and is often associated with maxillary fractures.

Treatment.—Reduction is best undertaken using general anaesthesia and a pharyngeal pack. However, it may be done in a co-operative patient using local anaesthesia with adrenaline. (1) *Lateral injury*—Using a Walsham's forceps (fig. 528) covered with rubber tubing, the deformity is increased, thus freeing the impacted

FIG. 528.—Walsham's forceps.

FIG. 530.—Asch's forceps.

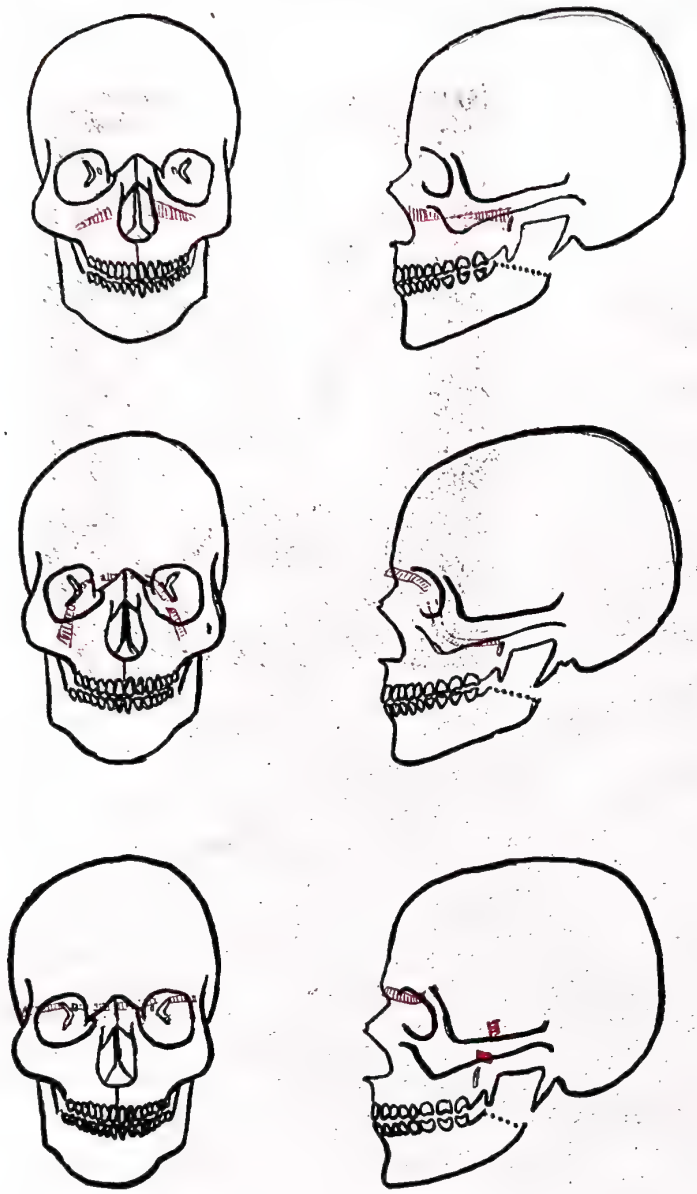
FIG. 529.—Reduced nasal fracture. Position may be maintained by P.O.P. cast (see text). (*E. Melmed, F.R.C.S., Dallas, U.S.A.*)

bone. Both sides are then aligned using the same forceps. The corrected position can be maintained by a plaster of Paris cast (fig. 529) but this is not essential. (ii) *Frontal injury*—The septum is gripped with Asch's forceps (fig. 530) and the whole nose is elevated. It may be necessary to hold the position with trans-nasal wires over lead plates. The septum must always be carefully aligned with Asch's forceps.

Fractures of the maxilla are classified according to Le Fort[1] (fig. 531). The likelihood of a fracture being present is suggested by the type of accident, the facial injury (dish-face deformity, split-open face, or swelling), the inability to close the jaws (open-bite deformity), or diplopia due to upward displacement of the floor of the orbit. Injuries to the eye and mandible are present in over 40% of cases. High fractures across the root of the nose may involve the cribriform plate and result in C.S.F. rhinorrhoea. An X-ray confirms the type of fracture. *Treatment* is best carried out in a facio-maxillary centre. A tracheostomy may be necessary. In addition to the repair of the face (p. 512), the displaced maxilla is freed, by rocking with bone forceps, and restored to its normal position. According to the type of fracture, stability is maintained by either (1) wiring the upper and lower jaws together in proper occlusion, (2) by wiring a pliable metal bar to the teeth or the edentulous alveolus, and fixing this by a system of extra-oral rods (scaffolding) (fig. 532), (3) by internal wire sutures (maxilla to malar bone).

[1] René Le Fort, Surgeon, Paris, defined these fractures as early as 1901, by macabre research, in which he dropped rocks and other heavy objects on the faces of cadavers.

William Johnson Walsham, 1847–1903. Surgeon, St. Bartholomew's Hospital, London.
Morris Joseph Asch, 1833–1902. Surgeon, New York Eye and Ear Hospital, New York, U.S.A.



Le Fort I. Fracture involving the maxilla only. The fracture line passes through the base of the antrum on either side and across the nasal floor through the septum.

Le Fort II. Posteriorly the fracture line passes up behind the nose in the direction of the malar-maxillary junction, across the posterior wall of the antrum, and across the pterygoid process in the middle or upper third. The anterior fracture line passes into the orbit in the area of the lachrymal bone, and soon emerges again to break across the fronto-nasal process of the maxilla and the bridge of the nose to meet a similar fracture line on the opposite side. The posterior wall of the orbit is not fractured in this type.

Le Fort III. There is a craniofacial disjunction, the fracture line passing through both zygomatic arches, both external angular processes of the malar bones, across the back of both orbits, and the back of the nose in the ethmoid area. There is a separation of the nasal bones from the frontal bone. Posteriorly the septum is fractured high up and likewise the pterygoid processes. There is a complete separation of the maxilla, nose and ethmoids and the palatal bones from the base of the skull.

FIG. 531.—Naso-maxillary fractures, Le Fort classification.

The **Malar bone and Zygomatic Arch** may be fractured and depressed by a direct blow. The important physical signs indicating the necessity for reduction are diplopia and obstruction to opening of the mouth. Unsightly deformity results (fig. 533), and anæsthesia of the cheek may occur due to pressure on the infra-orbital nerve. Pain on mastication is commonly noticed. Fracture of the orbital floor may result in trapping or prolapse of the inferior oblique muscle and gives rise to diplopia when looking upwards and outwards to the affected side. A palpable notch may be felt on gentle palpation of the infra-orbital margin.

Treatment.—(i) *Elevation:* The simplest approach is to make an incision in the temple hair margin through the temporalis fascia. A Bristow's elevator is then passed behind the zygomatic arch and the malar is replaced. Sometimes an audible click is heard as it locks back into position. (ii) *Fixation:* In simple fractures (e.g. rugby injuries) often no fixation is necessary if the reduction is stable. If unstable, it is best to wire the fronto-zygomatic suture and the malar-maxillary infra-orbital margins using 0.35 mm. stainless steel wire. If the malar is collapsed, it may be necessary to pack the maxillary antrum to maintain contour. This is approached via a

Walter Rowley Bristow, 1882–1947. Orthopædic Surgeon, St. Thomas's Hospital, London.

Caldwell-Luc antrostomy (p. 532) and the cavity packed with ribbon gauze soaked in antiseptic varnish (Whitehead's). The pack is kept in position a minimum of one month.

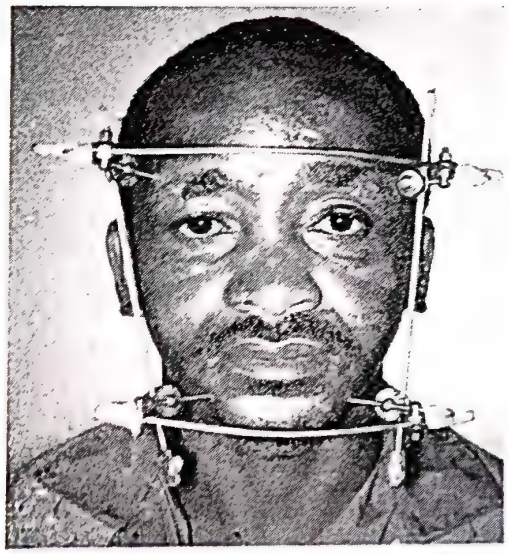


FIG. 532.—Extra-oral rods maintaining position of jaw in facio-maxillary injury (Le Fort II). *(E. Melmed, F.R.C.S., Dallas, U.S.A.)*

FIG. 533.—Depressed fracture of left zygomatic arch. Motor cycle accident. *(T. McNair, F.R.C.S., Edinburgh.)*

The **Mandible** is usually fractured in one of three situations (fig. 534):

(1) The *neck of the condyle* is occasionally fractured, in which case it is displaced forwards and inwards by the pull of the attached external pterygoid muscle. Localised pain occurs on movements of the jaw, and crepitus is detected by the patient or surgeon.

(2) The *ascending ramus* may be fractured, usually in the region of the angle of the jaw. The opposite condyle may be fractured at the same time. Little displacement occurs, as the masseter on the outside and internal pterygoid muscle on the inner aspect sandwich the fragments between them. The injury is suspected on account of persistent localised pain, and is confirmed by an X-ray. Mastication is limited to soft food for three weeks.

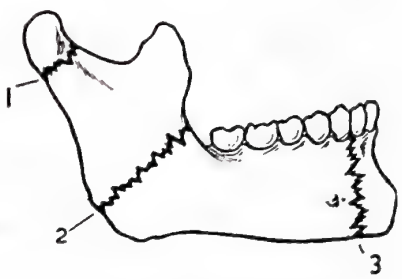

FIG. 534.—Lower Jaw.
1. Neck of condyle.
2. Through the angle or ascending ramus.
3. Anterior to the mental foramen, through the canine fossa.

(3) The *body of the jaw* is the part most commonly fractured, sometimes as the result of a blow with a fist. The fracture frequently occurs at the site of the socket of the canine tooth, the cavity of which weakens the bone, and also because this region is the junction of two curves. Occasionally the fracture is bilateral, in which case the central portion of the jaw is displaced downwards by the anterior bellies of the digastric muscles and the muscles attached to the genial tubercles. Owing to the firm attachment of the mucoperiosteum to the bone, the fracture is nearly always compound.

Diagnosis is usually obvious, as speech and swallowing are impaired. Blood-stained saliva trickles from the mouth, and irregularity of the line of the teeth is apparent. Crepitus can be elicited with ease.

Walter Whitehead, 1840–1913. Surgeon, Manchester Royal Infirmary, Manchester, England.

Principles of Treatment

As soon as possible the patient is referred to the dental surgeon for fixation of the fracture. The simplest method is to wire the jaws together in occlusion by interdental wiring (fig. 535). An alternative is an interdental splint which fits over the teeth adjacent to the fracture. A corresponding splint is fitted to the upper jaw, and the two splints are fixed together, in occlusion, by wire or elastic bands. Any obviously infected teeth, or an interposed tooth, are removed during the fitting. In edentulous patients, either dentures or acrylic moulds are wired to the alveolus and thence together.

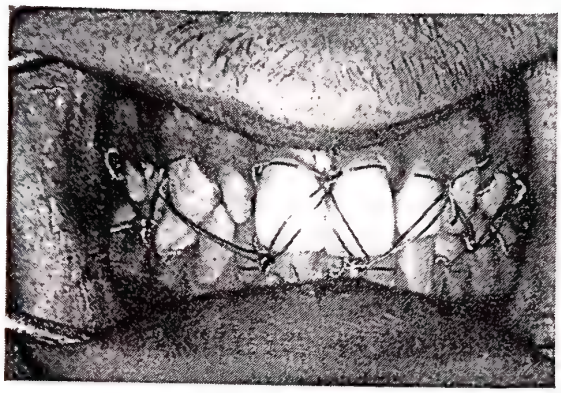

FIG. 535.—Interdental wiring for fractured mandible. (*E. Melmed, F.R.C.S., Dallas, U.S.A.*)

Post-operative Care.—As the fracture is compound, infection from the mouth is likely, particularly if pyorrhœa or infected teeth are present. Warm antiseptic mouth-washes are therefore used almost continuously. The diet is confined to fluids, which are taken temporarily through a rubber tube. Antibiotic cover is necessary.

Complications are mainly due to infection. Thus necrosis of bone and delayed union are not uncommon, while submandibular cellulitis may require operative intervention. Aspiration pneumonia is a grave danger, particularly in old or alcoholic patients with pyorrhœa.

SPECIAL INFECTIONS OF THE FACE

Boils and 'Pimples' in the region of the 'danger' (mask) area of the face (fig. 536) should never be squeezed, pricked, or incised, for by so doing the infection can reach the cavernous sinus by venous connections and cause cavernous sinus thrombosis, a fatal condition in the pre-antibiotic days. The local treatment of boils and 'pimples' include dressings with magnesium sulphate and glycerin paste, or short-wave diathermy. A broad-spectrum antibiotic is given, with review following the culture of any pus. Massive doses of antibiotics (e.g. 25 mega units of penicillin daily) are commenced immediately there are any local signs or general symptoms (rigors) suggestive of cavernous sinus thrombosis, and they are continued (in reduced dosage) for a prolonged period.

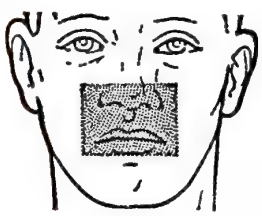

FIG. 536.—The 'danger' area of the face.

FIG. 537.—Chronic infected facial 'cyst'. Inset, the causative lesion, showing a chronic abscess attached to a root. (*D.C. Bodenham, F.R.C.S.(Edin.), Bristol.*)

Infected Facial 'Cyst' of Dental Origin.—Silent dental infection can be responsible for producing a chronic subcutaneous abscess of the face. Almost without exception this is diagnosed as an infected epidermoid cyst. What is even worse is that frequently the 'cyst' is excised, and a chronic discharging sinus results. When an example of such a condition as shown in fig. 537 presents, if there is a filled, apparently sound tooth in the vicinity,

or a gap of a previous extraction (possibly a root fragment was not removed), the patient should be subjected to dental radiography. When a root abscess is the cause of the facial lesion, extraction of the offending tooth or the responsible remnant thereof will rapidly render other treatment, other than perhaps a tiny incision, unnecessary.

Anthrax (p. 30).

Lupus (p. 103).

Leprosy (p. 35).

NEOPLASMS OF THE FACE

Benign and malignant neoplasms of the skin of the face are considered on pp. 103 to 115.

CHAPTER 29

THE TEETH AND GUMS. JAWS. NOSE. EAR

Congenital Anomalies.—The third molars and upper second incisors may be absent. Supernumerary teeth sometimes occur in clusters. The presence of a fourth molar may cause trigeminal neuralgia (Shah). Rarely seen now are the notched, peg-shaped incisors of Hutchinson, and turret molars of Moon, in congenital syphilis (p. 42).

IMPACTION OF A TOOTH

The tooth most often to be affected in this way is the third lower molar (the 'wisdom' tooth). It is prevented from normal eruption by an adjacent tooth. The unerupted portion of the crown is overhung by a pocket or flap of the gum, known as an operculum, viz. → where food debris collects, resulting in infection, which tends to spread to the cheek and sometimes to the neck. Trismus[1] is often present.

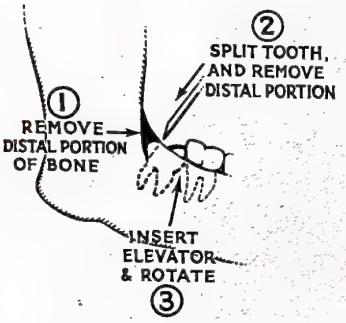

FIG. 538.—Steps in extracting a vertically impacted mandibular molar tooth. (*After Professor H. H. Stones.*)

Treatment.—If trismus is severe the patient should be given a general anæsthetic to release the spasm of the muscles of mastication and permit the insertion of a mouth-prop. If an abscess is present beneath the operculum, it is drained. When the acute symptoms have subsided, the impacted tooth should be extracted (fig. 538), unless one of the molar teeth anterior to it is carious. Extraction of the carious tooth may then afford room for the impacted molar to erupt.

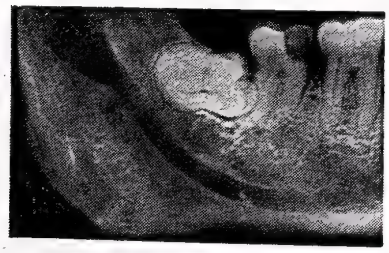

FIG. 539.— Radiograph showing horizontal impaction of third molar. (*Dr. Sydney Blackman, London.*)

In horizontal impaction (fig. 539), the second molar may be extracted first and the third impacted molar removed by (*a*) chiselling away the overlying alveolus; (*b*) dividing the tooth; (*c*) removing the fragments with an elevator, viz. →

HÆMORRHAGE AFTER TOOTH EXTRACTION

Especially in males, it is necessary to exclude hæmophilia (p. 76). As a rule, the bleeding is not due to this cause. Often within the socket there is an open artery that in more accessible situations would have been ligated in the first instance. Quite often the bony alveolus has been fractured, and a loose fragment or a spicule of bone is present, either of which prevents firm clotting within the socket.

Treatment.—Provided the blood pressure is satisfactory the patient should sit bolt upright. A mouth gag is placed in position, the edge of the socket is everted with a pair of dissecting forceps, and with another pair the cavity is mopped with suitable pledgets of cotton-wool. Loose bone or spicules, if present, are removed. Firm pressure with a pledget for a few minutes may stop the hæmorrhage. When the hæmorrhage comes from the depths of the socket many dental surgeons use liquor ferri perchlor. as a styptic, and having packed the cavity, a small roll of gauze, upon

[1] Trismus—Greek τρισμός = clenching.

C. S. Shah, Contemporary. Dental Surgeon, Rajkot, India.

which the patient bites, is placed over the socket; a firm four-tailed bandage is applied. Snake venom (Stypven) and absorbable gauze or gelatin sponge may also be used.

Should the hæmorrhage come from the gum margin and is persistent, the flow can be arrested by a stitch passed through the gum on either side of the tooth socket.

Oro-Antral Fistula.—A hole between mouth and antrum via a tooth socket is attributed to the special use of narrow elevators for removing the apex of a tooth (Fickling). Air will escape when the patient blows his nose, or a sinogram will confirm the diagnosis. *Treatment.*—(1) Immediate suture of the socket, and cover (not pack) by ribbon gauze. (2) If seen later with sinusitis give saline irrigations and parenteral antibiotics. (3) Failure to heal in six to eight weeks requires the operation of inkwell inversion of freed circularly incised mucosa and cover by a long muco-periostal flap.

DENTAL CARIES

Ætiology.—*Diet.*—The teeth of those Esquimaux who live exclusively on fish, flesh, and fowl, and of African pygmies who consume uncooked foods only, are almost free from dental caries. The incidence rises steeply among civilised people whose diet includes carbohydrates in highly refined forms, e.g. white bread, and sweets eaten between meals. Dental caries is rife before the age of twenty-five, particularly in early childhood because the deciduous teeth are vulnerable to decay.

Acid-producing and Proteolytic Oral Bacteria.—Carbohydrate material clinging to the teeth is subjected to the activity of bacterial enzymes (sucrases), forming dental plaques of dextran, which is later broken down to lactic acid, which is capable of dissolving dental enamel. Once the enamel shell has been penetrated, proteolytic enzymes, generated by other bacteria, disintegrate dentine, which forms the bulk of the tooth (fig. 540).

Minor enamel hypoplasia resulting from lack of vitamins and possibly from fluoride deficiency in domestic water supplies, is a factor in producing an increased incidence of caries in children (Mellanby).

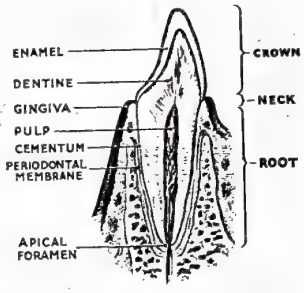

FIG. 540.—Sagittal section through an incisor tooth *in situ*.

The Stages of Dental Decay

Stage 1.—*Erosion of the enamel* is symptomless, and will almost certainly be overlooked unless each tooth is examined systematically with a dental probe.

Stage 2.—*Dissolution of dentine* is also painless until it has progressed to near the pulp, when thermal changes (heat, and especially cold) and mastication of sweets may bring on the familiar pain (toothache). Tapping the tooth causes no pain.

Stage 3.—*Part of the crown collapses*, due to undermining. The cavity is now more easily seen. Pressure of debris in the cavity causes pain ; such pain may be referred to a sound tooth on the same side.

Stage 4.—*Acute Pulpitis.*—Pain is throbbing and intermittent, and thermal changes cause pain. Tapping the tooth is painless, but pressure of a piece of cotton-wool inserted into the cavity is painful. Pulpitis terminates in disintegration of the pulp.

Untreated, acute pulpitis is liable to lead to an alveolar abscess. Chronic pulpitis is the harbinger of a periapical abscess.

Dental Caries and the Surgical Patient.—The culmination of caries, a mouth full of broken teeth, stumps and tartar, increases the risk of morbidity from surgical procedures. Pre- and post-operatively there is a likelihood of stomatitis, and, in conditions leading to dehydration (e.g. intestinal obstruction), of acute parotitis (p. 558). Mastication at mealtimes will massage bacteria from infected roots into the blood stream, so causing recurrent bacteriæmia which may be detrimental to recovery from any operation.

Thus, special attention must be given to oral hygiene in the pre- and post-operative periods. A dental opinion and the help of a dental hygienist is

Benjamin William Fickling, Contemporary. Dental Surgeon, St. George's Hospital, London.
Lady Mary Mellanby, Contemporary. Formerly Investigator for the Medical Research Council, London.

invaluable, and in non-emergencies dental extraction prior to surgery may be considered. This tends to delay operation by four to six weeks in order that the gums should be soundly healed, so dispersing all chances of bacteriæmia.

During anæsthesia, special care must be taken to prevent loosening or breaking of a tooth, which may be inhaled to cause collapse of a segment or lobe of a lung and then a lung abscess. Thus, prior to anæsthesia a note should be made of the state and numbers of teeth and, if possible, the patient should be warned that a loose tooth is in jeopardy and may require removal for safety. In the case of a missing tooth, believed inhaled, an X-ray of the chest, and possibly bronchoscopy, will be required.

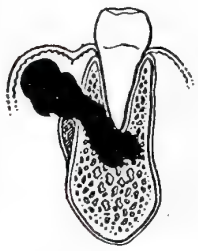

FIG. 541.—Alveolar abscess eroding the lateral plate of the alveolus. This is the most common course, because the roots point in this direction, and the lateral plate is about half the thickness of the medial plate.

ALVEOLAR ABSCESS

While an acute alveolar abscess can occur at any age, it does so most often during childhood and early adult life. Abscesses in the first dentition can occur in either jaw, while those connected with the second dentition concern particularly the teeth of the lower jaw, more especially a molar tooth.

Pathology.—As a result of acute pulpitis, the putrifying pulp generates gases that exert pressure through the root canal into the osseous tissue around the apex of the tooth. Localised osteitis and abscess formation (gumboil) ensue. Almost always the abscess points on the labial aspect (fig. 541). One abscess to point lingually is that in relation to the upper lateral incisor, which gives rise to a swelling on the palate (p. 510), and an abscess from an impacted wisdom tooth can burst through the medial wall of the alveolus and cause the dangerous Ludwig's angina (submandibular cellulitis, p. 578).

If early resolution is not brought about by antibiotic therapy, or if the abscess is not drained promptly and effectively, osteomyelitis of the jaw is to be expected (p. 524).

FIG. 542.—Extensive alveolar abscess.

Clinical Features.—The pain is dull and constant. Swelling of the cheek (fig. 542) and redness and œdema of the gum in the neighbourhood of the culpable tooth are characteristic signs. The general reaction to the infective process may be considerable, and a tender enlargement of the regional lymph nodes is usual.

Diagnosis and Radiography.—Every swelling of the jaw demands a careful dental and radiological examination. For alveolar abscess a dental cause must be found—caries, an impacted 'wisdom', retained roots, or a dead tooth (p. 521). Only when sufficient time (ten days or more) has elapsed for resorption of bone to occur will rarefaction around the apex of the affected tooth become apparent on X-ray.

Treatment. Drainage and Antibiotics.—Surgical principles must be followed. (1) An abscess must be drained. (2) Antibiotics are not used in place of a drainage operation: they are of value early, before pus has formed, i.e. in the stage of indurated cellulitis, and they are used in support of the drainage operation. Here penicillin is usually employed, to be changed if necessary when the antibiotic sensitivities of the organisms grown from the pus are known.

Physical Agents.—Cold applications externally and hot intra-oral irrigations are useful adjuncts. Hot external poultices are avoided as they promote external pointing which, cosmetically, is to be avoided (fig. 543).

FIG. 543.—Sinus following bursting of an alveolar abscess externally.

Drainage of an Alveolar Abscess:

(*a*) *Into the Mouth.*—When a cystic swelling in relation to the gum becomes apparent, the abscess should be opened into the mouth by incising the periosteum. If an alveolar abscess has been opened, ten days should elapse before the dental extraction.

(*b*) *Drainage by Extraction of the Offending Tooth.*—In the case of the primary dentition this is an accepted and generally successful procedure. In the case of the second dentition gentle and proper dentistry is vital. *General anæsthesia* must be used. Rough dentistry and local anæsthesia may engender osteomyelitis, in spite of antibiotic cover.

ROOT ABSCESSES

While an alveolar abscess is usually acute, a root abscess is nearly always chronic. It arises by extension of infection from the pulp through the apical canal. As a rule there are no symptoms, and no visible signs of a root abscess, which is only revealed by a dental radiograph (fig. 544). The absence of pain, or sensory response to hot or cold stimuli means a *dead tooth.* If so, it will look grey-blue and has an altered percussion note. Occasionally a chronic root abscess breaks its confines, and burrows to present externally in the form of a medial mental abscess sinus (p. 525), or a facial 'cyst' (p. 516), which respond to drainage by extraction of the affected tooth.

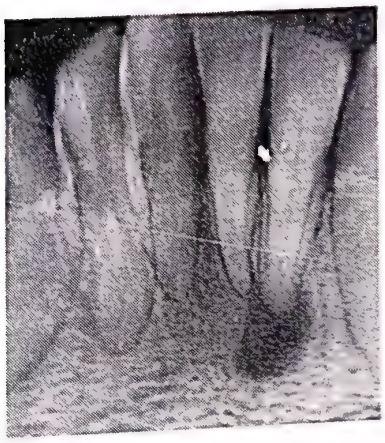

FIG. 544.—Dental radiograph showing root abscess of the left lower lateral incisor tooth.

THE GUMS

GINGIVITIS AND PYORRHŒA ALVEOLARIS

The periodontal membrane is the periosteum lining the tooth socket. Its fibres are arranged to form a sling for the root (or roots) of a tooth in its bed of bone.

Clinico-pathological Features.—The fundamental predisposing cause of these conditions is gum recession and an excessive deposit of tartar. The tartar pushes the gingival margin away from the teeth with the result that (a) the periodontal membrane is broken, (b) the gum recedes, and (c) particles of food accumulate between the gum and the teeth. *In gingivitis*, the gums are swollen, spongy, and bleed readily. *In pyorrhœa*, pus can be expressed from the gingival pockets. Fetor oris may be extreme. The teeth become loose and fall out.

Gingivitis may be associated with general stomatitis (p. 539), Vincent's stomatitis (p. 540), or be in evidence in scurvy and in chronic mercurial poisoning. In chronic lead, and bismuth poisoning, there is a characteristic narrow line of blue-black dots on the gums near the dental margin.

Treatment.—Comparatively early cases are often benefited by regular scaling, daily massage of the gums with the fingers, removing debris with a wooden toothpick and the frequent use of an astringent mouth-wash, (e.g. ferric chloride). If this treatment is unsuccessful and the majority of the remaining teeth are sound, gingivectomy (see below) is advised in order to eradicate the periodontal pockets.

When the condition is fully established, cure is unlikely, if not impossible, without extracting the teeth implicated.

Dangers of Dental Extraction in Pyorrhœa Alveolaris.—Clearing the jaws of teeth is not to be undertaken lightly in cases of pyorrhœa alveolaris. The bacteriæmia that follows is liable to set up broncho-pneumonia, and also may infect any existing endocardial valvular lesion; frequently the onset of subacute bacterial endocarditis dates from dental extraction. Therefore extraction in cases of pyorrhœa alveolaris should be carried out only under full antibiotic cover.

HYPERTROPHY OF THE GUMS

Hyperplastic Gingivitis.—The gums around the labial aspect of the upper incisors and their inter-dental papillæ are affected most. Bleeding is frequent. On pressure, pus usually oozes from the gingival pockets. In some long-standing cases the hypertrophied gum almost buries the teeth.

Gingivitis Gravidarum.—Consisting of granulation tissue, the hyperplastic 'tumours' may grow as large as currants and they may require cauterisation or diathermy.

In the treatment of epilepsy, the administration of sodium phenytoin leads to hyperplasia of the gums in susceptible individuals.

Treatment is gingivectomy or, if a radiograph shows the bone to be hypertrophied, alveolectomy in addition.

Localised hypertrophy of the gum due to pressure of an ill-fitting denture is common. If removal of the cause does not remedy matters in a fortnight, the hypertrophied area must be excised and examined histologically to see if the lesion is neoplastic.

GINGIVECTOMY

Indications.—(1) Hypertrophy of the gums; (2) to remove periodontal pockets around otherwise sound teeth.

FIG. 545.—Gingivectomy. The obliquity of the resection promotes drainage and prevents recurrence.

Operation.—Under local anæsthesia, the excess of gum is excised *obliquely* (fig. 545) on both the labial and the lingual sides, together with the interdental papillæ. A cautery arrests bleeding, and a paste (zinc oxide and eugenol[1]) is applied to the raw surface and left for a week to prevent granulation and to allow epithelialisation. If both sides are affected there are three (fortnightly) stages of removal : (*a*) both left sides as far as the canine teeth ; (*b*) both right sides similarly; (*c*) the remainder.

ALVEOLECTOMY

Indications.—(*a*) Hypertrophy of gums with hypertrophy of alveolus before fitting dentures. (*b*) Irregularities of alveolus, e.g. after extractions. (*c*) Sometimes in cases of fibrous epulis.

[1] Eugenol—an active principle extracted from oil of cloves.

Operation.—Any remaining teeth are extracted. With a stout scalpel, an incision is made right down to the bone. Employing a periosteal elevator, a flap is raised on the labial aspect, and a similar one on the palatal aspect. The irregularities of the bone are removed with a hammer and chisel. The cut edges of the mucosa are sutured over the alveolus.

TUMOURS OF THE ALVEOLUS (EPULIS)

'Epulis' is an ancient term with no pathological significance; it merely indicates that there is a solid swelling 'situated on the gum'. There are four varieties of epulides:

1. **Granulomatous Epulis.**—A mass of granulomatous tissue forms around a carious tooth, or at the site of irritation by a denture, requiring extraction of the tooth and scraping away the granulations. A portion must be examined histologically. *Gingivitis Gravidarum* is referred to on p. 522.

2. **Fibrous (fibroid) Epulis.**—The commonest form, is a simple whorled fibroma arising from the periodontal membrane, present under the gum. Rarely a soft, bluish-red, bleeding, and rapidly growing fibrosarcomatous type occurs (fig. 546). Both require removal of the adjacent tooth or teeth and resection of a wedge of bone, including the portion of the gum containing the growth.

FIG. 546.—Fibrosarcomatous epulis.

3. **Giant-celled ('myeloid') Epulis** is an osteoclastoma, arising peripherally in the jaw and presenting under the gum. It is soft, and the over-lying gum is sessile and plum-coloured from vascularity. Ulceration and serious hæmorrhage can occur. X-rays show bone destruction with ridging of the walls (pseudo-trabeculation). The treatment is curettage for small tumours, but radical excision (even requiring a graft for a mandible) for large tumours.

4. **Carcinomatous Epulis.**—An epithelioma of the gum may start around a tooth, or in a socket, causing a painful, infected, and infiltrating lesion which later becomes frankly fungating and ulcerating, invading bone and spreading to cervical lymph nodes. A biopsy must be performed to confirm the diagnosis. Treatment depends upon adequate resection (grafting for mandible, excision of maxilla). Radiotherapy may be useful.

THE JAWS

A CLASSIFICATION OF JAW SWELLINGS

This is merely for guidance. The epulides, by definition 'swellings of the gum,' are excluded.

1. INFLAMMATORY.	2. ODONTOMES (epithelial).	3. BONE TUMOURS
		Benign.
(*a*) Alveolar abscess.	(*a*) Dental cyst.	(*a*) The fibro-osseus group.
(*b*) Osteomyelitis.	(*b*) Dentigerous cyst.	(*b*) Osteoclastoma, and the giant-celled reparative granuloma.
(*c*) Actinomycosis. *(Not specifically of the jaw but related to it.)*	(*c*) Adamantinoma.	Malignant.
		(*a*) Osteosarcoma.
		(*b*) Carcinoma of the maxillary antrum (destroying bone) (and see p. 529).

1. INFLAMMATORY SWELLINGS

(*a*) **Alveolar Abscess.**—This has been described (p. 520).

(*b*) **Osteomyelitis of the Jaws.**

This can be acute, subacute, or chronic.

Acute osteomyelitis is rare. In infants it may be a complication of acute specific fevers (measles or scarlet fever), and either the maxilla or mandible may be affected. In other cases infection may spread from the antrum, lachrymal sac, or a dental sac of the first molar tooth. If the maxilla is affected, puffiness of the eyelids occurs (fig. 547). The lateral aspect of the alveolus will be found swollen. A discharging sinus may be seen and pressure over the maxilla will cause pus to run from the nostril and sinus. Radiographs are of no value (Cavanagh). The condition is often mistaken for dacryocystitis.

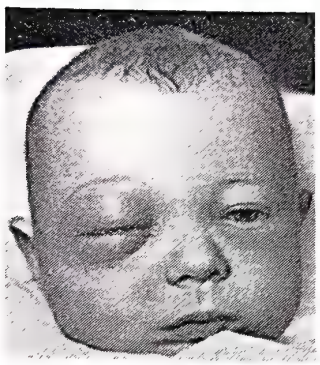

FIG. 547.—Acute osteomyelitis of the maxilla. (*Florence Cavanagh, F.R.C.S. (Edin.), Manchester.*)

Treatment.—Though the antrum is small, a polythene tube is introduced by trocar and cannula via the nose, and the cavity is irrigated with normal saline twice daily, the tube being strapped to the cheek. Appropriate antibiotics are given for seven to ten days.

Subacute Osteomyelitis.—The commonest type, it affects adults and is caused by the spread of apical dental infection or an alveolar abscess. The condition may follow a fractured jaw, which is almost invariably compound into the mouth. The organism is usually the *Staphylococcus aureus*. The mandible is usually affected, probably because it has a single, rather tenuous blood supply running in the long axis of the bone, which is easily obstructed by infection or trauma. Obstruction to the blood supply causes bone necrosis, which is the essence of osteomyelitis of the jaw. The maxilla is better protected by a series of vertical arteries with anastomoses. Injudicious extractions performed under a local anæsthetic, and poor general condition (anæmia and under-nutrition), are local and general factors (Wass).

Thus osteomyelitis must be suspected if there is pain, swelling, tenderness after dental extraction or a treated alveolar abscess. There may be a discharging internal or external sinus; this may relieve tension within the bone and so pain is relieved. Increased tension in the dental canal compresses the inferior dental nerve (as well as the vessels) so numbness of the chin in the distribution of the mental nerve is diagnostic. Radiological evidence of bone necrosis takes three weeks or longer to become evident.

FIG. 548.—Osteomyelitis of the lower jaw shortly after a very large sequestrum had been removed.

Differential Diagnosis.—Osteomyelitis must be distinguished from the two other jaw infections—alveolar abscess (p. 520) and, in particular, actinomycosis (p. 33). Sarcoma, though clinically similar, has distinct X-ray appearances.

Treatment.—If osteomyelitis is suspected clinically but not confirmed radiologically, *weekly X-rays* must be taken. As soon as bone necrosis is

Florence Cavanagh, Contemporary. Honorary Clinical Lecturer in Child Health, University of Manchester.
Samuel Hall Wass, 1907–1970. Surgeon, Guy's Hospital, London.

seen, *operation* is required to relieve tension and remove diseased and dead bone (sequestrum) (fig. 548). *Antibiotics* are given: (a) during the waiting period, providing one is not thereby lulled into a false sense of security (weekly X-rays must continue); (b) as an aid to operative surgery. Bone recovery (involucrum) is poor. It occurs in young patients, but after middle life there is hardly any regeneration and pathological fracture may occur.

Chronic Osteomyelitis.—Again the mandible is affected more often than the maxilla, and necrosis occurs in a number of ways.

(i) **After Apical Dental Infection,** *Alveolar Abscess, or Peridental Suppuration.*—Most patients are over fifty years of age. In 50 per cent. of cases dental extraction precedes the onset of symptoms. Many months may elapse before the patient seeks advice. X-ray will show local osteitis with sequestrum formation or a localised abscess (a Brodie's abscess similar to chronic osteomyelitis in long bones).

(ii) **After fractures.**

(iii) **Radiation and Chemical Necrosis.**—Radium and irradiation necrosis, though seemingly non-bacterial, has a large infective element, probably due to the spread of apical dental infection after the vascular thrombosis caused by the irradiation of tumours in the area. There is also a danger of necrosis if extractions are performed after radiation. 'Phossy-jaw' necrosis due to phosphorus poisoning, is rarely seen nowadays, since the crude element is no longer used in the manufacture of matches.

Tuberculous, syphilitic, and actinomycotic necrosis are rare. A hole in the hard palate following a gumma is an example of syphilitic necrosis (p. 43).

Treatment.—Dependent drainage gives the best results. A suitable incision is made beneath the mandible, and a trough is chiselled in the bone, any sequestrum present being removed. The wound is left open and packed lightly with petroleum jelly gauze. Appropriate antibiotics are given.

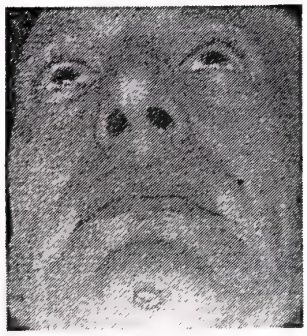

FIG. 549.—Median mental sinus.

Median mental sinus (fig. 549) is a clinical entity which is often diagnosed and treated incorrectly. It is produced by an apical abscess on one (or more) of the lower incisors which has penetrated the buccal cortical plate below the origin of the mentalis muscles. These muscles take origin from the labial surface of the alveolar process at or just above the bottom of the labial sulcus and diverge to be inserted into the skin of the chin. Thus pus which accumulated deep to mentalis muscles can escape to the surface only in the mid-line and consequently discharges through a sinus in the centre of the chin.

Often the offending tooth has become pulpless as a result of a blow so there is no obvious cause for necrosis of the pulp. The lower incisors should be tested for vitality to establish the causative tooth which preferably should be root filled as replacement of a single lower incisor is difficult. The sinus will close spontaneously once the infection is controlled.

(*c*) Actinomycosis

The cervico-facial type of actinomycosis (swelling of the soft tissues, p. 33) has clinical similarities to osteomyelitis of the mandible and must be con-

Sir Benjamin Collins Brodie, 1783–1862. Surgeon, St. George's Hospital, London.

sidered in the differential diagnosis of inflammatory swellings of the jaw. There is swelling of the soft tissues with sinuses, with or without pain. The swelling is more brawny than in osteomyelitis, and the skin is bluish. External sinuses are common, being uncommon in osteomyelitis. 'Sulphur granules' may be seen in the discharge from the sinuses, but their absence, and the inability to grow the streptothrix actinomyces does not rule out this diagnosis. In fact, such a swelling with persistent negative X-ray appearances of the jaw, is considered to be actinomycosis and treated accordingly (p. 34).

2. THE ODONTOMES

Odontomes are cysts, tooth malformations, or tumours arising from the epithelial or mesothelial elements of the teeth, or sometimes from both. Only the three epithelial odontomes are common and important: (*a*) Dental cyst, (*b*) Dentigerous cyst, (*c*) Adamantinoma.

(*a*) **Dental cyst** occurs in connection with the root of a normally erupted, but chronically infected, usually pulpless, tooth, viz. :⟶ Epithelial cells, believed to be derived from the enamel-organ, proliferate and degenerate, forming a cyst. The cyst enlarges, causing expansion of the alveolus, and eventually most of the epithelial lining disappears. These cysts, which can appear at any age, are more frequent in the upper jaw, and when they attain a large size they encroach upon the antra or the nasal fossæ, but rarely open into these cavities. Usually the fluid in the cyst is clear, and it often contains cholesterol crystals ; as a rule it is sterile, but secondary infection can occur. When not infected, the condition is painless.

(*b*) **Dentigerous cyst** (*syn.* follicular odontome) arises, usually in young adults, in connection with a non-erupted permanent tooth. The swelling consists of a cyst containing a tooth, most commonly an upper or a lower third molar, often well developed except for truncated roots, lying obliquely in a cavity filled with viscid fluid, viz:⟶

These cysts expand the outer table of the jaw even to causing egg-shell crackling. The stronger inner table prevents pathological fracture. Ridges of bone on the side walls cause a pseudo-trabecular or a soap-bubble appearance on X-ray.

FIG. 550.—Naso-palatine cyst.

Treatment of Dental and Dentigerous Cysts.—The essential point in the operative treatment is the excision of the whole epithelial lining of the cyst. After preoperative dental hygiene, treatment of caries etc., cysts in the upper jaw or small cysts in the lower jaw are exposed through an intra-oral approach to the outer table by raising a muco-periosteal flap. An external approach is used for a large mandibular cyst. After excision the bone cavity is obliterated by a soft tissue 'push-in', or with bone chips, and the wound is sutured.

Naso-palatine Cyst (fig. 550).—A rare cyst, arising in connection with the naso-palatine canal and *not* with incisor teeth, which need not be sacrificed (Roper-Hall).

Harry Thomas Roper-Hall, 1890–1969. Dental Surgeon, Birmingham and Midland Eye Hospital.
Rupert Allan Willis, Contemporary. Formerly Professor of Pathology, Royal College of Surgeons of England, London.

(*c*) **Adamantinoma** (*syn.* multilocular cystic disease; ameloblastoma) is an epithelial tumour possibly arising from ameloblasts (enamel-forming cells). It is more common in coloured races. It behaves pathologically and looks histologically like a basal-celled carcinoma (p. 109). (Willis believes it arises from the ectodermal epithelium of the stomadæum.) Unlike the other two odontomes just described, it is a locally invasive solid tumour, but undergoes multicentric cystic degeneration. Some of the loculi are separated by true bony trabeculæ. An adamantinoma will recur if simply curetted, but it does not metastasise to lymph nodes. It usually occurs in the third decade, nearly always affecting the mandible causing expansion, mostly of the outer table in the region of the molar teeth (fig. 551). It rarely causes pain. The cystic degeneration leads to areas of softening or egg-shell crackling.

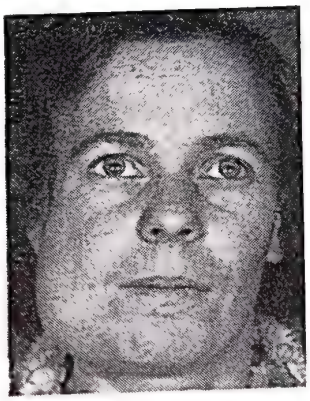

FIG. 551.—Adamantinoma of the mandible. (*A. H. Lendon, F.R.C.S., Adelaide.*)

An X-ray shows large loculi, but also a fine honey-comb appearance which is characteristic and distinguishes it from some dentigerous cysts or an osteoclastoma (fig. 552).

FIG. 552.—X-ray of adamantinoma (large loculi and small honey-combing). (*The late H. S. Wass, F.R.C.S., London.*)

Treatment. — Evacuation and curettage of the cysts is followed invariably by recurrence. X-ray or radium therapy is without permanent value. Therefore resection of that portion of the jaw bearing the tumour, together with a margin of healthy bone, is essential. Before this is undertaken provision should be made for retention of the remaining portions of the bone in normal relationship by means of dental fixation. Provided no recurrence takes place, after an interval of several months the mandibular defect can be bridged with a bone graft.

3. BONE TUMOURS OF THE JAWS (BENIGN)

(*a*). **The Fibro-osseus Group.**—The jaws are membrane bones; there is no cartilage. The ' tumours ' of this group are composed of varying proportions of fibrous tissue and bone, being hard if mainly bone, softer, if fibrous tissue, while myxomatous degeneration causes softening in parts. The condition can be localised or diffuse. Thus the variety of types and their descriptive names are many. For example, a mainly fibrous tumour is called *Monostotic fibrous dysplasia* if localised, or *Polyostotic fibrous dysplasia* if diffuse. If solely of bone and localised, it is an *Ivory osteoma* (fig. 553) or *Leontiasis ossea* if diffuse. Radiological appearances vary between uniform sclerosis and irregular mottling.

FIG. 553.—Ivory osteoma of the left maxilla. The tumour has been growing slowly for eight years.

The cause is obscure. Dental sepsis was once thought responsible (Leontiasis Ossea being due to a creeping periostitis). The behaviour of the ' tumours ' is unlike that of a true neoplasm, for they appear in the first or second decade and usually stop growing when the individual is fully grown. Thus Wass believed that they are aberrations of ossification in membrane. When growth has finished, the unsightly swellings of small local lesions can be removed under antibiotic cover.

Paget's Disease of the Jaws (fig. 554).—This condition can be part of a generalised Paget's disease, or confined mainly to the jaws. It may be confused with that diffuse bony variety of the fibro-osseus group, leontiasis ossea, but it occurs in older people, pain is often present, other bones are affected, and the radiological appearances of the teeth (if there are any) show apical club-shaped swellings (cementosis). As the need arises the alveolus and, if necessary, the anterior surface of the maxilla, is reduced in size by chiselling away the excessive bone formation.

FIG. 554.—Paget's disease of the maxillæ. After partial resection of both upper jaws the patient emigrated to New Zealand.

Complication.—Sarcoma develops more often than is the case in other bones affected with Paget's disease.

(*b*) **Osteoclastoma and Giant-celled Reparative Granuloma.**—Both these conditions are rare. *Osteoclastoma*, besides occurring under the gum as a myeloid epulis (p. 523), can expand bone, though Wass encountered only one instance (in the maxilla) out of 350 jaw tumours.

Giant-celled reparative granuloma is often mistaken for an osteoclastoma (Jaffe). The lesion appears to be related to the occurrence of a hæmorrhage within the bone marrow. Somewhat rare, it occurs more frequently in females than in males, and nearly always between the ages of ten and twenty-five years, whereas a *bona fide* giant-celled tumour appears in patients between twenty-five and forty years of age. The lesion causes a painless swelling of the jaw, situated much more frequently in the mandible than in the maxilla.

Radiography.—There is a rounded or oval area of radio-translucency (fig. 555). The granuloma thins and expands, but does not perforate the cortex.

Pathology.—Multinuclear cells are small, sparse, and distributed unevenly. Histologically it is difficult or impossible to distinguish this lesion from the so-called brown tumour of hyperparathyroidism.

Differential Diagnosis. — Hyperparathyroidism should be excluded by ascertaining the serum calcium level and by radiography of other parts of the skeleton (p. 620). It is also important to exclude an adamantinoma (p. 526), for the treatment of the latter condition must be more radical. At operation a giant-celled granuloma will be found to consist of opaque, semi-solid, dark red material, whereas an adamantinoma is filled with transparent fluid or jelly.

Treatment.—The treatment of choice is thorough curettage through an external incision without opening the bone cavity into the mouth. Should the condition recur, hyperparathyroidism must again be excluded.

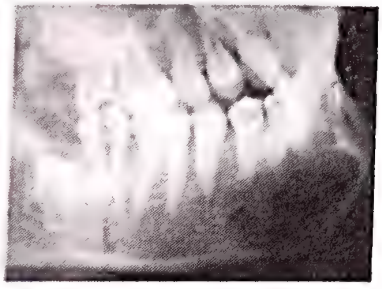

FIG. 555. — Radiograph showing a giant-celled reparative granuloma of the mandible. (*Dr. H. L. Jaffe, New York.*)

3. TUMOURS OF THE JAWS (MALIGNANT)

Malignant Neoplasms of the Maxilla.—The clinical diagnosis of 'malignant upper jaw' embraces a number of pathological conditions.

(*a*) **Osteogenic sarcoma** is usually of the round-celled variety; rarely it is a highly differentiated fibro-myxochondro-sarcoma.

(*b*) **Columnar-celled carcinoma**—of the maxillary antrum (fig. 556).

(*c*) **Squamous-celled carcinoma**—derived from the epithelium overlying the hard palate, from a tooth socket, or from the gum.

(*d*) **Invasion of the maxilla by a sarcoma of the ethmoid.**

(*e*) **Malignant Lymphoma of Africa (Burkitt Tumour)** (p. 184).

(*a*) **Osteogenic Sarcoma.**—While neither sex nor any age is exempt, this disease has a curious predilection for women about the age of forty.

Sir James Paget, 1814–1899. Surgeon, St. Bartholomew's Hospital, London.
Henry Lewis Jaffe, Contemporary. Formerly Director of Laboratories, Hospital for Joint Diseases, New York, U.S.A.

When of the periosteal variety—and this is the more usual—it is the *anterior* aspect of the jaw which is maximally affected, but the condition soon shows itself on the inferior or palatal wall as well. Pain, nasal obstruction, and epiphora[1] usually occur late in the disease.

(*b*) **Carcinoma commencing in the maxillary antrum** is much more frequent than the foregoing, and the age incidence of this group is similar to that of carcinomas elsewhere. These neoplasms are divided about equally between the sexes, and most cases are associated with secondary infection of the nasal sinuses. Growths that originate on the floor of the antrum frequently cause pain in the teeth, and a dental surgeon is consulted, but without relief of the pain; however, pain usually results in a comparatively early diagnosis. A foul, purulent and blood-stained discharge from the nose is common. Free bleeding associated with antral puncture should always suggest the possibility of carcinoma of the antrum. The main clinical features vary in accordance with the direction in which the tumour spreads:

FIG. 556.—Carcinoma commencing in the maxillary antrum.

If posteriorly, there is little if any alteration in contour of the face.

If the medial wall is implicated, there will be nasal obstruction and epiphora.

If the antero-lateral wall is involved, there will be evident swelling of the face (fig. 556).

If the floor of the antrum is transgressed, the hard palate will bulge.

If the roof is invaded, there will be proptosis and diplopia.

Metastasis occurs relatively late, the upper jugular lymph nodes being the first to be affected, giving rise to a swelling beneath the angle of the jaw. A third of the cases have metastases when they are first seen.

Radiography.—In the early stages there is opacity and increase in size of the antrum. Later decalcification of the bony walls is visible.

Biopsy.—All nasal polypi should be submitted to microscopical examination. Unfortunately cases in which polypi are present are comparatively few. Fragments of the neoplasm may be washed out by antral lavage and solid matter, after centrifuging, should be examined microscopically. As a rule, a diagnostic Caldwell-Luc operation (p. 532) is necessary to obtain biopsy material, and as histological examination is a cardinal step in diagnosis, no effort should be spared in obtaining a representative specimen.

Treatment.—Collaboration between surgeon and radiotherapist is essential.

Combined Irradiation and Conservative Surgery for Carcinoma of the Maxilla.—In several clinics the following plan is adopted:

(*a*) A course of high-voltage irradiation or gamma rays from a teleradium unit is given.

(*b*) Six to eight weeks after the conclusion of the irradiation, by which

[1] Epiphora—Greek, *ἐπιφορά* = overflow. An abnormal overflow of tears down the cheek usually due to obstruction of the lachrymal duct.

time the inflammatory reaction has abated, palatal antrostomy is performed. The purpose is to remove any residual irradiated growth and to discover whether and where any viable malignant tissue remains by taking a series of geographic biopsies. It also allows easy follow-up inspection of the cavity.

The plate of bone forming the antro-nasal wall is nibbled away. The inferior and middle turbinate bones and the tissue involved in the growth are removed with a diathermy needle, if possible in one piece; doubtful areas are coagulated. A pack or plastic obturator is inserted. The patient is given antibiotic therapy for a week.

(*c*) In 30 per cent. of cases the tissue removed shows no evidence of malignancy, and nothing more is required. When the tissue removed at operation shows evidence of active malignancy a hollow plastic applicator, made by a dental surgeon, is filled with wax and drilled so as to take radium tubes. In this way further irradiation is given. If the post-ethmoidal or sphenoidal regions are involved, radium needles are inserted directly into those areas.

(*d*) A block dissection of the neck is undertaken if lymph nodes are palpable (p. 584).

(*e*) A permanent obturator bearing teeth is fitted at least three months after operation.

Excision of the Maxilla.—Since the introduction of intratracheal anæsthesia the operative mortality is low. There is surprisingly little deformity after this formidable operation, especially if a prosthesis is constructed by a dental expert as soon as the wound has granulated. Such treatment offers hope of a cure. Whether surgical excision should precede or follow irradiation is still undecided, as comparable results are obtained by either method (Maxwell Ellis).

If recurrences occur they may be treated by diathermy excision, intracavity irradiation or infusion with *cytotoxic drugs* (p. 677). The overall five-year survival rate is 35 to 50 per cent.

MALIGNANT NEOPLASMS OF THE MANDIBLE

The mandible is rarely the site of a primary malignant neoplasm or of a metastasis. However, rather frequently it becomes directly involved by an advancing primary carcinoma of the tongue or of the floor of the mouth. Sometimes an advanced carcinoma of the lip spreads to this bone through the mental foramen. A third method of neoplastic involvement is occasioned by the relation of the facial lymph node which lies in juxtaposition to the mandible near the groove on this bone for the facial artery. Should this inconstant node be the seat of a secondary deposit, it tends to invade the mandible.

Treatment.—So regularly does irradiation cause necrosis of the mandible, that when the bone is involved by growth, it is usually necessary to resect a portion or perform hemi-mandibulectomy. If the chin itself can be spared, gross deformity is avoided.

SARCOMA OF THE ETHMOID

Sarcoma of the ethmoid is rare. As it expands it widens the space between the orbits and flattens the nasal bones, producing that clinical entity, the 'frog-faced man'. Still later the superior maxillæ are invaded.

Treatment.—The treatment by combined irradiation and operation does not differ

Maxwell Philip Ellis, Contemporary. Formerly Surgeon, Royal National Throat, Nose and Ear Hospital, London.

in principle from that described for carcinoma of the maxillary antrum. When the air sinus is infected, drainage is essential before irradiation is commenced.

INFECTION OF THE MAXILLARY ANTRUM

Surgical Anatomy.—The maxillary antrum (of Highmore) is rudimentary at birth and attains full development by the age of twelve years. Lined with ciliated epithelium, it communicates with the middle meatus of the nose by a small ostium situated high on its medial wall (fig. 557). The apices of the roots of the second premolar and the first and second molar teeth are in close apposition to the floor of the antrum being separated only by periosteum and mucous membrane. Rarely, the first premolar and the canine teeth are related similarly.

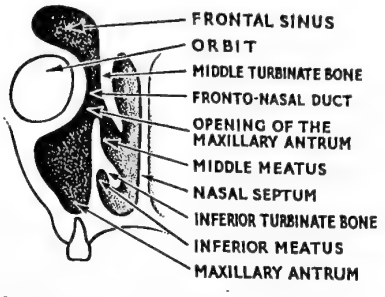

FIG. 557.—Coronal section of the maxillary antrum.

Maxillary sinusitis may be unilateral or, much less frequently, bilateral. Infection occurs as an extension from the nose. One epidemic of acute respiratory infection (common 'cold') brings as an aftermath many cases of infection of the accessory nasal sinuses, of which the maxillary antrum always heads the list; while another epidemic, in all other respects similar, is free from this complication. A less frequent cause is penetration of the floor of the antrum by bacteria from a periodontal abscess connected with a carious tooth; also entry of infected water during swimming.

Acute Empyema Antri.—As a rule the general symptoms are severe, especially when the pus is confined by occlusion of the natural ostium. Pain and tenderness are present over the affected maxilla; sometimes the pain is referred along one of the divisions of the trigeminal nerve. Breathing through the nostril on the side of the lesion is impaired and often obstructed. If the ostium is patent, which is unusual in acute cases, a flow of pus can be obtained when the head is held downwards and forwards with the affected side uppermost.

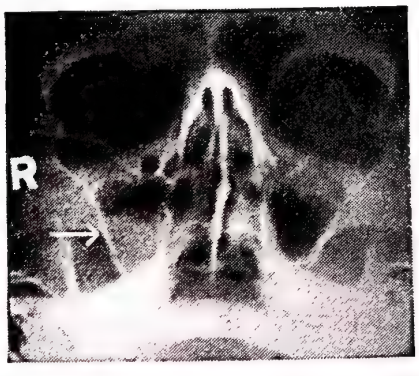

FIG. 558.—Radiograph showing pus in the right antrum of Highmore.

Transillumination of the antrum and a radiograph (fig. 558) are likely to reveal a relative opacity of the affected antrum.

Treatment.—This includes bed rest, analgesics, ephedrine 1 per cent. in saline by a nebulizer, menthol inhalations, and systemic chemotherapy if the temperature is over 38°C. Puncturing the antrum is for diagnostic and therapeutic purposes. An antral trocar and cannula punctures the antrum beneath the inferior turbinate bone after application of surface anæsthesia. Pus is aspirated and washouts are performed with normal saline.

Chronic Empyema Antri.—Pain and swelling are often absent, and frequently the only symptom is an intermittent flow of pus from the nostril on the affected side. When the ostium is patent, the information gained by an examination with a nasal speculum may be diagnostic.

Nathaniel Highmore, 1613–1685. General Practitioner, Sherborne, Dorset, England. Published a treatise on anatomy in 1651.

Treatment.—Purulent maxillary sinusitis not responding to three weeks' trial of irrigation warrants adequate drainage:

Caldwell-Luc Operation.—This is a good standard procedure, though not advocated in children as dentition may be affected. Under general anæsthesia, with oral intubation and packing, an intra-oral incision 2·5 cm long is made in the buccolabial sulcus, centred over the canine fossa. The muco-periosteum is elevated and a gouge is used to make an opening about 12 mm in diameter through the anterior wall of the antrum (fig. 559). All the mucous membrane is removed with Luc's forceps (fig. 560) and any diseased ethmoid cells can be exenterated. An intranasal antrostomy completes the procedure, allowing post-operative washouts.

FIG. 559.—Caldwell-Luc operation (see text).
(*H. Holden, F.R.C.S., London.*)

Intranasal Antrostomy is performed in children in order to avoid affecting dentition, and as an operation of compromise in some patients with recurrent sinusitis. Under a general anæsthetic, a piece of the medial wall of the antrum is removed to allow drainage into the nose.

Nasal Polypi. — Nasal polypi (œdematous ethmoid sinus mucosa) are usually multiple and are found prolapsing from the ethmoid cells in the region of the middle turbinate (fig. 557), and are recognised by their glistening gelatinous appearance when light is focused upon them.

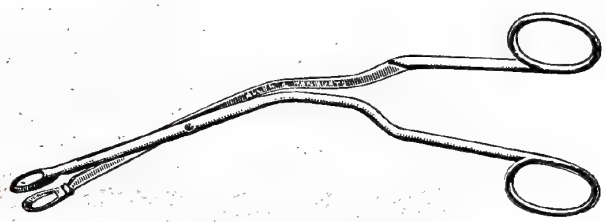

FIG. 560.—Luc's ethmoidal forceps.

They are practically confined to adults, and patients complain of nasal obstruction, nasal discharge, and some loss of smell. Many of the sufferers are allergic to dusts and pollens that initiate in them attacks of sneezing and acute rhinitis.

Treatment.—Nasal polypi together with pieces of carious ethmoid are removed under surface anæsthesia with Luc's forceps (fig. 560). If there is an associated sinusitis it must be eradicated also. Antihistamines should be used after removal, since recurrence is common.

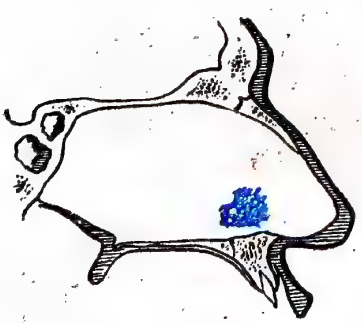

FIG. 561.—Little's area.

EPISTAXIS

Source and Cause of the Bleeding.—The bleeding may be arterial or venous. In 90 per cent. of cases it comes from a plexus of veins (sometimes varicose) situated in Little's area (fig. 561) on the antero-inferior portion of the septum. The most frequent cause is nose-picking—epistaxis digitorum. Other causes include trauma, nasal infection, neoplasms, hypertension, blood dyscrasias, acute specific fevers, nephritis and uræmia.

George Walter Caldwell, 1866–1946. Otolaryngologist who practised successively in New York, San Francisco and Los Angeles. Described his operation for treating suppuration of the maxillary antrum in 1893.
Henri Luc, 1855–1925. Otolaryngologist, Paris. Described his operation in 1889.
James Lawrence Little, 1836–1885. Professor of Surgery, University of Vermont, Burlington, Vermont, U.S.A.

Treatment.—Sit the patient up so that blood does not run down the throat. Blow nose to remove clots. Pinch the nose for ten minutes. An ice-pack or cold sponge applied to the nose is often helpful.

Sedation with morphine and admission to hospital are necessary if bleeding is uncontrolled. Blood transfusion may be required. If the patient is hypertensive, some loss of blood may be beneficial.

Cauterising the bleeding-point with trichloracetic acid, 50 per cent., or electric cautery, is undertaken if the bleeding-point can be seen.

Packing: *Anterior Packing.*—After anæsthetising the mucous membrane with 4 per cent. xylocaine, ribbon gauze saturated in liquid paraffin is inserted so as to fill the nasal cavity, and if the bleeding is from the septum the nasal cavity of the opposite side is packed also. Antibiotics are given to combat infection.

Posterior Packing.—The insertion of a cone-shaped gauze tampon (fig. 562), moistened with liquid paraffin is the most satisfactory although a quick method is to insert a Foley-type catheter as far as possible to the back of the nasal cavity and inflate the balloon (Plummer). The pack can be left in for five days if an antibiotic is administered.

FIG. 562.—Method of inserting a posterior nasal tampon (Dickie's method).

Arterial Ligation.—When the above methods fail, or profuse hæmorrhage recurs and it is likely that the source of the bleeding is more posterior, ligation of the anterior ethmoidal artery in the orbit is indicated, particularly in traumatic cases (fig. 563). Trans-antral ligation of the internal maxillary artery, and ligation of the external carotid artery are other methods which are sometimes called upon.

FIG. 563.—Incision for the approach to the anterior ethmoidal artery.

DEFLECTED NASAL SEPTUM

Although the majority of adults do not have a completely straight septum, it is only the grosser deflections causing symptoms which require correction. Septal deformities are caused either by trauma or by disproportionate growth during development. They may produce nasal obstruction or headaches in the region of the nasion.

The submucous resection (S.M.R.) operation consists of the removal of cartilaginous and bony spurs from between the two coverings of mucoperichondrium and mucoperiosteum. This allows the septum to take a more midline position.

Nasal Bone Fractures (p. 512).

THE EAR

Now follows a brief presentation of well-known afflictions of the ear. The reader is referred to the appropriate text-books for fuller accounts and descriptions of operative surgery.

Surgical Anatomy (fig. 564).—The ear consists of four parts: (1) Pinna, (2) External auditory canal, (3) Middle ear, (4) Inner ear and Eighth nerve track.

The pinna is cartilaginous, covered by stratified squamous epithelium. The external auditory canal is in two parts: the outer cartilaginous part, which is lined by similar epithelium, tapers to its narrowest part

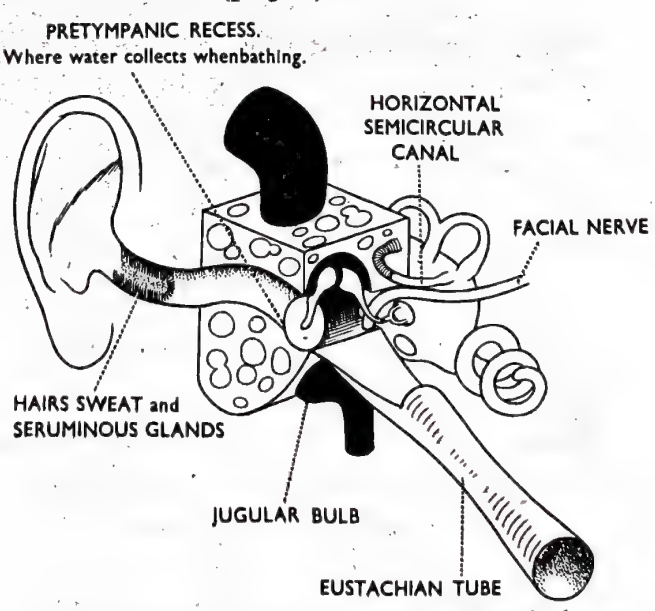

FIG. 564.—Diagram showing the surgical anatomy of the ear.

where it joins the bony external auditory canal. This is lined by a thin stratified epithelium containing no glands or hair follicles, and widens medially until closed off by the tympanic membrane at an angle of 60° to the vertical.

The middle ear is part of the mastoid bone. Above, is the attic connected by the aditus to the mastoid antrum and variable air cells. Below, it communicates with the nasopharynx via the Eustachian tube. It contains (*a*) three ossicles: malleus, incus, and stapes; (*b*) two muscles—tensor tympani and stapedius; (*c*) two windows—oval and round; (*d*) one nerve—chorda tympani. The facial nerve traverses the superior and posterior wall in its bony canal. The horizontal semicircular canal lies in the attic.

Congenital Abnormalities.—These are: partial or complete absence of pinna; partial or complete occlusion of external auditory canal; partial or complete absence of middle ear—the stapes is nearly always present. Treatment is surgical reconstruction.

EXTERNAL EAR

Wax.—This is best removed by syringing with warm water and bicarbonate of soda solution (1 per cent.) after appropriate oily drops have been introduced for the previous two nights. An aural syringe with a small nozzle must be used, and directed upwards and backwards. An intact drum is unlikely to rupture if these rules are followed.

Foreign bodies easily become wedged in the narrow part of the meatus. In children, beads can be removed manually by a loop, or by syringing[1] providing the child is cooperative, but a general anæsthetic may be required. Flies in the ears of motor-cyclists are removed by syringing.

Inflammation.—Inflammation of the external canal may be localised (furuncle) or widespread (external otitis).

FIG. 565.—Carcinoma of the pinna.

Furuncles are staphylococcal in origin, and produce pain, pyrexia, periauricular swelling and, characteristically, a painful pinna on movement.

Treatment.—Decongestive drops or wicks (e.g. glycerine and icthyol or

[1] Celsus (see p. 21) recommended tying the patient on a wooden plank with the affected ear downwards and hitting the plank with a hammer.

antibiotic hydrocortisone cream). If symptoms are severe or generalised (pyrexia), broad spectrum antibiotics are required.

External otitis (*syn.* telephonist's ear, Singapore ear) is often fungal and secondary to dandruff or athlete's foot. Irritation, discharge, and minimal deafness are the symptoms—secondary bacterial infection introduced by scratching the ear leads to further discharge and pain. Antifungal preparations combined with a local antibiotic either as drops or cream is indicated. The primary cause, scalp or toes, must be treated at the same time and the ears kept dry. Mild sedation, e.g. Phenergan 25 mg. may be advisable.

Carcinoma of the Pinna (fig. 565) is of the squamous-celled type, and the condition is often comparatively advanced before the patient seeks relief. However, if treated early, favourable results accrue from excision of a part, or the whole of the pinna. Acrylic and rubber prostheses effectively replace the lost part.

Bony Exostoses.[1]—Bony exostoses of the deep meatus produce a bizarre appearance (fig. 566). Only if the remaining chink past them is very small is removal indicated to alleviate deafness. They are removed by elevating the meatal skin and drilling away the bony exostosis. There is a potential danger to the facial nerve.

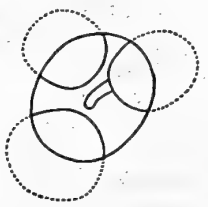

FIG. 566.—Bony exostoses of the meatus, as seen through the auroscope.

MIDDLE EAR

Acute otitis media is secondary to upper respiratory infection and presents as a sudden, painful, deaf ear. The temperature is raised and examination of the ear shows a red bulging drum.

Treatment.—In the very early cases, antibiotics are given. If they are used, they must be given in *full* doses for five days. Nasal decongestants (e.g. 1 per cent. Ephedrine spray) are given in all cases. If the drum is full and bulging, incision (myringotomy) is necessary (figs. 567 and 568). Otorrhœa is treated either by dry mopping under direct vision with the aid of a head-lamp, or by gentle syringing with sodium bicarbonate solution (1 per cent.), followed by antibiotic hydrocortisone drops instilled freely forty-eight hours after myringotomy.

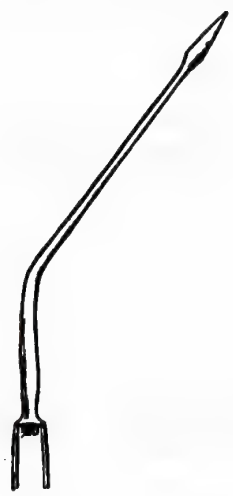

FIG. 567.—Myringotomy knife.

Complications.—Inadequate chemotherapy causes latent mastoiditis. Unresolved otitis media is likely to flare up a week or so later as acute mastoiditis.

Acute Mastoiditis.—The symptoms are pain deep in the ear, periauricular swelling, pyrexia. The pinna is not painful on movement (as distinct from a furuncle). Conduction deafness is marked.

Treatment.—Pus must be let out. Therefore a simple mastoidectomy is performed, with an adequate course of antibiotics in support.

The operation entails the removal of the infected air-

[1] Supposed to afflict those who indulge in under-water swimming.

cells through a posterior auricular incision. The middle ear is not disturbed. The wound is drained for twenty-four hours.

Complications (fig. 569) are lateral sinus thrombosis, extradural abscess, meningitis, cerebral or cerebellar abscess, facial palsy, and, rarely, labyrinthitis.

Chronic otitis media is of silent onset. First symptoms are a foul scanty otorrhœa with increasing deafness. Perforations of various types are seen, e.g., attic or central, (figs 570, 571) with scanty pus and marked conduction

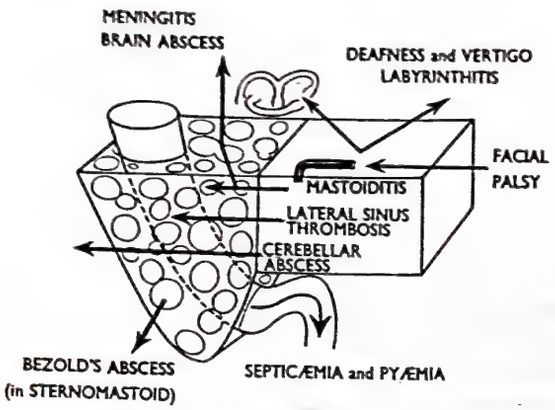

FIG. 569.—The complications of acute mastoiditis.

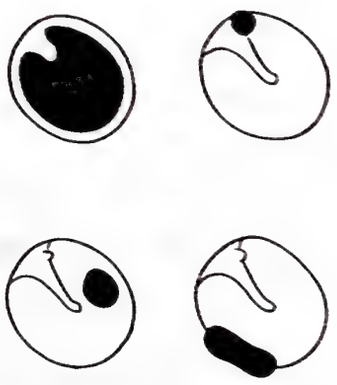

FIG. 570.—Types of perforation of tympanic membrane in chronic otitis media.

deafness. *Treatment* varies from simple reconstruction (myringoplasty, fig. 571) to that which centres upon a modified or radical mastoidectomy with preservation of the stapes, and reconstruction of the tympanum (tympanoplasty).

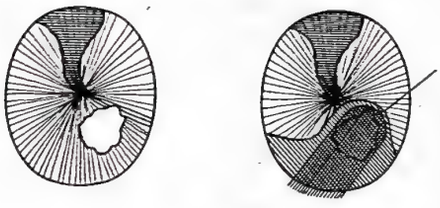

FIG. 571.—Myringoplasty. (*a*) Central perforation. (*b*) Epithelium elevated and fascial graft inserted to cover perforation. The epithelium is then replaced over fascia.

Tympanoplasty (fig. 572).—Operations and procedures under this group are designed to repair or reconstruct the tympanic membrane and ossicular chain of the

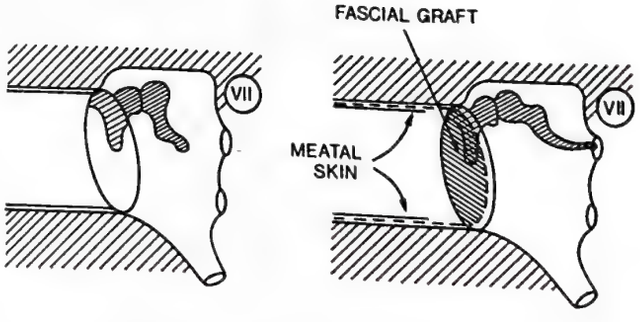

FIG. 572.—Tympanoplasty (a) Subtotal perforation with erosion of ossicles and loss of stapes. (b) Repair with fascia and ossicular continuity re-established by incus repositioning.

middle ear. Various tissues have been used including homografts from cadavers and animals but the most widely accepted are autogenous fascia with repositioned ossicles or shaped bone chips.

Complications.—Conduction deafness with ossicular chain destruction, labyrinthitis (common), facial palsy, cerebral meningitis, cerebral and cerebellar abscess. A *cholesteatoma* (skinball), whose origin is debatable,

produces otorrhœa and the above complications by pressure necrosis. *Treatment* is as above, with the removal of all the lining membranes.

Ruptured drum is due to trauma, e.g. hard slap on ear or syringing. There is sudden pain and deafness, with tinnitus and bloodstained discharge.

Treatment—Do not touch. No eardrops. Examine the patient daily. No antibiotics required except if infection has been caused by syringing.

Otosclerosis produces bilateral conduction deafness. Common in females, it is often hereditary, and may be exacerbated by pregnancy.

Treatment by hearing aid or operation—stapedectomy with Teflon (or wire) strut and vein (or fat) graft (fig. 573). This produces improvement permanently in 90 per cent. and it has replaced the fenestration operation.

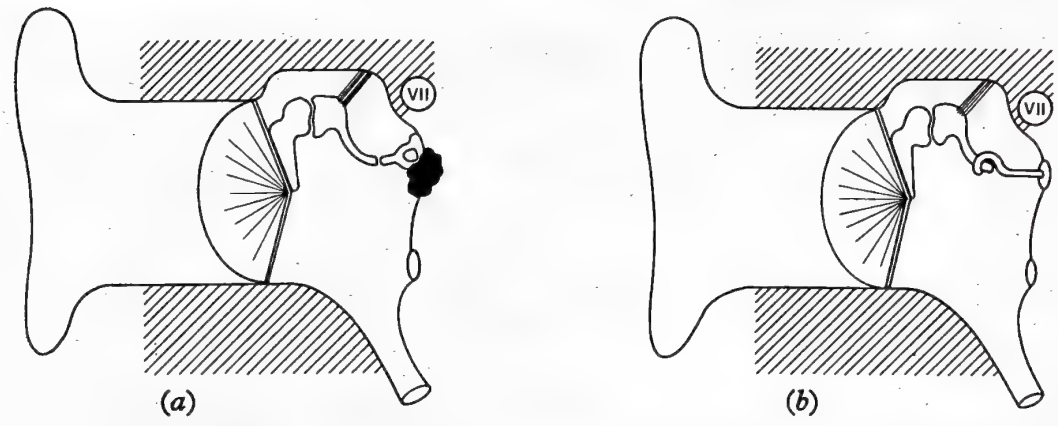

FIG. 573.—Stapedectomy. (*a*) Condition prior to removal of stapes and footplate. (*b*) After removal of stapes; sound conduction restored by a Teflon prosthesis.

Serous Otitis Media is a non-inflammatory effusion into the middle ear, the causes of which include blocked Eustachian tube (due to enlarged infected adenoids), inadequate antibiotic therapy for an acute ear infection, and allergy. The condition is becoming increasingly common, especially in children, when it is termed 'glue ear' due to the viscosity of the fluid. A conductive deafness is produced and occasionally pain. The drum is usually retracted with either a bluish or golden tinge depending on the consistency of the fluid in the middle ear. Treatment is to remove adenoids if present and perform a myringotomy. A 'grommet tube' can be inserted for continued drainage (fig. 574).

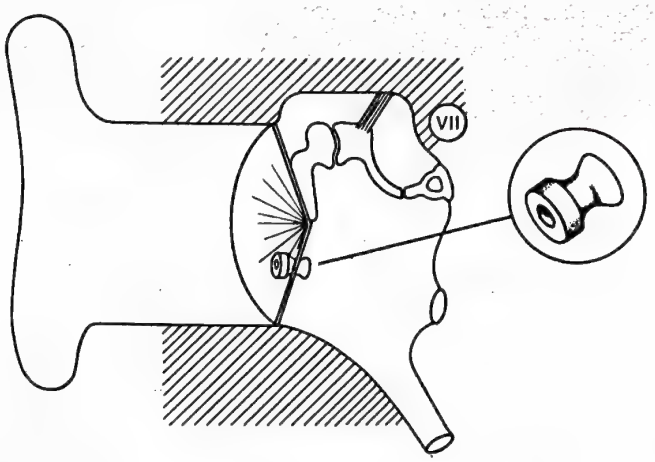

FIG. 574.—Grommet tube positioned in a anterior-inferior quadrant of drum.

Barotrauma due to sudden changes in atmospheric pressure (e.g. descent in flying or diving) may produce a similar picture. It is treated by decongestants and, if persistent, myringotomy and drainage.

Malignant Tumours. — Excluding the pinna (fig. 565), **squamous-celled carcinoma,** though uncommon, can arise in the middle ear or mastoid cells. There is pain and otorrhœa (which may be long-standing), becoming bloodstained. Deafness is variable. Biopsy will confirm. Treatment is by combined surgery and radiotherapy, but the prognosis is poor.

Glomus jugulare tumours are rare but of special interest as they resemble carotid body tumours (p. 581). Slow growing and locally invasive, they are highly vascular.

with nests of epithelioid cells and fibrous tissue. Early signs are seventh nerve palsy, pulsatile tinnitus, and free bleeding. Radiotherapy diminishes both size and vascularity. Cryosurgery is effective for small tumours.

THE INNER EAR

Presbyacusis[1].—High-tone bilateral perception deafness gradually affects lower tones with advancing years. It is often associated with atherosclerosis. Treatment is by a hearing aid.

Cochlear Concussion.—Hearing at 4,000 Hz is commonly affected, but if concussion is repeated daily (e.g. gunfire, road-driller, or aircraft pilot not using ear defender), the loss spreads up and down. Failure to hear the telephone bell is often the first symptom.

Menière's syndrome is unilateral perception deafness, intermittent true rotational vertigo associated with nausea, continuous tinnitus, and headache. It may be associated with hyper- or hypo-tension, intracranial lesions, syphilis, or disseminated sclerosis. But if all these are excluded, and labyrinthine function tests show loss of function on one side, it is true Menière's disease.

Treatment may be (*a*) medical—Tab. nicotinic acid 100 mg., t.d.s. (vasodilator), Avomine, Stemetil, or (*b*) surgical—1. Operations to reduce endolymphatic pressure by a surgical approach to the endolymphatic sac for drainage can prove satisfactory. Also relatively minor procedures such as ultra-sonic or cryosurgery applied to the labyrinth may indirectly produce a similar result.

2. Labyrinthine destruction. A labyrinthectomy may be indicated in cases where the hearing is severely impaired and the patient is getting vertigo symptoms not controlled by other means.

Eighth nerve tumour causes perception deafness (unilateral), tinnitus, vertigo, severe headache, pain in malar region, and loss of the corneal reflex. Advanced specialised diagnostic techniques (audiometric) are now used in conjunction with X-ray tomography to establish the diagnosis. A neurosurgeon can remove the tumour via a posterior fossa craniotomy (fig. 486), or by a translabyrinthine approach.

Congenital Deafness.—This is due to intrauterine viral toxins in the first three months of pregnancy (e.g. rubella, influenza, etc.).

[1]Presbys (Gr.) = old.

Prosper Menière, 1799–1862. Physician, Institute for the Deaf and Dumb, Paris. Described this condition in 1861.

CHAPTER 30

THE MOUTH, THE CHEEK, THE TONGUE

INFECTIONS

Stomatitis is a general term that embraces all forms of diffuse inflammation of the mouth.

The inflammation may be caused by an injury that is mechanical, thermal, chemical, or by radiotherapy. Secondary to this injury, or sometimes when no obvious injury can be detected, infection occurs.

In addition to these causes the mucosa is affected by malnutrition. It becomes atrophic, and although not strictly speaking an inflammation, is often described in such terms as stomatitis, angular stomatitis, glossitis, etc. The atrophic and mal-nourished mucosa less readily withstands trauma and infection. Such conditions are seen in the Vitamin B deficiencies, in sprue, in protein malnutrition (kwashiorkor[1]), in pernicious anæmia and in the iron deficiency anæmias.

The Infecting Organisms.—Numerous organisms may be found in the mouths of healthy persons and in disease. These can be divided into the following categories:

1. *True Saprophytes.*—These are not pathogenic, and are found in man's normal environment—in the air, in plants, in dust, etc., and arrive in his mouth as it were by accident and are never the cause of disease.
2. *True Pathogens.*—These cause human diseases.
3. *Facultative Pathogens.*—There are a very large number of organisms indigenous to man not found in his mineral or vegetable environment. They are transmitted from man to man, and may in some cases be found in animals. Such organisms often inhabit healthy mouths but may give rise to, or be found in, many human pathological lesions.

Quite clearly then, the varieties and variations of stomatitis are innumerable, but some of the more important conditions are described below.

Traumatic Stomatitis.—A simple cut or burn of the mouth usually heals rapidly. It is quickly covered by a thin grey glistening coagulum. Salivation is increased, but because the mouth is painful, movements are restricted and fur collects on the tongue. Because of the stagnation the breath becomes fœtid. In healthy persons no treatment is required, but frequent rinsing of the mouth with a saline mouth wash or glycerin of thymol may give some relief. A simple cut should be epithelialised within one week.

Traumatic lesions are commonly produced by too vigorous use of a hard toothbrush, by ill-fitting or unclean dentures, and by jagged teeth. The typical non-specific ulcer of the tongue is described on p. 550. Burns of the mouth are not uncommon in children, and they may be especially extensive in those children who put their mouths to the spouts of kettles or teapots in order to ' taste the steam '.

[1] The name means "the red boy" or "the disease the child gets when the next baby is born" in the Ga language of Ghana.

Aphthous[1] Stomatitis.—The three main varieties are as follows:

1. *Monilial stomatitis* (thrush) of infants occurs usually in the first few weeks of life, most often in maternity hospitals and crèches. It is due to *Candida albicans* (p. 31), a fungus found especially in pregnant women and nursing mothers. The disease appears as spots on the buccal mucous membrane. They are at first red and later become coloured with a white exudate composed of desquamated epithelial cells entangled in the mycelium. Pain and salivation are constant accompaniments. The condition subsides gradually without treatment, but the mouth should be kept clean by the use of glycerin of thymol applied on a swab stick. Nystatin is a specific anti-fungal antibiotic and should be used in the more severe cases. Precautions must be taken to ensure that the milk is fresh and that utensils in which it is served are scrupulously clean.

The condition is not entirely confined to infants, and is seen in debilitated patients, occasionally in those with leukæmia, and in the 'denture-sore' mouth. Diabetes may be brought to light in this way.

2. *A virus infection* causes another form of aphthous stomatitis in children which occurs usually below the age of six. The aphthæ or mouth ulcers are usually numerous, small, regular ulcers in a raised, furred, swollen area of mucosa, usually at the anterior part of the mouth. Treatment is merely to improve general oral hygiene with frequent mouth washes. The children usually recover in about ten to sixteen days.

3. *Recurrent aphthous ulceration* (fig. 575) is not uncommon in adults. (Mikulicz' aphthæ[2]). The lesions usually occur on the inner side of the lips and cheeks, and the under-surface of the tongue. These ulcers recur in different parts of the mouth over the course of many years. They are not contagious. There is a familial predisposition. They are twice as common in women as in men. In 50 per cent. of the female patients but only in 2 per cent of the male are concomitant lesions seen on the external genitalia (Sircus). The ulcers are usually single but may be multiple. Usually they are very painful but heal in between seven and fourteen days without a scar. The treatment is to keep the mouth clean, and if the ulcers are very painful an oral gel or paste containing choline salicylate may be helpful. A culture should be taken from the mouth, and if this shows a preponderance of a pathogenic organism, the appropriate antibiotic may be given.

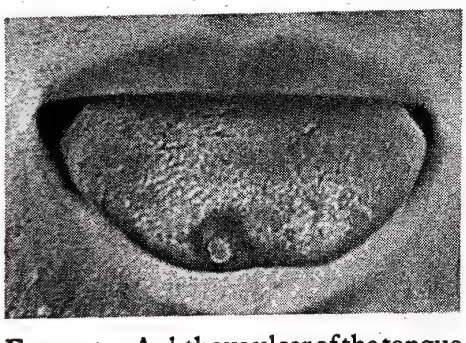

FIG. 575.—Aphthous ulcer of the tongue.

Vincent's angina (*syn.* ulcero-membranous stomatitis or acute ulcerative gingivitis) is another form of stomatitis:—

Ætiology.—*Borrelia vincenti* is an anaerobic spirochaete with three to five loose spirals. Seen in a wet smear by dark-ground illumination it is actively motile.

[1] Aphthous—Greek, ἄφθαι = mouth ulcers.

[2] Known in the U.S.A. as canker sores, and in Dutch-speaking medical circles as sprouw, because it is the first arresting symptom in tropical sprue.

Johann von Mikulicz-Radecki, 1850–1905. Professor of Surgery, Breslau, Germany (now Wroclaw, Poland).
Wilfred Sircus, Contemporary. Physician, Western General Hospital, Edinburgh.
Jean Hyacinthe Vincent, 1862–1950. Professor of Epidemiology, Val-de-Grâce Military Hospital, Paris.

Fusiformis fusiformis is a Gram negative anaerobic, spindle-shaped rod. Both these organisms may be found in normal mouths but are present in large numbers in association with lesions of Vincent's stomatitis. Whether they are the cause of the disease or secondary invaders is debatable. This disease is not communicable. (Findings of the Research Commission of the American Dental Association.)

Clinical Features.—The disease is one of early adult life; rarely does it occur after the age of thirty-five years, and almost never in the edentulous. In acute cases the prodromal symptoms are general malaise, pyrexia, and increased salivation. About thirty-six hours after the onset the patient complains of dull, generalised toothache, and notices that the gums are bleeding. On examination there is overpowering fœtor. The gums, especially the interdental papillæ of the incisors and around the third molars, are red and inflamed, and later covered by yellowish-white pseudo-membrane. If a portion of this membrane is peeled away and the gum wiped free from blood, small ulcers are revealed. Untreated, the ulceration often spreads to the cheeks, palate, fauces, and pharynx, but rarely to the tongue. The regional lymph nodes become enlarged and tender. When the fauces are involved, the condition must be distinguished from diphtheria and secondary syphilis. In subacute and chronic varieties the gingivæ are dark red and swollen, and there is gradual destruction of periodontal tissue with pus-pocket formation.

Treatment.—The mouth should be cleansed with mouth washes and the pseudo-membrane on the surface and the cellular debris between the teeth swabbed away with pledgets of cotton wool soaked in hydrogen peroxide. Penicillin should be given systemically. When the acute attack has subsided, dental treatment for the chronic disease of the periodontal tissues and carious teeth will be required.

Acute Pyogenic Stomatitis.—Acute stomatitis can be caused by staphylococcal, streptococcal, or gonococcal infections. A certain diagnosis can only be made by bacteriological examination. Treatment consists of systemic antibiotic therapy and local mouth washes.

THE ORAL MUCOSA AND NUTRITION

The mucosa of the tongue undergoes atrophy in a great variety of nutritional deficiencies. The atrophic process may also affect other parts of the alimentary tract lower down. The variations in the pattern of this atrophy are very great. In some the condition can be rapidly reversed by treatment; some respond slowly and some not at all. The thinning of the mucosa makes the mouth more susceptive to trauma, and hot drinks and spices may be so painful that they cannot be tolerated by the patient.

Vitamin B *Riboflavine* deficiency gives rise to a diffuse atrophy of the lingual papillæ and is accompanied by a slight magenta tint to the redness of the tongue. On giving Vitamin B_2 improvement takes place in a few weeks. This condition is hardly ever seen in its pure form.

Nicotinic acid (the pellagra-preventing vitamin). Pellagra means a rough skin. Disease occurs in areas with a deficient diet, largely consisting of maize. In the acute stages the mouth is painful and becomes fiery red. Salivation is profuse and the epithelium of the tongue desquamates over wide areas. The skin as a whole becomes thick and irregular and patchy desquamation may occur, leaving unpigmented areas. This is a dangerous condition, but, if diagnosed, is rapidly cured by giving nicotinic acid or nicotinamide.

Vitamin C deficiency (scurvy) was rife in the days of the sailing ships. It was eradicated in the Royal Navy[1] by a compulsory ration of lime juice. Leading features of the stomatitis due to this cause are bleeding gums and loosening of the teeth. (For scurvy-rickets, p. 288.)

Iron-deficiency anaemia of long standing, especially in women about the menopause, may be accompanied by a smooth tongue and, if the pharyngeal mucosa is also affected, by dysphagia (Paterson-Kelly, or Plummer-Vinson syndrome, p. 772). The

[1] Lind urged the use of lime juice, and it was due to him that scurvy was eventually eradicated from the Royal Navy. British sailors are known abroad as 'limeys'.

Hans Christian Joachim Gram, 1853–1938. Professor of Medicine, Copenhagen.
James Lind, 1716–1794. Surgeon's Mate, Royal Navy; later Physician (civilian), Royal Naval Hospital, Haslar, Gosport, England. He is buried in the church of Portchester Castle.

condition may be held in check and slowly relieved by the prolonged administration of iron. If left untreated, carcinoma of the hypopharynx or of the mouth is liable to develop.

Pernicious anaemia also produces a smooth tongue, but less often dysphagia. Vitamin B_{12} sometimes partially restores the buccal mucosa but not the lack of gastric secretion.

Tropical sprue, the malabsorption syndromes and post-gastrectomy malnutrition all give rise to a similar condition. If adequately treated, some recovery is probable.

Angular Stomatitis (*syn.* Cheilosis) (fig. 576).—Although cracks at the corner of the mouth were a recognised manifestation of congenital or tertiary syphilis, they are now much more likely to be due to other causes.

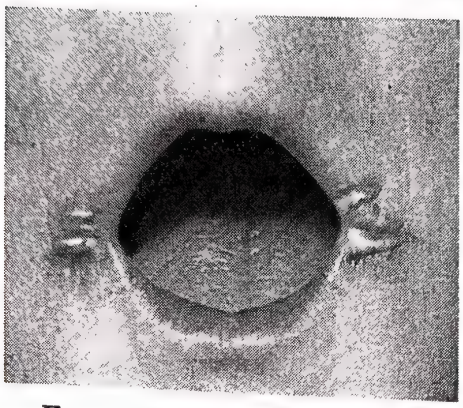

FIG. 576.—Angular stomatitis.
(*Professor Charles Wells, Liverpool.*)

(*a*) *Perlèche*[1] is a superficial ulceration limited to the angles of the mouth. It appears in children of school age and is of interest chiefly because it has to be distinguished from syphilis. The corners of the mouth become somewhat brown in colour, and often moist fissures make their appearance. There is a burning sensation, and the patient licks the patches frequently, hence the name. They will become secondarily infected by such organisms as streptococci and *Candida albicans*. The lesions usually heal without scarring. Treatment consists in improving general hygiene and in making sure that the diet is adequate.

(*b*) *Overclosure* is the commonest cause of angular stomatitis in older patients. It can be seen in its most marked form in the 'dentureless edentulous' people. The condition is aggravated if the oral mucosa is atrophied or if there is a tendency to seborrhœic dermatitis. These patients should be referred to a dental surgeon for correction of the overclosure.

Stomatitis due to Drugs.—Excessive doses of bismuth, lead, iodides, and especially mercury give rise to stomatitis, and gingivitis, accompanied by profuse salivation and loosening of the teeth.

Foot and Mouth Disease.—Occasionally this well known disease of cattle is transmitted to man by direct contact or through infected milk. The causative organism is a virus present in the fluid of the vesicles. The incubation period is from two to five days. In man, the constitutional symptoms are usually of moderate severity. The buccal mucosa becomes congested and swollen, and two or three days later vesicles appear on the lips, tongue, cheek and, pharyngeal wall. Later the vesicles rupture, leaving tender, reddish, shallow ulcers, which soon heal. Similar lesions on the hands and feet, particularly round the nails, are usual. The attack confers no lasting immunity. Treatment consists of maintaining satisfactory oral cleanliness with bland mouth washes.

Cancrum Oris.—This condition is now seldom seen except as a complication of serious diseases such as the blood dyscrasias or in the undernourished. There is rapid swelling of the affected area, which is rendered ischæmic and eventually gangrenous. Large areas of lips, cheeks, or jaw may be destroyed. Toxæmia is always severe, and unless treatment with antibiotics is begun early the patient usually dies.

[1] Perlèche—French, *se pourlécher* = to lick one's lips.

CYSTS IN THE MOUTH

Retention cyst of a buccal mucous gland (fig. 577) occurs in any part of the mucous surface of the mouth. It forms a translucent globular swelling which should be excised under local anaesthesia.

FIG. 577.—Retention cyst of a buccal mucous gland.

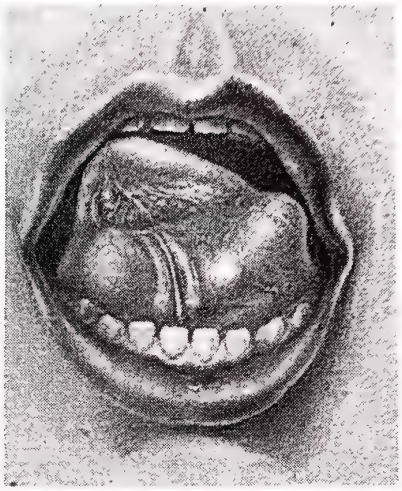

FIG. 578.—A large ranula.

A ranula[1] implies a *transparent* cystic swelling in the floor of the mouth, mainly, unilateral (fig. 578).

Simple Ranula.—The patient may state that the swelling has appeared before and burst, perhaps several times. Before concluding the examination the possibility of a deep prolongation of the cyst must be excluded by palpating beneath the mandible. The diagnosis of simple ranula is, as Butlin remarked, " plainly written on the face of the tumour ".

Treatment.—*Complete Excision.*—A difficulty hindering ideal treatment is that the cyst bursts before dissection can be completed. If some of the fluid within the cyst can be aspirated before commencing enucleation, complete dissection is usually possible. Often, however, the contents are of the consistency of jelly, and will not flow through a hollow needle.

Partial Excision with Marsupialisation.—A considerable portion of the cyst wall, together with its superimposed mucous membrane, is excised. The cut edge of the cyst wall is then united by sutures to the cut edge of the mucous membrane ; thus the cavity becomes part of the floor of the mouth.

Whichever method is practised, it is necessary to preserve the integrity of Wharton's duct.

Deep or plunging ranula, from the mouth, appears to be a typical ranula, but when the neck is examined a cervical prolongation is found continuous with the intrabuccal one. Possibly these cysts are derived from the cervical sinus—an embryological structure. In any case, this hypothesis furnishes a logical basis for adequate surgery; this type of ranula must be approached through the neck. Complete destruction of the wall of the sac is essential.

Sublingual Dermoid.—Although congenital, sublingual dermoids are seldom noticed below the age of ten years ; usually the patient seeks

[1] So named because of the likeness of the swelling to the belly of a little frog (Latin, *ranula*, diminutive of *rana* = a frog.)

Sir Henry Trentham Butlin, 1845–1912. Surgeon, St. Bartholomew's Hospital, London.
Thomas Wharton, 1614–1673. Physician, St. Thomas's Hospital, London.

advice between the ages of thirteen and twenty-five. These swellings are divided into two varieties, median and lateral. Each is again subdivided into those situated above and those situated below the diaphragm of the mouth (the mylohyoid muscles). All are thin-walled cysts filled with sebaceous material, and, unlike other dermoid cysts, never contain hair.

FIG. 579.—Large median sublingual dermoid.

Median variety, which is probably derived from inclusion of ectoderm between the halves of the developing mandible. *When situated above the mylohyoid,* the cyst often attains considerable dimensions (fig. 579) with, apparently, but little inconvenience. *When situated below the mylohyoid,* the patient, if a female, often seeks advice because of a double chin. In this situation considerable care must be exercised in making a diagnosis, for it is not possible to rule out with certainty a suprahyoid thyroglossal cyst. An ectopic thyroid must also be taken into consideration.

Lateral variety, which is somewhat less common than the median variety, is derived from the second branchial cleft. *When situated above the mylohyoid* (fig. 580), there is an opaque swelling in the floor of the mouth to one side of the middle line as opposed to a transparent one (a ranula). *When situated below the mylohyoid,* a cystic swelling in the region of the submandibular salivary gland is present. Both these varieties are rare.

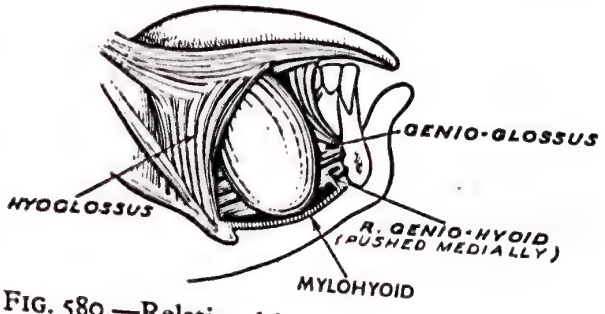

FIG. 580.—Relationships of a lateral sublingual dermoid situated above the mylohyoid.

Treatment of both varieties is removal by dissection through an external incision beneath the mandible.

TUMOURS OF THE CHEEK AND THE FLOOR OF THE MOUTH

Papilloma.—A true papilloma is uncommon. It is soft and fleshy. It should be removed with an adequate margin of tissue. There is a remote chance of malignancy.

Fibro-epithelial polypi are firmer and usually arise after repeated trauma to the inner side of the cheek. They have a dense core of fibrous tissue (fig. 581).

FIG. 581.—Fibro-epithelial polypus of the mucosa of the cheek.

Lipomas can arise in any part of the fatty supporting structures of the mouth.

Hæmangioma sometimes occurs under the mucous membrane of the cheek and the floor of the mouth.

Mixed Salivary Tumours may arise from any of the salivary glands in the mouth and occasionally in ectopic tissue.

Adenitis of the Facial Lymph Node.—A few individuals possess a facial lymph node (which lies on the mandible in relation to the facial artery); consequently infection coursing along the lymphatics of the cheek usually passes direct to the submandibular nodes. When a facial lymph node is present its enlargement will perplex the diagnostician unaware of its existence.

Carcinoma can arise in any part of the mucous lining of the mouth. In Western races, although carcinoma of the mucous membrane of the cheek is not a rarity, it is less common than carcinoma of the tongue or that of the floor of the mouth. In those Eastern races who indulge in chewing the betel-nut[1] and store the quid thereof in their cheek, carcinoma of the mucous aspect of the cheek is a common occurrence.

Treatment of Carcinoma of the Cheek.—The indications for irradiation do not differ from those of carcinoma of the tongue (p. 551). In environments where irradiation is not readily available, excision of the buccal aspect of the cheek is performed. The resulting defect may be made good by reflecting a flap of skin from over the temporal region and turning it down through a suitable opening into the mouth, so that the buccal aspect is now lined with skin. The donor area in the temporal region is made good with a split skin graft.

THE TONGUE

Tongue-tie.—Although tongue-tie is really a very rare condition, nearly every mother fears that her first-born is tongue-tied (fig. 582). A former generation of surgeons must have agreed with the mothers; for witness, the grooved director (fig. 583) is even today fitted with a guard for use when dividing the frænum linguæ. This shield is held against the uplifted tongue and the frænum is snipped near the floor of the mouth, the better to avoid the frænal artery and veins. The operation is rarely indicated, as a short frænum has little or no effect on speech or on eating. Its division, especially if done too drastically and followed by sepsis, may lead to fibrosis which might then, in fact, anchor the tongue.

FIG. 582.—Short frænum linguæ.

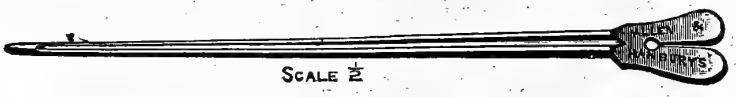

FIG. 583.—Director with guard and frænum slit.

Macroglossia

While acute parenchymatous inflammation results in very great enlargement of the tongue (p. 546) the term macroglossia should be reserved for cases of chronic painless enlargement of the organ.

Lymphangioma.—When noticed soon after birth usually there is only a small circumscribed patch of dilated lymph vesicles. Occasionally the lesion remains stationary in size for long periods; more often it increases rapidly. Attacks of inflammation occur at irregular intervals. At last the swollen tongue protrudes permanently from the mouth—lymphangiomatous macroglossia. Treatment is by excision or irradiation.

Hæmangioma, when widespread, can result in great enlargement of the tongue. Occasionally congenital fistula between the lingual artery and vein gives rise to an enormous protruding tongue that sometimes pulsates. Partial excision or, in the case of an arterio-venous fistula, ligation of both lingual arteries, followed by partial glossectomy, is the treatment, but it often does not control the progressive enlargement.

---

[1] This Indian masticatory is a very hard woody nut; the shavings have sharp spicules. A mass of this is rolled in a pepper leaf with lime and catechu.

Neurofibroma is on rare occasions the cause of macroglossia, which is sometimes confined to one half of the tongue. Usually other manifestations of von Recklinghausen's disease of nerves (p. 52) are present.

Muscular macroglossia is practically confined to idiots and cretins (p. 590). The large tongue protrudes from the mouth and is liable to become dry and cracked. It is bitten constantly, and if the patient has attained the age of three years, the protruding portion should be excised.

Primary Mesodermal Amyloidosis.—Attention is sometimes drawn to this disease by the macroglossia which it produces.

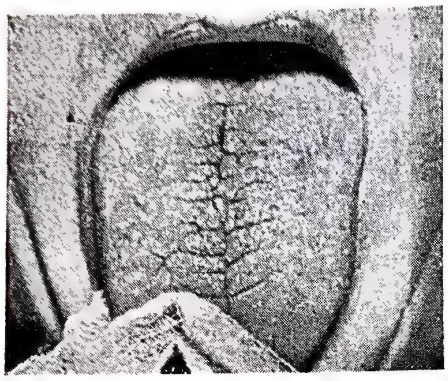

FIG. 584.—Congenital fissured tongue. Note the transverse direction of the fissures.

Congenital Fissured Tongue (*syn.* Congenital Furrowing)

When a patient presents a fissured tongue, it used to be assumed that he or she is suffering from hereditary or acquired syphilis. Fissures, even deep fissures, are usually due to congenital furrowing. John Thomson, after a study of a large number of cases, showed that the furrowing of the tongue was not present at birth, but was acquired in early childhood. In congenital fissured tongue the fissures are mainly *transverse* (fig. 584), covered with sensitive thin epithelium, whereas in syphilitic fissured tongue they are inclined to be longitudinal.

Traumatic Lesions

Injuries.—Anæsthetists are familiar with the possibility of the unconscious patient biting his tongue, and so commonly does this accident occur in epileptics that attendants are provided with rubber gags to put between the patient's teeth when a seizure is imminent. The most common deep wound of the tongue follows a blow or a fall while the patient is smoking a pipe, which breaks and is driven into the musculature of the tongue.

As a means of checking severe hæmorrhage from the posterior part of the tongue, Heath recommended passing the finger as far back as possible and hooking the tongue forward on to the jaw, and so applying pressure on the wound.

Sutured wounds of the tongue heal readily with simple mouth-washes, and an almost completely divided segment, if sutured into position, will often remain viable and unite.

Extravasation of blood into the tongue, floor of the mouth, and the adjacent fascial spaces, is a relatively common manifestation of hæmophilia (p. 76). As a rule the hæmorrhage occurs spontaneously. If facilities for endotracheal intubation are not available, immediate tracheostomy is required.

INFLAMMATIONS OF THE TONGUE

Acute superficial glossitis may follow scalds other or injuries. Under this heading is included *herpes of the tongue*, which is unilateral and painful. Healing occurs rapidly under treatment by bland mouth-washes (see stomatitis, p. 539).

Acute Parenchymatous Glossitis.—In well-marked cases the tongue swells enormously, protrudes from the mouth, and threatens life by asphyxiation. The patient often becomes extremely toxic. The condition, which is rare, arises in a number of different ways:

1. Classically, a wasp inserts its sting into the tongue of a holiday-maker who is drinking beer from a bottle which has been left open. Adrenalin (1 ml. of 1:1000 soln) should be given and ice to suck. In severe allergic cases tracheostomy may be necessary in order to relieve œdema of the glottis.
2. From pyogenic infection of a deep lingual wound.
3. As a complication of Ludwig's angina (p. 578).

John Thomson, 1856–1926. Physician, Royal Hospital for Sick Children, Edinburgh.
Christopher Heath, 1835–1905. Professor of Surgery, University College Hospital, London.

It is necessary to be prepared for tracheostomy, which, however, in cases of bacterial infection, is seldom required if the patient is treated as follows : Ice is applied to the tongue, oxygen inhaled as required through a Hewitt's air way if necessary. An antibiotic, usually penicillin, is administered, and the patient is reassured.

Furring of the tongue.—Furring of the tongue is produced by:

(1) Accumulation of food debris between the filiform papillæ of the tongue;

(2) The desquamating cells are not removed by the normal movements of the tongue.

(3) Overgrowth of the normal bacterial flora of the mouth.

In an acutely ill person with malaise and anorexia, such as a patient with peritonitis, the normal movements of the tongue are reduced and the products mentioned above accumulate and produce a fur.

In people who are up and about and eating normally, no fur forms unless the epithelium is constantly irritated by tobacco smoke. In a fit person a furred tongue usually means an excessive smoker. In such individuals, if the fur is thick it is often black or brown in colour. In the atrophic tongue with no filiform papillæ, a fur cannot form.

Black Hairy Tongue is due to a hyperkeratosis of the mucous membrane and tends to occur in heavy smokers. A fungus, *Aspergillus niger*, may be found. It may respond to daily brushing by a toothbrush dipped in a solution of 40 per cent. urea in water.

Median Rhomboid Glossitis (Glossitis Rhombica Mediana). This is a developmental abnormality of the tongue. In it a reddish patch, found in the midline immediately in front of the circumvallate papillæ, is probably due to inadequate covering of the tuberculum impar in the formation of the anterior part of the tongue. The condition requires no treatment, but it is occasionally mistaken for squamous carcinoma of the dorsum of the tongue or a syphilitic ' wart ' (p. 549).

Chronic Superficial Glossitis and Leukoplakia

Tradition has it that the six leading ætiological factors are *S*moking, *S*yphilis, *S*epsis, *S*harp edge of a tooth, *S*pirits, and *S*pices, to which one might add *S*usceptibility to explain why the condition sometimes occurs without any obvious cause.

The essential process in leukoplakia is a slowly progressive hyperkeratosis. The milder changes are widespread, but as the condition gets worse the more severe stages are found in smaller and smaller patches within the widespread areas.

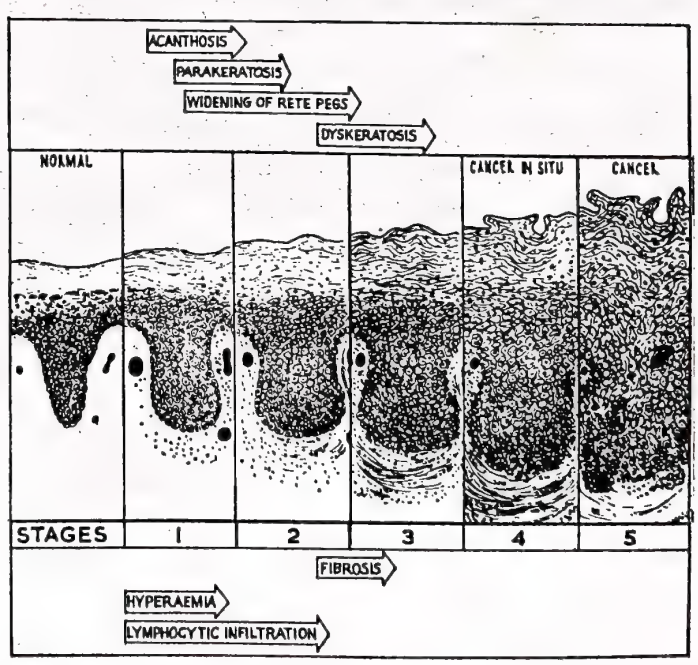

FIG. 585.—Diagram of the histological stages of leukoplakia leading to carcinoma.

Clinical Features.—Five stages are recognisable. These correspond approximately with the stages shown in fig. 585 which is a diagram of the histological stages of leukoplakia leading to carcinoma.

Stage 1.—There is a mild thickening of the surface producing a *thin milky film* usually over a widespread area of the mouth; within this area where the hyperkeratosis has progressed we see:

Sir Frederic William Hewitt, 1857–1916. Anæsthetist, St. George's Hospital, London.

Stage 2. — Here the mucosa looks as if it is covered with areas of *smooth paint.*

Stage 3.—As the surface thickens still further it becomes irregular like *wrinkled paint.*

Stage 4. — Little *warty projections* appear—this is the stage of 'cancer in situ'.

The instability of the abnormal mucosa allows another phenomenon to be superimposed on this pattern—desquamation. The surface is shed and leaves *red glazed patches* of smooth mucosa. These raw looking patches are more likely to occur in women especially if they suffer from iron deficiency and already have a thin mucosa.

Microscopically the essential changes seem to be 1. A more rapid multiplication of epidermal cells than normal. 2. Chronic inflammatory changes in the dermis. In the epidermis the change is an acanthosis (*ἄκανθα* thorn or prickle) which is a proliferation of the prickle cell layer. This produces a widening of the downward projections of epidermis called the rete pegs. The cells are still not mature when they reach the superficial layer and retain their nuclei—(parakeratosis). As the disorganisation of the epidermis becomes greater it is called dyskeratosis and although at this stage there is no infiltration eventually it resembles the appearances of cancer, and epithelial 'pearls' may be seen in the epidermis—intra-epidermal cancer or cancer *in situ.* These changes are shown diagrammatically in fig. 585.

Distribution.—If there is a local cause such as a jagged tooth or the habit of holding a pipe always in the same place, the leukoplakia may be localised to that one area, but in some cases the disease is diffuse and affects the whole lining of the mouth.

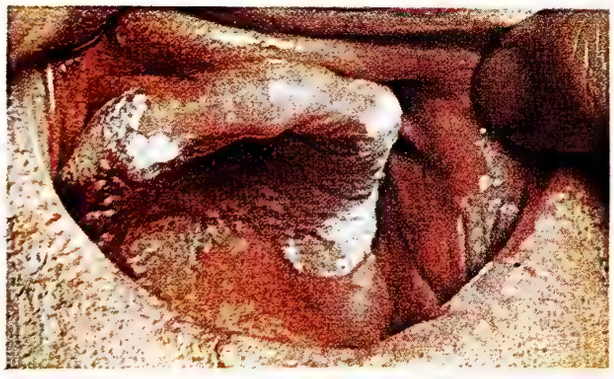

FIG. 586.—Leukoplakia on the palate and cheeks of an edentulous patient. This patient had had three carcinomas 'in situ' removed from his tongue.

Symptoms are few, and apart from some soreness in the bare red patches of desquamation, the main complaints are of the peculiar look of the tongue and of difficulty with dentures.

Treatment. — Leukoplakia may be pre-malignant, and although the severity of the condition is often suggested by the clinical appearance, early *biopsy* to confirm the diagnosis and to indicate any epithelial dysplasia is necessary. In particular, an indurated white patch appearing in the adult mouth should be biopsied at once, since squamous carcinoma may present in this way.

Small patches of leukoplakia may be removed. When the affected area is larger than can be excised and the diagnosis has been confirmed histologically, the patient should be examined at intervals of not longer than three months. Any areas of 'warty excrescence' or any doubtful area which appears, must be removed and examined histologically.

Radiotherapy will improve the appearance of the condition but probably

increase the likelihood of malignant disease, and this, if it occurs, will then probably be resistant to further radiotherapy.

Primary Syphilis of the tongue.—An extra-genital chancre can occur on the tongue. The submaxillary and submental lymph nodes become greatly enlarged, as in the case of a similar lesion on the lip.

Secondary Syphilis.—1. *Multiple shallow* (*'snail track'*) *ulcers* may be present on the sides and under-surface of the tongue. 2. *Mucous patches* occur on the tongue as well as on the fauces. 3. *Hutchinson's wart*, really a condyloma, is a strictly median 'wart' (fig. 587) and has to be distinguished from a papilloma which happens to occupy the middle line and Median Rhomboid Glossitis (p. 547).

Tertiary Syphilis.—1. *Gumma of the tongue* which is extremely rare in England nearly always occupies the middle line. It possesses the characteristics of gummata elsewhere and does not tether the tongue (fig. 65). The frequency of chronic superficial glossitis in syphilitic patients has been noted already.

FIG. 587.—Hutchinson's wart. Wassermann reaction strongly positive.

Lingual Tuberculosis.—At the present time secondary lingual tuberculous ulcers are encountered only in persons with established but *undiagnosed* pulmonary tuberculosis. Typical tuberculous ulcers of the tongue are shallow, often multiple, ovoid and greyish-yellow, with a slightly reddened margin. When the ulcer or ulcers are situated on a mobile portion of the tongue, they are so painful as to require amethocaine lozenges for their relief.

Geographical tongue (*syn.* glossitis areata exfoliata, glossitis migrans).

This condition is seen most commonly in patients who have a severe abdominal condition such as peritonitis and who are being treated by broad spectrum antibiotics, gastric suction and continuous intravenous feeding. It possibly indicates that the patient's power to regenerate his alimentary epithelium as a whole is deranged.

The tongue is at first heavily furred. Then, on about the third or fourth day of the illness, when the patient is still very ill and feverish, the tongue becomes a little sore,

FIG. 588.—March 5th. FIG. 589.—March 7th. FIG. 590.—March 9th. FIG. 591.—March 12th, patient making satisfactory recovery.

FIGS. 588–591.—Glossitis migrans—this patient had a partial gastrectomy on March 1st, followed by paralytic ileus and pulmonary collapse which was treated by tetracycline.

and large areas rapidly desquamate in an irregular circinate pattern. The areas change from day to day (figs. 588 to 591). No causative organism is known to produce the condition, but there is always a change in the flora of the mouth and *Candida albicans* is almost always present in abundance.

No local treatment is indicated. As the patient's general condition improves, the tongue returns to normal.

Sir Jonathan Hutchinson, 1828–1913. Surgeon, The London Hospital.
August von Wassermann, 1866–1925. Director of the Kaiser Wilhelm Institute for Experimental Therapeutics, Berlin.

Ulcers of the Tongue

It is advisable at this stage to review briefly the more common types of ulcers of the tongue, as their differential diagnosis is so important in clinical surgery.

Dental ulcers always occur at the side of the tongue and are due to the laceration of the mucosa by a sharp tooth or sharp clasp of a denture. They are therefore longitudinal scratches that have become infected. The cause should be removed.

Post-pertussis ulcer is seen at the frænun linguæ only in whooping-cough.

Chronic non-specific ulcer is usually situated on the forepart of the tongue. There is no history or obvious cause to attribute the lesion to trauma. The Wassermann reaction is negative. There is no evidence of tuberculosis.

Local excision should be carried out in order to confirm the diagnosis, as well as to cure the condition.

Aphthous ulcer (p. 540).

Specific.—**Syphilitic Ulcer** (p. 61).

Tuberculous ulcers (p. 549).

Malignant.—**Carcinomatous ulcer** (p. 551) has the clinical features of a squamous-celled carcinoma—viz. an everted edge and an indurated base.

If doubt exists as to the nature of an ulcer—and it is sometimes difficult to be certain when dealing with cases of early carcinoma—the ulcer should be excised under local anæsthesia and submitted to histological examination. In this instance a Wassermann reaction is a hindrance rather than a help in establishing the diagnosis, for even at the present time it is not unusual for a patient with carcinoma of the tongue to have had syphilis.

Nerve Lesions of the Tongue

Lingual neuralgia can occur idiopathically, or be due to the lingual nerve being implicated in scar tissue or neoplastic infiltration. A not infrequent cause is as an aftermath of lingual herpes. In persistent cases section of the chorda tympani nerve brings relief. The chorda tympani contains not only gustatory and secretory fibres, but also sensory fibres.

Glossodynia, or burning tongue, is a troublesome condition: In many cases, especially in women over forty years of age, nothing amiss with the tongue can be discovered.

Hemiatrophy of the Tongue.—In so far as the tongue, the floor of the mouth, and the submaxillary region are concerned, hemiatrophy of the tongue is the result of damage to the hypoglossal nerve. This causes paralysis of the musculature of the tongue, so that on protrusion the tongue deviates to the affected side.

BENIGN NEOPLASMS

Benign neoplasms of the tongue are comparatively rare: they are overshadowed by the frequency of carcinoma of this organ. The following, in order of frequency, occur from time to time:

Papilloma is the most common benign tumour of the tongue. It can be sessile or pedunculated, and must be distinguished from a Hutchinson's wart (fig. 587). It should be excised, together with a small wedge of normal tissue about its base and subjected to histological examination.

Angioma in this situation is usually venous. The veins which form the tumour are liable to become wounded and bleed. Such hæmorrhage may be so persistent as to render the patient severely anæmic.

The treatment is excision of the tumour.

The 'Caviare' Lesion of the Under-surface of the Tongue.—On asking the patient to put the tip of the tongue on the palate, so as to display the under-surface of the tongue, it is not uncommon in ageing persons to see a cluster of small varicose veins beneath the transparent, shiny mucous membrane. When pronounced, these blue-black clusters resemble sturgeon's eggs—hence the name. They are not neoplastic.

Lingual thyroid (p. 615).

Lymphangioma (Macroglossia, p. 545).

Plexiform neuroma, Neurofibroma (Macroglossia, p. 546).

FIG. 592.—A large pedunculated lipoma of the tongue which the patient seemed to be able to accommodate within the mouth.

A lipoma of the tongue is never very large, because the patient is continually conscious of its presence, and seeks advice early, but not always! (fig. 592).

Osteoma of the tongue is a clinical curiosity. A hard swelling is discovered in the posterior third of the tongue. Most of the osteomas reported have been centred beneath the foramen cæcum. The bone arises from a remnant of a branchial arch.

CARCINOMA OF THE TONGUE

Since 1910 there has been a decreasing incidence of carcinoma of the tongue *in males*. The more efficient treatment of syphilis, the passing of the clay pipe, the price of tobacco, the welcome activity of our dental colleagues, and possibly the decrease in the consumption of spirituous liquors are the chief reasons for this decline.

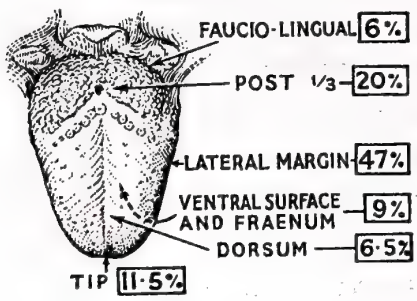

FIG. 593.—Relative frequency of the seat of carcinoma of the tongue. (*Birmingham United Hospitals' Statistics.*)

While the reduction in the incidence of carcinoma of the tongue in males is gratifying, it is perhaps all the more disconcerting to learn that there has been an increase in the number of female sufferers (Russell). The sex incidence is now equal.

Clinical Features.—As in carcinoma in other situations, in its early stages carcinoma of the tongue is virtually symptomless. The most frequent locations are the lateral margins of the anterior two-thirds of the tongue (fig. 593). If the patient is observant and fastidious, he or she seeks advice because of the actual lesion on the tongue, such as:

1. A small warty outgrowth, 2. An ulcer (fig. 594), 3. A fissure, or 4. An indurated mass.

Marion H. Russell, 1907–1966. Medical Statistician, Christie Hospital, Manchester, England.

FIG. 594.—Carcinomatous ulcer of the tongue. (*Denis Bodenham, F.R.C.S., Bristol.*)

It is a sad fact that a large number of patients fail to notice or else disregard the lesion in its early stages; consequently the average lapse of time between the onset of symptoms and seeking relief is five months, the patient reporting only because of one or more of the later symptoms, which are:

(*a*) *Pain* is experienced either in the tongue, or it is referred to the ear. The latter is not unusual, and many a patient with carcinoma of the tongue presents with a wad of cotton-wool in his ear, complaining solely of earache. The explanation of this phenomenon is that the lingual nerve is involved and the pain is referred to another branch of the third division of the fifth cranial nerve, the auriculo-temporal nerve.

(*b*) *Salivation.*—Profuse salivary secretion is common in lingual carcinoma. If an elderly man, sitting in the surgical out-patient department, is seen to spit repeatedly into his handkerchief, it is highly probable that he has a carcinoma of the tongue. In late stages the saliva is blood-stained.

(*c*) *Ankyloglossia.*—The tongue cannot protrude fully and deviates to the affected side. This bespeaks extensive carcinomatous infiltration of the lingual musculature or the floor of the mouth.

(*d*) *Dysphagia.*—The patient experiences difficulty in swallowing. This symptom is more pronounced when the growth is in the posterior third of the tongue.

(*e*) *Inability to Articulate Clearly.*—Factors (*a*), (*b*) and (*c*) may all play a part.

(*f*) *Fœtor.*—The patient becomes offensive to his associates because of the secondary bacterial stomatitis.

(*g*) *A lump in the neck*, due to secondary deposits in the cervical lymph nodes.

A growth situated at the very back of the tongue often escapes the notice of an intelligent patient and even of his medical adviser. *Early alteration of the voice* is often a feature of these cases. Palpation of the posterior part of the tongue and laryngoscopic examination are cardinal methods in detecting aneoplasm in this situation. Because the diagnosis of a growth in this secluded area is late, its average diameter is greater and the incidence of palpable cervical lymph nodes is higher than when a carcinoma is situated in other parts of the tongue.

Spread of the Disease.—(1) **Local.**—*Carcinoma of the anterior two-thirds of the tongue*, which usually starts on the lateral margin, invades the floor of the mouth early but seldom extends across in the midline. *Carcinoma of the posterior third of the tongue* tends to spread to the corresponding tonsil, the epiglottis, and the soft palate.

(2) **Lymphatic.**—It is important to realise that in 50 per cent. of individuals the lymphatic vessels draining the anterior two-thirds of the tongue and the floor of the mouth traverse the periosteum of the mandible on the way to the submental and submandibular lymph nodes. Long before

carcinoma-bearing cervical lymph nodes are palpable, careful microscopical scrutiny reveals that some of them are implicated. Because of their secluded position and consequent late diagnosis, growths of the posterior part of the tongue show the highest incidence of cervical metastases.

(3) **By the Blood-stream.**—Metastasis by this route is exceptional; indeed it occurs in only 2 per cent. of patients, and in these the neoplasm is situated in the extreme posterior part of the tongue in almost every instance.

Terminal Events.—Unsuccessfully treated, the disease runs a variable, but inevitably fatal, course. Death occurs usually in one of the following ways:

1. *Inhalation bronchopneumonia*, from the superadded oral sepsis.
2. *Combined cancerous cachexia and starvation.*
3. *Hæmorrhage*, from the primary growth, or on account of involved lymph nodes ulcerating and eroding an artery.
4. *Asphyxia*, which is due either to secondary carcinomatous cervical lymph nodes pressing upon the air passages or to œdema of the glottis. The latter is rare, and is due to an extension of lymphatic œdema around a growth at the back of the tongue.

Treatment.—Surgery or radiotherapy may be used.

Preliminary measures must first be taken to make the mouth as clean as possible. (*a*) A culture of the ulcer is taken to determine the predominant organism and the most suitable antibiotic to use. (*b*) The mouth is cleaned by frequent antiseptic mouth washes. (*c*) Dental treatment for carious teeth or gingival sepsis is carried out. (*d*) If the Wassermann reaction is positive, anti-syphilitic treatment is obligatory.

Surgery.—(*a*) *If the lesion is small*, under 1 cm. in diameter, or if it is one of the doubtful excrescences like a 'fragment of cauliflower', excisional biopsy is required—a wide margin of mucosa not less than 1 cm. being removed around the lesion. If this shows either a cancer 'in situ' or that an early invasive carcinoma has been adequately excised, no further treatment is required but *monthly follow-up is obligatory*. (*b*) *Larger lesions* should be treated by radiotherapy (p. 555) which is successful in a majority of cases (40–80 per cent., depending on the site and type of the tumour). In those cases that fail to respond within two months of the completion of treatment, surgery, and usually major surgery, is indicated. If the lesion is still clinically localized to the anterior two-thirds of the tongue, wide local excision (fig. 595), or partial (fig. 596), or sub-total glossectomy (removal of the anterior two-thirds) is carried out. To do this it may be necessary to split the lower lip in the midline and carry the incision through the mandible, bisecting it with a Gigli saw. Good access is obtained and the tongue can be removed under good vision. The mucosa of the floor of the mouth is sutured with catgut.

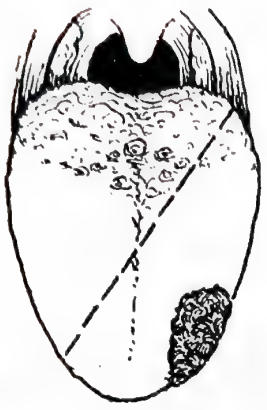
Diathermy in the mouth, although often used and recommended, is undesirable because it produces a deep burn which always becomes infected, healing is delayed until the slough separates and secondary hæmorrhage is thus encouraged. A scalpel or scissors should be used and bleeding arrested in the usual way.

(*c*) *Where the growth involves or reaches to within 2 cm. of the jaw*, removal of that half of the mandible is required.

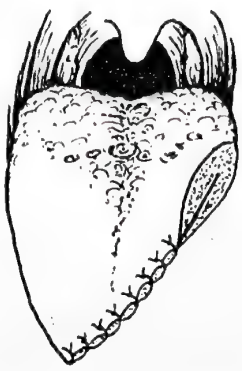
If the division of the mandible includes the attachments of the genio-glossus

Leonardo Gigli, 1863–1908. Director, Santa Maria Nuova Hospital, Florence, Italy. Invented this saw for pubiotomy in 1894.

and genio-hyoid muscles to the genial tubercles, tracheostomy may be required, especially if the patient has chronic bronchitis with copious sputum.



(*a*)



(*b*)

FIG. 595 (*a*) and (*b*).—Partial glossectomy suitable for neoplasms on the lateral margin or tip of the tongue.

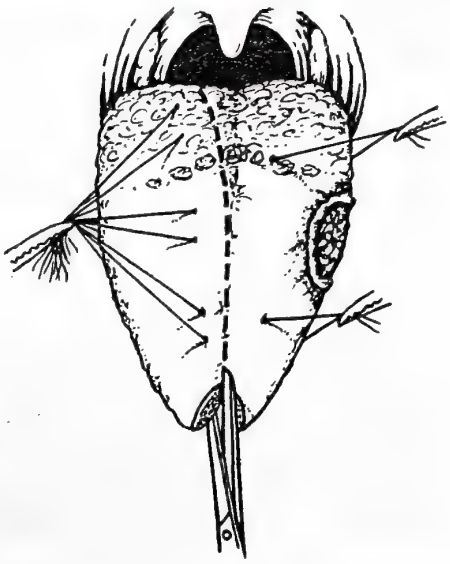


FIG. 596.—Hemiglossectomy with scissors. A diathermy knife should not be used.

It will be difficult for him to expectorate immediately after operation, and fatal broncho-pneumonia may otherwise occur. Eddey uses a piece of steel wire to hold the remaining half of the jaw in position (fig. 597). This can also be achieved by the use of dental prostheses. Even if no fixation is applied, the results are usually quite satisfactory.

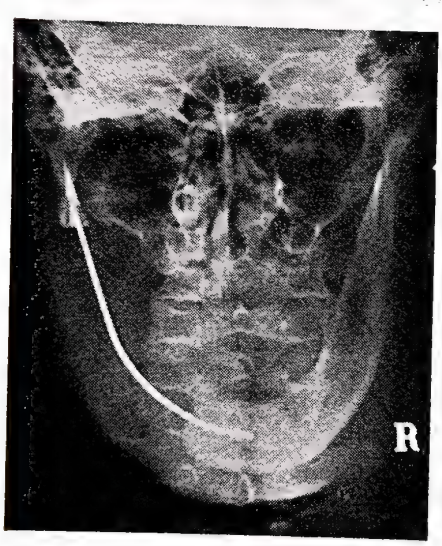

FIG. 597.—Kirschner's wire interposed between the cut surfaces of the mandible to hold the chin in a central position. (*H. H. Eddey, F.R.C.S., Melbourne.*)

(*d*) *If the lymph nodes are palpable and firm,* and they are suspected of being involved, procedures (*b*) and (*c*) (see above) are combined with a block dissection, the so-called Commando operation[1].

(*e*) *'Block' Dissection.*—Most surgeons do 'block' dissection (p. 584) only if lymphatic involvement is diagnosed clinically. A careful monthly follow-up is maintained, by the same surgeon if possible, and the operation performed only if the lymph nodes enlarge. The best results have been achieved by this policy although it is somewhat anomalous to do an operation which deliberately delays removing possible malignant tissue and also which leaves behind some of the tissue lying between the primary and the lymphatic deposits—namely, the floor of the mouth and the peri-mandibular tissues. The term 'block' dissection is thus a misnomer. If palpable lymph nodes appear on the other side,

[1] For want of a better name, these operations because of their extensive nature were given the name of 'Commando' by the house-surgeons of the Memorial Hospital, New York, in 1942, at the time of the combined commando operations against Dieppe, France.

Howard Hadfield Eddey, Contemporary. Professor of Surgery, Melbourne, Australia.
Martin Kirschner, 1879–1942. Professor of Surgery, Heidelberg, Germany.

'block' dissection on that side will be necessary. This carries a risk of disturbing the cerebral circulation caused by ligating both internal jugular veins simultaneously. Therefore only the vein on one side may be removed.

Radiotherapy.—(*a*) *Interstitial radiotherapy* is used for lesions larger than 1 cm in diameter in the anterior two-thirds. Radium needles, radon seeds, or radio-active tantalum or iridium wire, are placed in the tissues in one plane at 1 cm apart. These methods are unsuitable if the growth cannot be treated by a simple single plane implant. Therefore if the growth is larger than 2 cm in diameter or extends more than 1 cm into the tongue—and this is difficult to determine—then the radiotherapy of choice is some form of:

(*b*) *Teletherapy*.—The form usually used is the Cobalt 60 unit. When the growth is situated in the posterior one-third of the tongue, the anatomical difficulty of interstitial treatment is so great that teletherapy is employed for all such growths.

There is widespread agreement that radiotherapy is of little or no value in the treatment of lymphatic metastases whether as a primary treatment or when the disease is recurrent after 'block' dissection.

Radiotherapy in any form applied to the jaw renders it liable to necrosis, especially if it is already infected or involved in growth or if the radiotherapy is excessive. Necrosis of the jaw may lead to severe sepsis which will not subside until the jaw has been removed. Thus a growth involving the jaw should be excised and not irradiated.

Irradiation can cause a *delayed pathological fracture*, even years after treatment. This, although troublesome, is not a dangerous condition.

Chemotherapy.—Regional intra-arterial administration of Amethopterin (50 mg. per day for about five days) can be used, including its use as a preliminary to excision. Without excision the growth gets a little smaller in about 75 per cent. of cases and the patient improves for a few months. No long-term survival is likely (Johnston).

Prognosis.—The five-year survival rate after treatment (all varieties) is about 25 per cent.

Palliation

1. Radiotherapy to a large primary growth, even when untreatable secondaries are present, is well worth while.

2. Surgical resection of a recurrence after radiotherapy in the mouth, if feasible, often increases the patient's comfort even if irremovable metastases already exist. Cryosurgery (p. 678) may be very helpful instead of excision.

3. For the pain of the advanced growth, blocking the Vth nerve and the cervical plexus with 5 per cent. phenol may help.

4. Antibiotics are useful for a limited time by reducing the pain of secondary infection.

FIG. 598. — Malignant Melanoma of the tongue. There were secondaries in the cervical lymph nodes. (*Mohan Kumar, F.R.C.S., Calicut, South India.*)

Ivan David Alexander Johnston, Contemporary. Professor of Surgery, Newcastle-upon-Tyne, England.

5. Morphine or the 'Brompton cocktail' should be used when pain is severe and the patient's condition is deteriorating.

6. The stench of these patients for many months before the end may make them outcasts and deprive them of the comfort of family and friends. The odour can be lessened by irrigations with Eusol, Hydrogen peroxide (10 vols) and modern deodorant aerosols.

Sarcoma of the tongue is very rare, and almost invariably fatal.

Malignant Melanoma of the tongue (fig. 598) is also rare and carries a very poor prognosis.

CHAPTER 31

THE SALIVARY GLANDS

Surgical Anatomy of the Parotid Salivary Gland

Facial Nerve.—The trunk of the facial nerve emerges from the stylomastoid foramen and lies deeply beneath the surface in the angle between the bony external auditory meatus and the mastoid process. It passes forwards around the neck of the condyle of the mandible and rapidly becomes superficial. As it does so, it divides; first into an upper *temporofacial division* and a lower *cervicofacial division* and then subsequently into a varying number of branches, some of which may be interconnected (Pes Anserinus[1]).

The Parts of the Gland.—Because the branches of the facial nerve lie, broadly speaking, in the same plane, the gland is described as being composed of a *superficial part* or lobe and a *deep part* or lobe (fig. 599). The superficial part overlies the posterior border of the ramus of the mandible and the masseter muscle. A prolongation immediately above the parotid duct is called the *accessory parotid* (or socia parotidis), but only rarely is the latter separated from the rest of the gland. The size of the deep part is less obvious as it is tightly wedged into the space behind the mandible and medial pterygoid muscle. It embraces the lateral surface of the styloid process and the muscles attached thereto and insinuates itself into every adjacent crevice.

FIG. 599.—Showing the disposition of the facial (seventh) nerve in a case where the superficial lobe has been removed.

The Duct.—The parotid (Stensen's) duct is 2–3 mm in diameter. Beginning deep to and behind the angle of the mandible it curves upwards and forwards through the gland receiving interlobular ducts as it goes. The last three interlobular ducts join it from above, the final one being that from the accessory parotid. At its termination it turns inwards between the fibres of the buccinator muscle and then forwards submucosally to open into the mouth via a small papilla on the inside of the cheek, opposite the second upper molar tooth.

Surgical Anatomy of the Submandibular Gland

The gland is composed of a superficial part and a deep part.

The superficial part lies in the submandibular triangle, above and between the two bellies of the digastric muscle. It is superficial to the sloping undersurface of the mylohyoid muscle and superficial to the hyoglossus. One-third to half its bulk lies below the lower border of the mandible and one half to two-thirds above. The upper part lies in the concavity of the submandibular fossa on the medial aspect of the mandible.

The deep part varies in volume with the size of the posterior sublingual glands and lies below and lateral to the line of the submandibular duct, in the floor of the mouth, and above and deep to the mylohyoid (fig. 600).

---

[1] Pes Anserinus = Like the foot of a goose.

Niels Stensen, 1638–1686. Professor of Anatomy, Copenhagen. He abandoned medicine for the church on being appointed Bishop of Titiopolis. He is also regarded as "The Father of Geology."

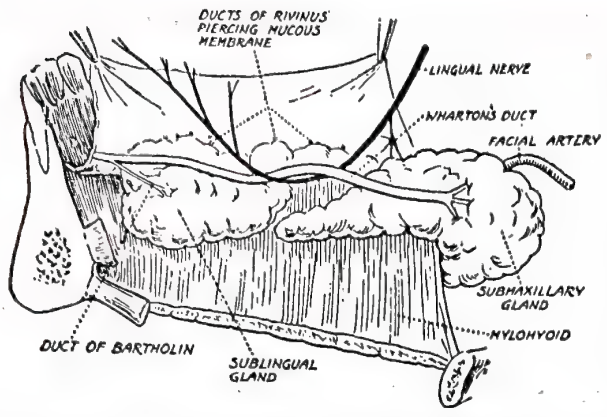

FIG. 600.—Dissection to show Wharton's duct and the structures in relation to it.
(*After Allen Thompson.*)

The duct (Wharton's duct), about 5 cm long, runs forward from the deep part of the gland to enter the floor of the mouth on a papilla beside the frenum of the tongue. The sublingual veins lie lateral and the sublingual artery medial to the duct, more anteriorly.

The lingual nerve is attached to the upper pole of the gland (superficial part) by the fascial sheath of the gland. The sublingual (submandibular) ganglion may be seen attached by two roots to the lower side of the nerve at this point. The nerve passes forwards and downwards between the duct and the deep part of the gland before passing medially under the duct opposite the first lower molar. While still lateral to the duct it gives off its sublingual branch, which runs close to the mandible, lateral to the sublingual glands.

The facial artery emerges from under the stylohyoid muscle and either enters the gland substance towards the posterior aspect of its deep surface or deeply grooves the gland. It passes upwards to gain the lateral surface of the gland deep to the lower border of the mandible, around which it curls to enter the face. It lies behind the duct and is at risk from incisions into the upper pole of the gland. Small vessels also enter the gland from the posterior border of the mylohyoid muscle which is firmly attached to the corresponding groove in the gland between the superficial and deep parts.

The venous drainage is into both the anterior facial vein and into the venæ comitantes of the lingual artery.

Sialography

A suitable radio-opaque liquid such as Hypaque® (sodium diatrizoate) or Lipiodol® is introduced into the duct system of the parotid or submandibular gland as appropriate and a radiograph taken (fig. 604). One-half to two ml of solution, depending on the gland, is introduced either through a fine polythene catheter, or a blunt metal cannula which is inserted into the orifice of the duct. The radiograph records the outline of the lumen of the duct system. By this means radiolucent obstructions, and dilatation and narrowing of the duct may be shown. The position and size of a salivary neoplasm, or even an extraglandular mass may be determined because the related ducts will be displaced by the expanding lesion. Fistulæ and abscess cavities can be displayed.

INFLAMMATIONS

Acute Parotitis

May be due to a virus, a non-specific bacterial infection or more rarely actinomycosis or tuberculosis. Mumps is the usual virus infection but other viruses such as the Coxsackie A virus may produce a similar illness. A tuberculous infection of a salivary gland is usually as a result of spread from a tuberculous lymph node.

Bacterial infections mostly reach the gland by ascending the duct from the oral cavity. There are two possible predisposing factors—either a reduction

Thomas Wharton, 1616–1675. Physician, St. Thomas's Hospital, London. Said to have remained on duty during the Great Plague.

in salivary flow or partial obstruction to the duct with retention of secretions. Salivary flow may be reduced:

Following Major Surgical Operations.—Acute parotitis as a complication of major surgery is less common now that the fluid and electrolyte balance is better controlled. Care should be taken to maintain a high standard of oral hygiene during the postoperative period, and patients with neglected mouths should have dental treatment pre-operatively. Serious acute infections in the dehydrated patient are usually due to *Staphylococcus aureus*, as are the rare metastatic abscesses of the parotid gland. Some infections secondary to obstruction of the duct also may be due to staphylococci but more often are due to *streptococcus viridans* or pneumococci.

During debilitating illness, especially those like typhoid fever and cholera, where the patient may become dehydrated, even while under medical care.

Following radiotherapy where one or more of the major salivary glands are within the field of irradiation. Usually the suppression of salivation following radiotherapy is temporary, but may be permanent.

In Sjögren's Syndrome where the gland substance is destroyed by auto-antibodies (p. 569).

Clinical Features.—There is a brawny swelling of the side of the face (fig. 601). In the case of a virus parotitis or early suppurative parotitis the swelling corresponds to the shape of the gland and raises the lobe of the ear. As suppurative parotitis progresses, widespread cellulitis is seen and the overlying skin becomes dusky red. Pus can be expressed from the parotid duct, and a swab should be taken for culture, identification of the organism, and antibiotic sensitivity tests. The temperature is usually well over 37·8 C. Fluctuation will be elicited only after pus has penetrated the dense fascia of the parotid sheath.

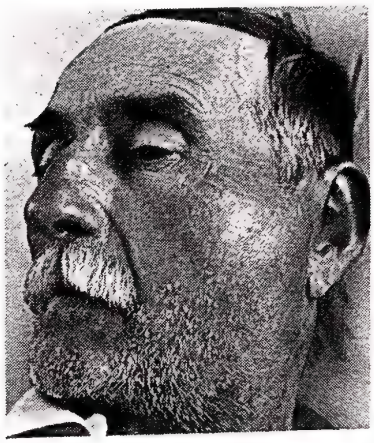

FIG. 601.—Acute parotitis.

Treatment.—Everything should be done to improve the general state of the patient, and antibiotics are administered. Meticulous oral hygiene should be practised with toothbrush and paste where teeth are present and with sodium bicarbonate mouthwashes for the edentulous patient. Dentures should be left out except at meal times. A soft diet is prescribed as chewing is difficult. The gland can be massaged gently at regular intervals to express pus. If pus ceases to drain through the duct, and improvement in the general and local condition is not seen within 48 hours of the start of treatment, drainage of the gland should be considered. Drainage is essential if the dusky redness becomes localised to the lower pole because an abscess here might drain spontaneously into the external auditory meatus.

Drainage of Suppurating Parotitis.—The line of the incision runs vertically in the crease in front of the tragus, curves under the lobe of the ear and curves forward again over the mastoid process and around the posterior aspect of the lower pole of the gland. The transverse incisions in the capsule traditionally used to decompress the gland are rarely necessary. Mosquito artery forceps can be thrust through the

Henrik Samuel Conrad Sjögren, Contemporary. Professor in Ophthalmology, Jönköping, Sweden.

fascia and opened within the gland at several levels to effect drainage. Both the extent of the incision and the drainage depend on the severity of the case. A corrugated drain is inserted. When the swelling reduces and drainage ceases the wound in front of the ear may be sutured under local anæsthesia.

Acute Suppurative Sialoadenitis of the Submandibular Gland

Is usually secondary to an obstruction to Wharton's duct. The organism is frequently sensitive to penicillin and incision and drainage rarely required, unless suppuration of the adjacent lymph nodes supervenes.

Recurrent Subacute and Chronic Sialoadenitis

These inflammations are always secondary to a pre-existing condition such as an obstruction of the duct or autoimmune disease (fig. 602). The recurrent attacks of pain and swelling are accompanied by the discharge of flecks of pus in the saliva (fig. 603). The infection should be controlled by antibiotics and then a sialogram performed. If the sialographic changes are

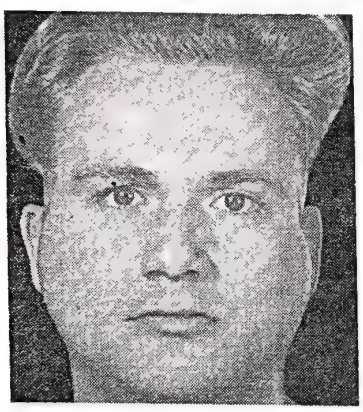

FIG. 602.—Sjögren's syndrome with superimposed bilateral chronic bacterial parotitis. Present for nine months.

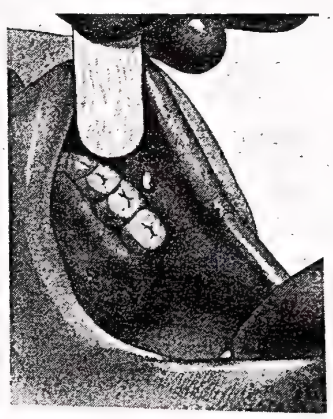

FIG. 603. — Purulent saliva being ejected from Stensen's duct.

confined to the side affected by infection then an obstructive cause is most likely (fig. 604). Where changes are present on both sides Sjögren's syndrome is the more likely predisposing cause even if the attacks of pain and swelling are only unilateral. However, calculi can be a complication of the reduced salivary flow of Sjögren's syndrome and this possibility should be borne in mind (p. 569).

Recurrent Subacute Parotitis of Childhood

The patient may present at any age between 3 months and 10 years with swelling of one of the parotid glands. Both pain and constitutional symptoms are mild. There may have been one or more previous episodes each lasting 10–14 days and affecting either gland. The first attack may have been mistaken for mumps. A sialogram reveals an appearance of multiple, small, proximal dilatations—like a snowstorm. The appearance is called punctate

sialectasis. While characteristic of this particular condition, punctate sialectasis, may also be seen in Sjögren's syndrome, or after irradiation of the gland.

Katzen has found that the condition remits spontaneously by age 15. His biopsy material shows an appearance suggestive of an autoimmune cause and similar to that seen in Sjögren's, but there is no evidence that the childhood condition precedes, or progresses to, adult Sjögren's. More than one child in the family and the children of more than one generation may be affected, suggesting a congenital predisposition to the condition. Antibiotics will control the acute episodes, but a sialogram will often cut short the attacks.

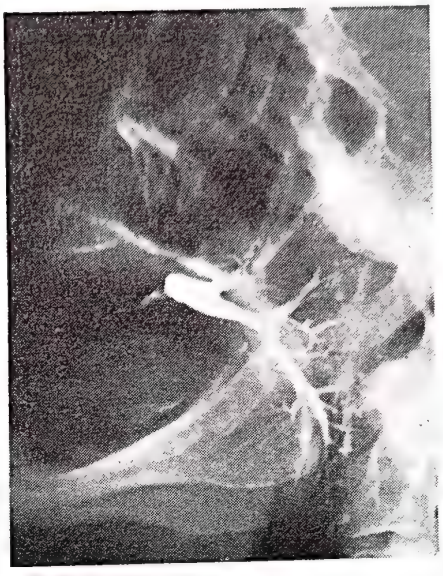

FIG. 604.—History of chronic infection of parotid gland. Sialogram of parotid (lateral view). Shows dilatation of duct starting abruptly opposite the anterior border of the masseter. Such an appearance is likely to be due to a calculus and attention should be given to other views in an endeavour to prove its presence.

Obstruction to the Duct of a Major Salivary Gland

The characteristic symptom is recurrent painful swelling of the affected gland at meal times (fig. 605), but the first indication may be an acute or subacute infection as described above.

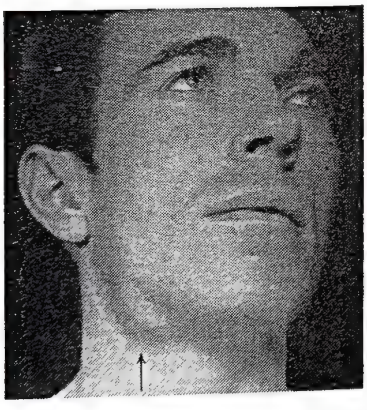

FIG. 605. — Enlargement of the submandibular salivary gland due to a calculus in Wharton's duct.

Proximal to a site of chronic obstruction the duct will be dilated with retention of secretions and chronic infection. Causes of obstruction include salivary calculi, strictures of the duct wall, œdema or fibrosis of the papilla, pressure on the duct due to an adjacent mass, or invasion of the duct by a malignant neoplasm.

Papillary Stenosis.—Ulceration of the papilla of either the submandibular or parotid duct may follow trauma from a denture. Ulceration of the parotid papilla may also follow irritation from a sharp tooth, or a bite of the cheek. The obstruction and recurrent swelling will subside as the ulcer heals. Repeated trauma results in fibrosis which is only relieved by papillotomy with suture of the duct lining to the oral mucosa.

Salivary Calculi.—*Submandibular calculi* are by far the most common and are relatively easy to demonstrate by plain radiography (fig. 606). *Calculi within the duct* may be removed via the floor of the mouth, although those near to the gland require special experience. For calculi anteriorly in the floor of the mouth a stitch is passed under the duct proximal to the stone to stop the stone slipping backwards. An incision is made in the mucosa over the duct and the latter mobilised. A stay suture is passed under the duct to bring it up into the top of the wound and to control it while the wall is incised to release the stone. *Where the calculus is within the intraglandular*

Michael Katzen, Contemporary. Surgeon, Transvaal Memorial Hospital for Children and Department of Pediatric Surgery, University of Witwatersrand, Johannesburg, South Africa.

part of the duct (fig. 607), or the gland severely damaged by chronic infection, then excision of the gland is indicated.

FIG. 606.—Radiograph of stone in Wharton's duct.

FIG. 607.—Salivary calculus within the submandibular salivary gland (actual size).

Excision of the submandibular gland proceeds as follows:—The gland is removed through an incision in a skin crease over the lower third of the gland and about 5 cm long. The tissues are divided down to the platysma muscle and the subcutaneous tissues separated from the surface of the muscle by pressure with a swab (gauze sponge) to facilitate closure of the wound in layers. The muscle is divided to expose the deep fascia which is opened with care to avoid damage to the facial nerve. The marginal mandibular branch of the facial nerve is sought beneath the deep fascia and retracted upwards. The anterior facial vein is found within the fat superficial to the gland. If the anterior facial vein is divided over the gland and below the marginal mandibular branch it may be retracted upwards, drawing the nerve upwards and out of the operative field, because the nerve passes superficial to the vein. The lower pole of the gland is freed keeping close to the surface of the gland, grasped with Allis' tissue forceps and turned upwards and forwards. The posterior belly of the digastric and the stylohyoid muscles are identified and retracted backwards with a Langenbeck's retractor. The facial artery with its veni comitantes will be seen emerging from deep to the muscles and entering the deep surface of the gland. It is ligated three times using an aneurysm needle and divided between the distal two ligatures. Double ligation of the proximal end is advisable as the artery retracts beneath the muscles once it is cut and a slipped ligature results in troublesome hæmorrhage. The facial artery is divided again at the lower border of the mandible and the gland drawn down and separated from the lower border of the jaw dissecting close to the gland substance. The submandibular branch of the facial artery will be divided as this is done. If the lower pole is now retracted backwards the posterior border of the mylohyoid muscle may be separated with scissors from the groove between the superficial and deep parts of the gland. Small arteries entering the gland from the muscle should be sealed with diathermy. A finger is passed around the gland separating loose connective tissue around the capsule and the gland drawn down to bring the lingual nerve into view. The nerve is within the fascial sheath of the gland at the upper pole and will be drawn into a V shape by traction on the gland. The nerve is separated under direct vision after which the duct may be drawn down through the loop of the nerve. The duct should be clamped, divided and ligated well forward to leave only a short stump. If the dissection keeps close to the under surface of the gland the hypoglossal nerve should remain covered with loose connective tissue and should not be at risk. Sometimes veins from the gland drain into the veni comitantes of the hypoglossal nerve or lingual artery and will be divided as the gland is separated. They must be clamped and ligated with care or the nerve will be damaged. The wound is closed in layers with vacuum drainage.

Parotid calculi are not infrequent, but only the larger ones can be seen against the soft tissue image of the cheek in plain radiographs. Sialograms are necessary to identify and locate them but even these are not always easy to interpret.

Oscar Huntingdon Allis, 1836–1921. American Surgeon.
Bernard Rudolph Konrad von Langenbeck, 1810–1887. German Surgeon.

Parotid calculi anterior to the accessory parotid can be reached via the oral cavity. A ≺ shaped incision is made around the parotid papilla and a flap raised which includes the submucosal part of the duct. The duct is mobilised for a distance out into the cheek and drawn as a loop into the mouth so that the calculus can be reached. Calculi in the intraglandular part of the duct are approached through a pre-auricular incision as for parotidectomy. The duct is identified at the anterior border of the gland and traced backwards until the calculus is uncovered. Care is taken to identify and conserve related branches of the facial nerve.

Strictures and Fistulæ

If a duct ulcerates around a calculus a characteristic short stricture will form after the calculus has been removed. There will then be a recurrence of mealtime swelling. Removal of the stricture or excision of the gland will be required. Fortunately the submandibular duct is the one most often affected. A stricture anterior to the second molar region may be circumvented by transecting the duct behind the obstruction, slitting the end to increase the size of the opening and implanting it in the floor of the mouth.

Some submandibular calculi ulcerate directly into the mouth and an internal fistula is formed. Unless there is also a stricture present this is of no consequence.

Bilateral strictures affecting sizeable lengths of the parotid ducts are seen. The ducts proximal to the stricture dilate and both recurrent obstructive swellings and recurrent infective swellings are experienced by the patient. Mostly these patients do not have positive tests for autoimmune antibodies, nor do they suffer from rheumatoid arthritis, and they lack the characteristic histological changes as seen in labial salivary gland biopsies in Sjögren's syndrome. Dilatation of the stricture with gum elastic filiform bougies lubricated with lignocaine gel will often relieve symptoms temporarily.

Partial excision or a laceration of the parotid gland may be followed by an accumulation of saliva in the tissues. Aspiration of the pool of saliva through an oblique needle track, followed by the application of a firm pressure dressing, and repeated as necessary will cure this, but may take some weeks or months. Incisional drainage of such a collection of saliva, or of pus in a parotid abscess can result in an external parotid fistula as can a laceration involving Wharton's duct.

Management of Fistulas.—Fistulas from divided gland substance usually granulate and heal. Duct fistulas need to be explored because quantities of saliva pour out on to the face each meal time, and even the amount which leaks out between meals is sufficient to keep the skin and a dressing moist. Following a pre-operative

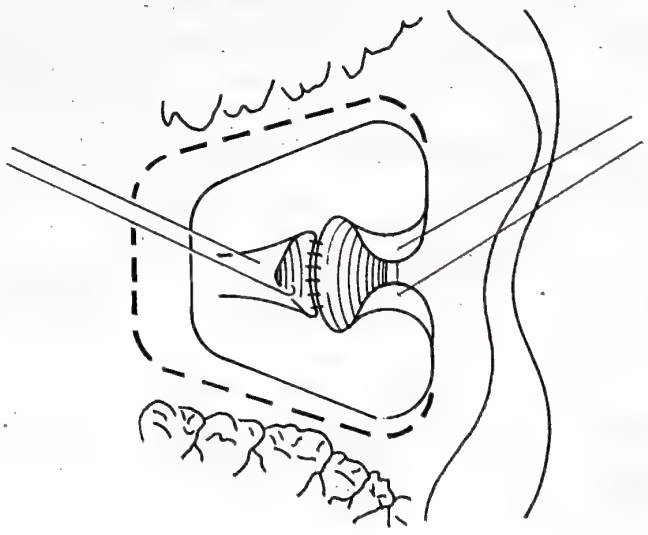

FIG. 608.—The technique of using a flap of cheek mucosa to repair a damaged parotid duct. The mucosa is tubed and sutured to the proximal segment of duct. In the case of a stricture the obstructed segment is excised prior to the anastomosis.

sialogram a flexible bougie is passed into the duct from the mouth, to mark the distal segment. A pre-auricular flap is raised and the proximal end is sought. If repair without tension is possible the ends of the divided duct are slit longitudinally so that they may be joined by an oblique suture line which will not contract to a stricture.

If the distal part has been destroyed, or if a stricture obliterates part of the distal 2 cm of duct, continuity can be restored using a rectangular pedicle flap of mucosa

from the inner aspect of the cheek which is rolled into a tube and anastomosed to the duct end (fig. 608). If no reconstructive procedure is possible the gland is excised.

FIG. 609.—Cyst of the parotid.

Cysts

As a rare entity a cyst lined with epithelium may be found in the parotid gland and behind the angle of the mandible (fig. 609). The origin of such cysts is uncertain, they may be related to the developmental preauricular sinuses occasionally seen in front of the ear, or they may be related to the branchial cleft cysts which more typically are found beneath the upper third of the sternomastoid muscle. A lateral dermoid cyst of the floor of the mouth which develops from the first branchial cleft can enlarge backwards until the submandibular salivary gland is spread out over its surface. It will then present as a fluctuant swelling both in the floor of the mouth and in the submandibular triangle. The treatment of these cysts is enucleation.

NEOPLASMS

The International Classification of Salivary Gland Tumours is recommended and reproduced below.

I. EPITHELIAL TUMOURS

A. Adenomas
   1. Pleomorphic[1] adenoma (mixed tumour)
   2. Monomorphic adenomas
      (a) Adenolymphoma
      (b) Oxyphilic adenoma
      (c) Other types
B. Mucoepidermoid tumours

II. NON-EPITHELIAL TUMOURS

C. Acinic cell tumour
D. Carcinoma
   1. Adenoid cystic carcinoma
   2. Adenocarcinoma
   3. Epidermoid carcinoma
   4. Undifferentiated carcinoma
   5. Carcinoma in pleomorphic adenoma

Many salivary neoplasms are distinctly rare and of interest only to the specialist surgeon and pathologist. Only those which are common enough to be of general interest will be described.

Incidence.—Approximately 75% of all salivary neoplasms arise in the parotid gland. Of these some 80% are benign and 80% of the benign tumours are pleomorphic adenomas.

Approximately 15% of salivary neoplasms arise in the submandibular salivary gland. Of these 60% are benign and 95% of the benign tumours are pleomorphic adenomas.

Approximately 10% of salivary neoplasms arise in the minor salivary glands of palate, lip and cheek and in the sublingual glands; with the site incidence decreasing in that order. Only 40% of these are benign but virtually all the benign tumours are pleomorphic adenomas.

Pleomorphic Adenomas.—Epithelial cells proliferate in strands and some take on a duct like arrangement. Other cells, probably of myoepithelial

[1] Pleomorphic = many forms.

origin, proliferate in sheets. In parts of the tumour a mucoid material is produced which separates the cells producing a myxomatous appearance and then an appearance resembling cartilage in histological sections. On occasions sufficient mucoid material may accumulate to produce a cystic part to the swelling. In general the tumour is slow growing and forms a firm or elastic, lobulated mass (fig. 610 and 611). The pleomorphic adenoma is

FIG. 610.—Pleomorphic adenoma of parotid gland, typical location.

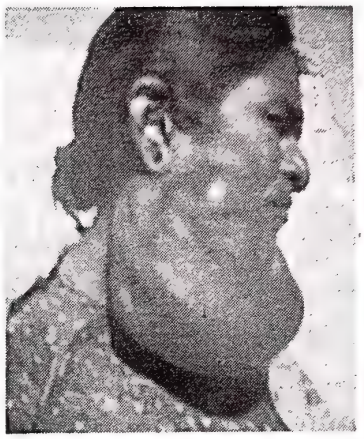

FIG. 611.—Unusually large pleomorphic adenoma of the submandibular salivary gland. It weighed 1·2 kg. *(M. K. Rana, M.S., Mandvi-Kutch, India.)*

classed as benign, but strands of tumour cells tend to penetrate the thin capsule of compressed gland substance and connective tissue which surrounds it. Further, lobules of tumour attached only by a narrow neck of tissue may extend beyond the main limits of the mass. For these reasons, simple enucleation will leave residual neoplasm behind and result in multicentric recurrence. After perhaps 10, 20 or 30 years a few pleomorphic adenomas will exhibit rapid growth and clinical signs of malignancy. This is described as a carcinoma arising in pleomorphic adenoma.

Adenolymphoma or Warthin's Tumour.—A benign neoplasm composed of a double-layered epithelium which lines spaces which are frequently cystic. The epithelium is markedly eosinophilic and the inner cells are columnar. It tends to be folded inwards into the cavities to produce a papillary appearance in section. Characteristically the stroma contains lymphoid tissue, including lymph follicles.

Clinically it presents as a slowly enlarging soft, sometimes fluctuant swelling, usually towards the lower pole of the parotid gland in a middle age or elderly male. More than one tumour may be found at times, either on one side, or one bilaterally. Adenolymphomas form 10% of parotid tumours, are rare in the submandibular gland, and found only exceptionally in the minor glands. Unlike all other neoplasms which form a 'cold' spot, the adenolymphoma produces a 'hot' spot in a $^{99}Tc^{m}$ Pertechnetate 'scan' so that a firm pre-operative diagnosis is possible without biopsy. Other types of monomorphic adenoma are rare.

Aldred Scott Warthin, 1866–1931. Professor of Pathology, University of Michigan, Ann Arbor, U.S.A.

Muco-epidermoid Tumour.—Is composed of sheets and masses of epidermoid cells and clefts and cystic spaces lined by mucous secreting cells. The cartilage-like appearance and myxoid appearance characteristic of the pleomorphic adenoma is not seen.

These tumours are of varying degrees of differentiation and speed of growth. Mostly they are slow growing and invade local tissues to a limited degree and only occasionally metastasise to lymph nodes or lungs. Clinically they are usually hard; noticeably harder than a typical pleomorphic adenoma, yet become fixed only when large. Mostly they do not cause facial paralysis when they occur in the parotid gland.

Adenoid cystic carcinoma consists of myoepithelial cells and duct epithelium cells. The former form sheets of cells within which a basophilic material accumulates in blobs to give them a cribriform, or lace-like appearance. Duct epithelium cells form strands and cords, but tend also to form duct-like structures and microcysts in which an eosinophilic material accumulates. These also add to the cribriform appearance.

Many adenoid cystic carcinomas are comparatively slow growing and difficult to differentiate clinically from the previously described tumours. However, sooner or later pain, areas of anæsthesia of the skin and paralysis of muscles appear due to involvement of related nerves. Unlike the previously described neoplasms, however, the chance of eradicating an adenoid cystic carcinoma is poor because it infiltrates for long distances in the perineural tissues of adjacent nerves and may invade medullary bone for many centimetres before inducing significant bone resorption. Thus, the tumour is always more extensive than the physical signs or radiographic appearances suggest. The percentage incidence increases from parotid to submandibular to accessory salivary glands. The adenoid cystic carcinoma tends to be both hard and fixed.

Adenocarcinomas, Epidermoid Carcinomas and Undifferentiated Carcinomas.—Some salivary carcinoma cells and cell arrangements resemble the various glandular elements seen in salivary glands. These are the adenocarcinomas. Some specialist pathologists subdivide these according to the predominant cell type, but their subdivisions are not of clinical importance. Epidermoid and undifferentiated carcinomas resemble those seen at other sites.

All these neoplasms tend, at an early stage, to produce obvious clinical signs of malignancy. These are fixation, resorption of adjacent bone, pain, anæsthesia of skin or mucous membrane and paralysis of muscles. In the case of the parotid gland, facial nerve irritability occurs and muscle spasm can be produced if the tissues over the nerve are tapped. Later this gives way to facial paralysis. Limitation of mandibular movement results from invasion of the jaw and masticatory muscles.

Treatment of Salivary Tumours

Treatment of Slow Growing Salivary Neoplasms.—Slow growing *parotid* neoplasms are assessed clinically and are *not biopsied* (p. 568).

Warthin's tumours and pleomorphic adenomas are usually recognisable with reasonable certainty. Both are excised by partial parotidectomy with conservation of the facial nerve (fig. 612). The main trunk is identified proximal

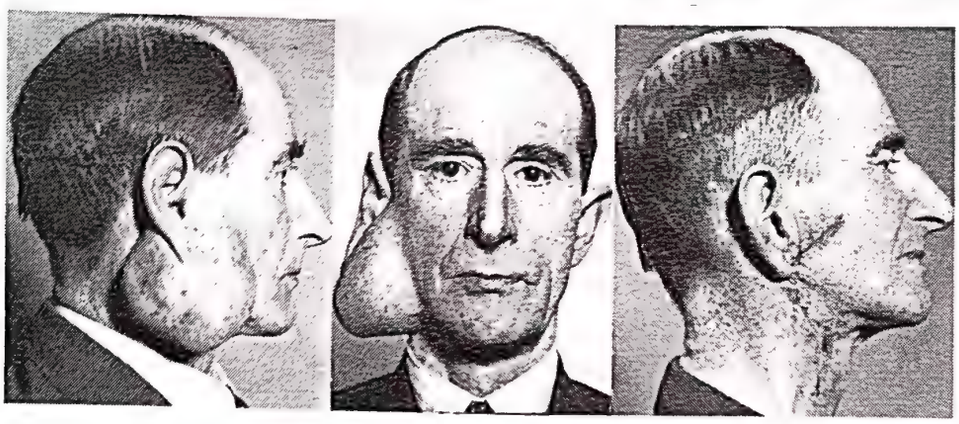

FIG. 612.—Mixed parotid tumour of over twenty years' duration, latterly increasing rapidly in size. Complete parotidectomy with preliminary ligation of the external carotid artery. The facial nerve was preserved. The patient was free from recurrence twelve years later.

to the gland and each branch is traced out in turn (fig. 613). A margin of normal gland and if necessary masseter muscle, is taken with a pleomorphic adenoma. The connective tissue sheath of the nerve is adequate margin at this site and only the occasional branches actually penetrating the tumour need be sacrificed and replaced by a graft. Unusually hard and fixed, slow

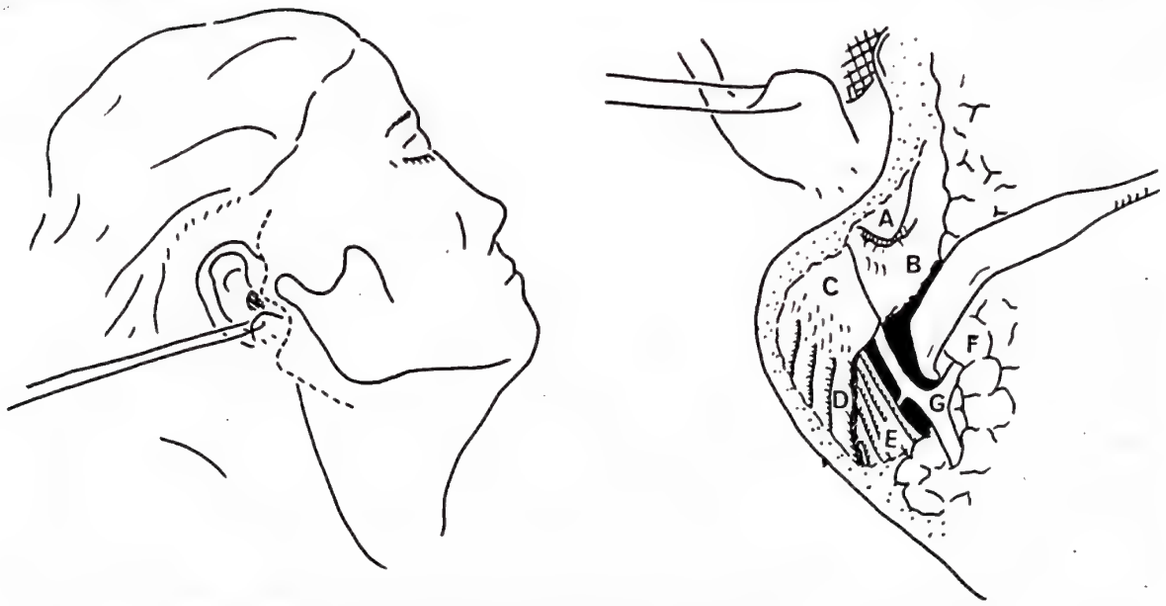

Fig. 613.—**Parotidectomy.** (a) The dotted line outlines the pre-auricular incision through which the parotid gland is explored. It starts within the hair line, uses the edge of the tragus, turns underneath the lobe of the ear and then turns again over the mastoid process to follow a skin crease in the neck. The whole or part of this line is used for an incision as indicated.

(b) The main trunk of the facial nerve (G) and the two main divisions as exposed at the beginning of a superficial parotidectomy. Each division and branch is traced out in turn to permit excision of the gland. The important landmarks for finding the nerve are:
(A) the pointed lower end of the tragal cartilage,
(B) the bony external auditory meatus,
(C) the mastoid process,
(D) the sternomastoid muscle,
(E) the posterior belly of the digastric.
(F) the retracted lower pole of the parotid gland.

growing, neoplasms are treated similarly, but a larger margin is taken with a greater readiness to sacrifice nerve branches. Further treatment depends on the histological report and adequacy of the excision. Most muco-epidermoid carcinomas will be effectively managed this way.

Slow growing *submandibular* gland neoplasms not fixed to the mandible are treated by excising the whole gland with the adjacent connective tissue, but conserving lingual and hypoglossal nerves. To prevent rupture and seeding of the neoplasm the gland must not be grasped with tissue forceps or other instruments, nor biopsied.

After a pre-operative biopsy, *palatal* pleomorphic adenomas are circumscribed with an incision well wide of the obvious swelling as the tumour here is flattened and dish-shaped rather than spherical. The periosteum is raised from the bone, the greater palatine vessels mobilised and drawn down until they can be clamped, divided, and diathermised beyond the tumour. The wound is packed and heals by granulation. Palatal bone need be sacrificed only if obviously invaded clinically or radiographically.

Biopsy?—Salivary neoplasms shed cells if they are incised and will 'seed' readily giving rise to recurrence. Biopsy of the parotid also carries the risk of damage to the facial nerve. Pre-operative biopsy is largely confined to tumours of the sublingual and accessory glands, as these carry the greatest likelihood of being malignant.

Treatment of Neoplasms which present with Clinical Signs of Malignancy

Where the neoplasm presents the clinical signs of malignancy, a radical excision is carried out. In the case of the parotid gland the facial nerve is sacrificed, but may be grafted using the great auricular nerve. Such other structures are sacrificed as are both surgically reasonable and necessary. A specimen can be taken for frozen section during the operation and before any irrevocable or mutilating step is carried out. Depending on the pathologist's report on the type of neoplasm and the adequacy of the surgical excision, postoperative radiotherapy is arranged. Unfortunately most salivary neoplasms are relatively radio-resistant.

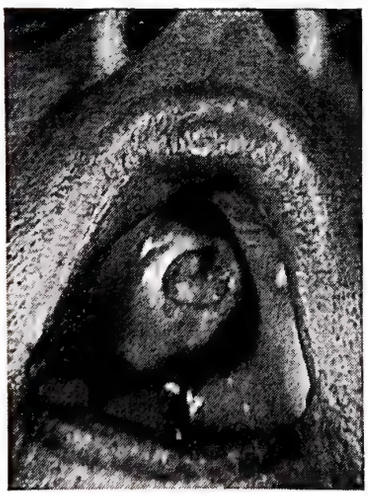

FIG. 614.—Ulcerating salivary gland neoplasm of palatal mucous salivary glands. A neoplasm presenting like this is likely to be a muco-epidermoid carcinoma or an adenocystic carcinoma.

Radical excision of a parotid neoplasm is limited by the internal carotid artery on its deep aspect and the cranial cavity posteriorly. Excision of the parotid including the mandible is straightforward, but inclusion of the temporal bone requires special surgical expertise.

A similar management is followed for the submandibular gland with fewer anatomical restraints. Radical excision of the submandibular gland with, if necessary, the adjacent mandible and tongue and in continuity with a neck node dissection presents no special problems.

In the case of the minor salivary glands a biopsy is

made pre-operatively (fig. 614). Excision with a wide margin is carried out. In the case of palatal neoplasms this means a maxillectomy. The cavity in the upper jaw is lined with a split skin graft held in place by a gutta percha bung on a dental plate which is wired to the remaining facial skeleton. Most adenoid cystic carcinomas require postoperative radiotherapy irrespective of their site of origin.

Postoperative Persistent Facial Paralysis

Where nerve grafting is not possible or proves unsuccessful following radical surgery, consideration can be given to transposing the hypoglossal nerve and anastomising it to the peripheral branches. Fascial slings may also be used to support facial tissues and mask the deformity (fig. 615).

Non-epithelial Tumours

Hæmangiomas, lymphangiomas and neurofibromas may involve the parotid salivary gland. Hæmangiomas most often present during childhood and account for almost half of the hamartomatous and neoplastic parotid lesions seen in this age group. Excision requires special care, not only because of the problems of hæmorrhage, but because the facial nerve is not so deeply placed in the child.

FIG. 615.—A strip of fascia lata inserted subcutaneously as shown helps to overcome the deformity of facial palsy. (*After W. O. Lodge.*)

THE AURICULO-TEMPORAL SYNDROME (FREY'S SYNDROME

In this condition there is flushing and sweating of the skin innervated by the auriculotemporal nerve whenever salivation is stimulated. The condition follows surgery in the region of the parotid gland or temporomandibular joint, but may follow accidental injury of the parotid gland or joint. Some cases are congenital and possibly due to birth trauma. It is thought that following injury to the auriculotemporal nerve, postganglionic parasympathetic fibres from the otic ganglion become united to sympathetic nerves from the superior cervical ganglion destined to supply the vessels and sweat glands of the skin. Mostly the condition is an inconvenience rather than a real disability. Only in severe cases is division of the lesser superficial petrosal nerve within the skull considered as a means of interrupting the secretomotor fibres.

SJÖGREN'S SYNDROME

Sjögren's syndrome is the clinical triad of dry eyes (keratoconjunctivitis sicca), dry mouth (xerostomia) and rheumatoid arthritis. More recently other connective tissue diseases such as systemic lupus erythematosis or scleroderma have been recognised as a possible third component. If only the dry eye and dry mouth aspects of the condition are present the patient is said to have the sicca syndrome. In these patients the salivary and lacrimal glands are infiltrated with lymphocytes and the acini progressively destroyed. The epithelium of the ducts becomes hyperplastic, forming casts within the lumen and blocking smaller ducts. Mucous gland metaplasia of the duct epithelium leads to the formation of a gelatinous saliva in some patients. Strictures, duct dilatations and ascending infection complicate the picture. The histological changes can be seen in biopsies of the labial mucous salivary glands. Hypergamma-globulinæmia may be detected in an electrophoretic strip and autoantibodies such as rheumatoid factor, antinuclear factor and salivary duct antibody may be demonstrated in the serum. The lack of lacrimal secretion can be shown by the Schirmer test and the keratitis by Rose Bengal and fluorescein staining. Salivary secretion studies are conducted by collecting saliva under standard conditions using small cups applied by a vacuum ring over the parotid papillæ. Gland function can also be quantified by $^{99}Tc^{m}$ Pertechnetate scans.

The effect of the disease in the salivary glands is a progressively more severe dryness of the mouth. Rampant, uncontrollable caries of the teeth follows. After the loss of the natural teeth, dentures are almost unwearable and lips, tongue and palate stick together. The tongue becomes cracked and attacks of monilia stomatitis occur.

Luiji Frey, 1889–1944. Physician, Neurological Clinic, Warsaw, Poland.
Derrick Samuel Conrad Sjögren, Contemporary. Professor of Ophthalmology, Gothenburg, Sweden described this syndrome in 1933.

Intense infiltration of the glands with lymphocytes can result in diffuse enlargement or the formation of localised nodules, which must be distinguished from neoplasms.

Mikulicz Disease.—Mikulicz described his triad which constituted (1) Symmetrical enlargement of all the salivary glands (2) Narrowing of the palpebral fissures due to enlargement of the lachrymal glands and (3) Parchment-like dryness of the mouth (fig. 616). Subsequently Mikulicz disease and Mikulicz syndrome were recognised, both producing the same clinical picture. Mikulicz syndrome is enlargement of the salivary and lacrimal glands due to leukæmia or some other generalised disease resulting in infiltration of the glands with round cells. Mikulicz disease is due to an autoimmune process in the glands themselves and is generally looked upon as a clinical variant of Sjögren's syndrome.

FIG. 616. — Mikulicz disease. (*C. Fischer.*)

Treatment.—The dry eyes can be treated by diathermy obliteration of the lacrimal punctum and the instillation of artificial tears composed of methyl cellulose drops. Meticulous oral hygiene with toothbrush and paste, dental floss and a special 1% chlorhexidine gluconate preparation will help control the caries and periodontal disease and delay tooth loss. Methyl cellulose mouth washes help to keep the mouth moist, but are less successful as artificial tears.

Steroids and immunosuppressive agents will generally alter the course of the disease, but their use is rarely warranted in view of their side effects. In addition, such treatment increases the risk of ascending infection. Radiotherapy will reduce the enlargement of Mikulicz disease, but increases both the dryness of the mouth and any tendency to attacks of infection.

Patients with Sjögren's syndrome are at greater risk than the rest of the population from the development of reticulum cell sarcoma, either in the glands, or in the related lymph nodes.

Other Causes of Salivary Gland Enlargement

A variety of drugs will cause enlargement of the salivary glands in a percentage of patients, notably those used in the treatment of thyrotoxicosis. Many other drugs reduce the salivary flow, cause dryness of the mouth, and predispose to ascending infection of the salivary glands.

Sialosis is enlargement of the salivary glands for metabolic reasons. It is seen in certain hormonal disturbances such as diabetes and acromegaly, in patients who stick to bizarre diets, and in patients who are overweight. In the case of the latter the glands may be infiltrated with fat. The condition is important in drawing attention to an underlying cause or in the differential diagnosis from other causes of salivary gland enlargement.

Johann von Mikulicz-Radecki, 1850–1905. (*See footnote p. 540*). *Described this disease in 1892.*

CHAPTER 32

THE NECK

THE BRANCHIAL APPARATUS AND ITS ABNORMALITIES

In a fœtus approximately thirty-five days old, four grooves can be seen on each side of the neck. These are the branchial clefts, which resemble the gills of a fish; the intervening bars are the branchial arches. Each arch contains a central cartilage. The clefts in human embryos are composed of grooves on the outside and pouches on the inside (pharynx). The first cleft persists as the external auditory meatus; the second, third, and fourth clefts normally disappear. The whole, or a portion, of one of the clefts that normally disappear may persist. Alternatively, a portion can become sequestrated.

Branchial Cyst.—Arising from the second branchial cleft is the most common of these vestigial remnants. It is nearly always lined by suamous epithelium and its contents are either clear fluid or a tooth-paste-like substance. It usually appears between the twentieth and twenty-fifth years but may occur in later life. It protrudes from beneath the anterior border of the upper third of the sternomastoid as a fluctuant swelling which may transilluminate. If infection has occurred, it may be difficult to differentiate from a tuberculous abscess. If the aspirated fluid contains cholesterol crystals, the diagnosis is made.

A rare variety of branchial cyst is found lying closely related to the pharynx. It is lined by columnar epithelium, and filled with mucus. Occasionally small symptomless cysts of this type are discovered at necropsy.

Treatment.—A branchial cyst should be excised. Through an incision parallel to the skin creases the anterior wall of the cyst is exposed and some of the content is aspirated. This procedure permits the wall of the cyst to be grasped in suitable forceps, and assists materially in a dissection which, in some instances, entails following a track that passes through the fork of the common carotid artery as far as the pharyngeal wall. It passes superficial to the hypoglossal and glossopharyngeal nerves but deep to the posterior belly of the digastric. The hypoglossal and the spinal accessory nerve may be in danger and should be recognised and protected. If the specimen is examined microscopically, the wall of the cyst is often found to be surrounded by a layer of lymphadenoid tissue. This suggests that the cyst arose as a result of branchial epithelium becoming entrapped within a lymph node during development. It also explains why branchial cysts become inflamed: the lymphadenoid shell participates in regional lymphadenitis.

Branchiogenic carcinoma is very rare; such a diagnosis is unjustifiable until every possible source of a primary growth in the mouth, pharynx, and external auditory meatus has been excluded.

Branchial fistula may be unilateral or bilateral (fig. 617) and it is highly probable that the fistula represents a persistent second branchial cleft, the occluding membrane of which has broken down. Nearly always the external orifice of the fistula is situated in the lower third of the neck near the anterior border of the sternomastoid muscle.

FIG. 617.—Bilateral branchial fistulæ; left side inflamed.

Branchial fistulæ which are clothed with muscle and lined by columnar ciliated epithelium, discharge mucus, and are often the seat of recurrent attacks of inflammation. In cases where the lining epithelium has been exposed to chronic infection for a long time, its characteristics are lost. When complete, commonly the internal orifice of the fistula is situated in the anterior aspect of the posterior pillar of the fauces, just behind the tonsil (Wilson). As a rule the track is incomplete and ends blindly in the region of the lateral pharyngeal wall; it is, therefore, strictly speaking, not a fistula, but a sinus. A branchial fistula is frequently a congenital condition, but it can be acquired. If a branchial cyst in an inflamed state is incised, the resulting sinus, which usually is situated in the upper or middle thirds of the neck, continues to discharge, either continuously or intermittently. The extent of the fistula can be determined by radiography following the injection of a radio-opaque medium.

Treatment.—When causing troublesome symptoms, e.g. by a discharge of mucus, branchial fistulæ should be excised.

Operation.—A ureteric catheter or a probe is passed up the track via the orifice, so that by means of an incision higher in the neck the track may easily be identified and dissected as it passes through the fork of the common carotid artery towards the pharyngeal wall. When the upper dissection is completed the orifice below is freed by a small elliptical incision and the whole of the lower part of the track can be eased out of the upper wound (Small) (fig. 618).

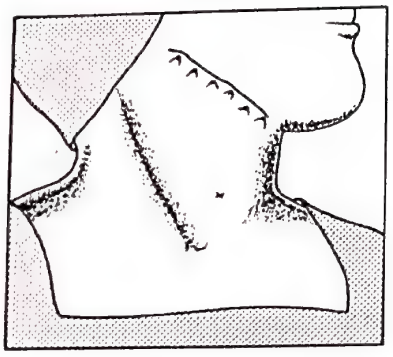

FIG. 618.—The catheter method of removing a branchial fistula, showing the lower elliptical incision marked by x.

Branchial Cartilage.—A small piece of cartilage, connected to the deep surface of a cutaneous dimple in the position of an external orifice of a branchial fistula, is occasionally encountered.

Cervical Auricle.—So named because of its morphological significance, this cutaneous projection is found almost invariably in the position of the external orifice of a branchial fistula. Cervical auricles were recognised in the days of the Roman Empire, and are represented in some of the statuary of that period.

Pharyngeal Pouch (p. 668)
Laryngocele (p. 684)
} are possibly derived from the branchial apparatus.

Cystic Hygroma (Cavernous Lymphangioma)

About the sixth week of embryonic life the primitive lymph sacs develop in mesoblast, the principal pair being situated in the neck between the jugular and subclavian veins; these, which correspond to the lymph hearts of lower animals, are known as the jugular lymph sacs. Sequestration of a portion of a jugular lymph sac from the lymphatic system accounts for the appearance of these swellings.

Of all the swellings of the neck, cystic hygroma rivals, and at times surpasses, sternomastoid 'tumour' as the earliest to appear: usually it manifests itself during early infancy, occasionally it is present at birth, and exceptionally it is so large as to obstruct labour. Typically, the swelling occupies the lower third of the neck, and as it enlarges it passes upwards towards the ear (fig. 619); often it is the posterior triangle of the neck that is mainly involved. Due to intercommunication of its many compartments, the swelling is softly

Charles Paul Wilson, 1900–1970. Surgeon, Ear, Nose and Throat Department, Middlesex Hospital, London.
Hugh Alan Dugleby Small, Contemporary. Formerly Surgeon, The Royal Northern Hospital, London.

cystic and is partially compressible; it visibly increases in size when the child coughs or cries, but *the* characteristic that distinguishes it from all other cervical swellings is that it is brilliantly translucent.

The cheek and the axilla are other, though less frequent, sites for a cystic hygroma. Another infrequent, though striking dual lesion is that of a cystic hygroma and a lymphangiogenetic macroglossia. Exceptionally a cystic hygroma occurs in the groin or in the mediastinum. When situated wholly within the thorax (Chap. 38), it cannot be differentiated, prior to operation, from other benign neoplasms.

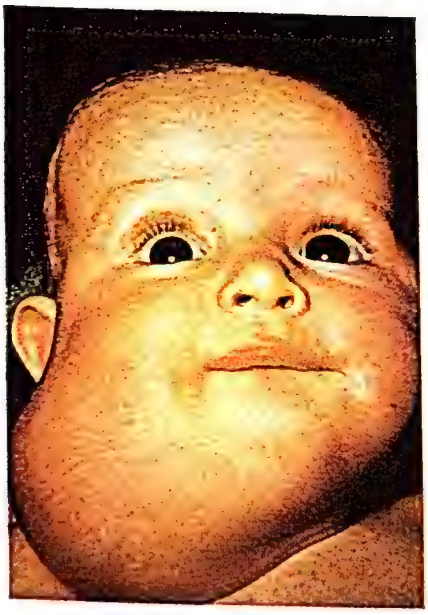

FIG. 619.—A cystic hygroma. (*Harold William Rodgers, F.R.C.S.*)

Pathology.—The swelling consists of an aggregation of cysts like a mass of soap bubbles. The larger cysts are near the surface, viz.: ——————→

while the smaller ones lie deeply and tend to infiltrate muscle planes. Each cyst is filled with clear lymph and is lined by a single layer of endothelium having the appearance of mosaic.

Clinical Course.—The behaviour of cystic hygromas during infancy is so uncertain that it is impossible at that age to prognosticate as to what will happen. Sometimes growth is extremely rapid and occasionally respiratory difficulty ensues, a contingency that demands immediate aspiration of much of the contents of the cysts and possible tracheostomy. At other times, as a result of nasopharyngeal infection, the swelling becomes inflamed and spontaneous regression of the cysts may then occur.

Treatment.—Excision of all the cysts at an early age is the treatment of election. It is often helpful to give preliminary injections, at weekly intervals, of boiling water into the cysts. The swelling will then slowly reduce in size and the cyst walls become more fibrous. Dissection is thus facilitated.

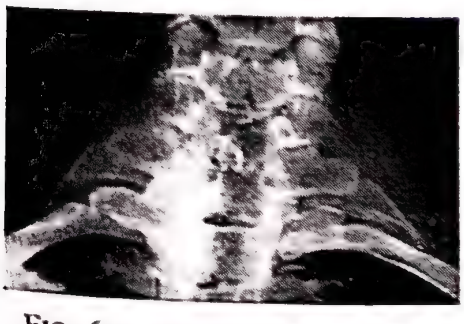

FIG. 620.—Cervical ribs that recurred after (subperiosteal) removal. Male aged forty-three years.

CERVICAL RIB AND THE SCALENE SYNDROME

By mass radiography it has been ascertained that a rib arising from the seventh cervical vertebra occurs in 0·46 per cent. of persons. In a little more than half of these the cervical rib is unilateral, and somewhat more frequent on the right side. It is paradoxical that a cervical rib or ribs found in the course of routine X-ray examination hardly ever gives rise to symptoms, whereas more often than not, when a radiograph of the cervical region is requested on account of nerve-pressure symptoms, no such rib is demonstrable.

Usually extra ribs spring from the seventh cervical vertebra (figs. 620 and 624) associated with spinal anomalies elsewhere.

Four main varieties of cervical rib are recognised:

(*a*) A complete rib, often containing a false joint in its length, articulates anteriorly with the manubrium or the first rib.——→

(*b*) The free end of rib expands into a large bony mass.——→

(*c*) A rib ending in a tapering point, which is connected by a fibrous band to the scalene tubercle of the first rib.——→

(*d*) A fibrous band closely applied to, or incorporated in, the scalenus medius alone is present. This not infrequent variety, of course, cannot be demonstrated radiologically.——→

At their exit from the neck, the branchial plexus and the subclavian artery pass through a narrow triangle (fig. 621). It is to the *base* of the triangle that attention must be focused.

Pathology.—Should the base of the triangle be raised the height of one vertebra by the interposition of a cervical rib, the subclavian artery and the first dorsal nerve are bound to be angulated, if not compressed, as they pass over the new floor, i.e. that formed by the cervical rib, instead of the first thoracic rib.

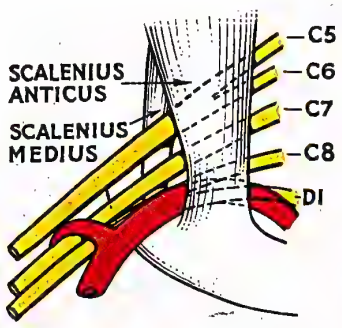

FIG. 621.—The anatomy of the parts concerned. (*After the late Professor Lambert Rogers, F.R.C.S., Cardiff.*)

FIG. 622.—A, showing the narrowing and post-stenotic dilatation of the vessel, with early thrombus formation; B, an embolus has been detached.

Pathology of the Vascular Symptoms.—Owing to the angulation over the cervical rib, the lumen of the artery at this site becomes constricted. *Pari passu* with the formation of the constriction, fusiform dilatation of the first 2 to 4 cm. of the artery occurs distal to the constriction (fig. 622A.) Within the post-stenotic dilatation (or possibly at the site of the constriction) clotting occurs on the intima. Portions of this mural thrombus may become detached, and give rise to an embolus (fig. 622B) or emboli. Also proximal extension of the thrombus can occur so that the vertebral artery may be involved and cerebrovascular embolic episodes occur[1]. (Shucksmith).

Pathology of the nerve-pressure symptoms is far less factual than the foregoing. It is surmised that the first dorsal nerve becomes similarly angulated and fibrosed.

Three clinical types are encountered:

1. **Cervical Rib with Local Symptoms.**—From time to time a patient

[1] Described by Sir Charles Symonds in 1927.

Henry Samuel Shucksmith, Contemporary. Formerly Surgeon, General Infirmary, Leeds, England.

presents on account of a lump in the lower part of the neck which may be visible, or, more commonly, because of tenderness in the supraclavicular fossa. On palpation the lump is found to be bony hard and totally fixed. Type (b), (p. 574), is most likely to give rise to these signs.

2. **Cervical Rib with Vascular Symptoms.**—*Vascular symptoms* occur only when a cervical rib is complete.

Pain is the prevailing symptom. It is located in the forearm, but in some instances it radiates to the upper arm. What is so characteristic is that the pain is brought on by use of the arm: should the arm be in a raised position at the time of exercising it, the onset of the pain is accelerated. The pain is relieved by rest. Without doubt, this pain is ischæmic muscle pain, comparable in all respects to intermittent claudication in the leg.

Temperature and Colour Changes.—Some observant patients notice that the hand on the affected side (*a*) is colder than its fellow, (*b*) becomes unduly pale when held aloft and (*c*) becomes unduly blue when it is dependent for any length of time. In any event the arm should be suitably positioned to ascertain if colour changes can be produced. At the same time the radial pulse should be sought. Sometimes it is as full as that of the other side; sometimes it is absent, and at others it is feeble, depending upon whether the collateral circulation is good, bad or indifferent. The distal part of the subclavian artery should be auscultated ; a systolic bruit is significant.

FIG. 623.—Cervical rib with vasomotor symptoms, culminating in gangrene of the index finger. (*Telford and Stopford, Manchester.*)

Numbness of the fingers may be complained of, in which event trophic changes with ulceration or, more rarely, gangrene (fig. 623) are liable to ensue. In these patients it is not unusual for the brachial, as well as the radial, pulse to be imperceptible, and arteriography may show that the greater part of the brachial artery is occluded.

Treatment is timely extraperiosteal excision of the cervical rib, together with any bony prominence of the first rib. At the same time it is advisable to perform sympathetic denervation of the upper limb.

3. **Cervical Rib with Nerve-Pressure Symptoms.**—Nerve-pressure symptoms, due to angulation of the first dorsal nerve is of doubtful occurrence and most, if not all, cases previously described were due to cervical spondylosis (p. 472) or the carpal tunnel syndrome (p. 295). Only if these and other localised nerve lesions are excluded, should the scalene syndrome be considered as the cause of pain and tingling in the hand and forearm, whether wasting of the thenar and hypothenar muscles is present or not.

Differential Diagnosis.—When nerve-pressure symptoms are present

the differential diagnosis must be made from progressive muscular atrophy, syringomyelia, and peripheral nerve injury. Above all, newer pathological concepts must be taken into consideration. First, many of the nerve-pressure symptoms formerly attributed to a cervical rib can be, and are, produced by pressure on the cervical roots in the region of the intervertebral foramina by lateral protrusion of intervertebral discs. Secondly, paræsthesia and wasting of the thenar eminence are often due to carpal tunnel syndrome (p. 295). Thirdly, hypothenar wasting can also arise from angulation of the ulnar nerve behind the elbow (Griffiths).

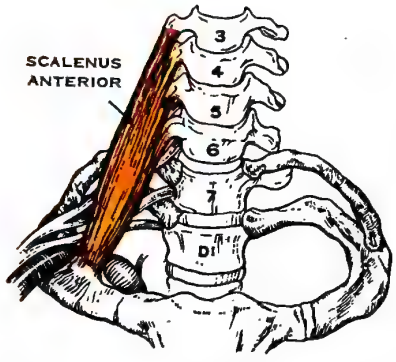

FIG. 624.—Showing the rational of scalenotomy.

Treatment.—In mild cases the use of a sling and exercises aimed at strengthening the muscles of the shoulder girdle may alleviate the symptoms, at least temporarily. In about 70 per cent. of cases even if a cervical rib cannot be recognised, the symptoms are relieved by dividing the scalenus anterior (scalenotomy) (fig. 624). Other surgeons remove the cervical rib or the corresponding band in addition, and in this way reduce the number of unsatisfactory results. When a cervical rib is excised, it is essential to remove it with its periosteum or it will probably regenerate (fig. 620).

INJURIES

Cut Throat.—In more than half the cases of cut throat that reach surgical aid the wound does not involve any vital structure—only the skin, platysma, and perhaps the sternomastoid or other muscles are severed.

Wounds above the Hyoid Bone.—Quite often it will be found that the cavity of the mouth has been entered. The epiglottis is often partially divided near its base. This should be repaired with catgut sutures. The mucosa of the pharynx is trimmed and united. Skin closure can then be undertaken.

Wounds of the Thyrohyoid Membrane.—Again the epiglottis is often damaged. The severed thyrohyoid membrane can usually be sutured. If there is respiratory distress, it is advisable to perform tracheostomy.

Division of the Thyroid Cartilage.—The thyroid cartilage can be repaired with sutures, provided these are not tied tightly, for a stitch through cartilage tends to cut out. Tracheostomy is usually indicated.

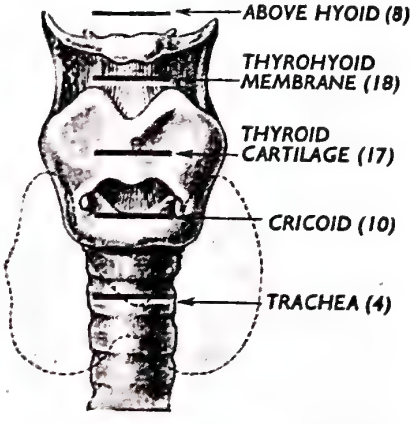

FIG. 625.—Position of the wound into the air passages of fifty-seven cases of suicidal cut throat with a deep wound.

Wounds about the Cricoid Cartilage.—Tracheostomy should be performed. The larynx is repaired with interrupted sutures, and after debridement the wound is closed with drainage.

Division of the Trachea.—Wounds of the trachea are comparatively rare. In order to obtain adequate exposure it is usually necessary to divide the thyroid isthmus between hæmostats. In most instances it is advisable to perform tracheostomy below the wound, and then to proceed to repair the latter with sutures.

Injury to Nerves.—It is remarkable how rarely important nerves are injured in self-inflicted wounds. In stab wounds any nerve may be involved (fig. 149). In one

David Lloyd Griffiths, Contemporary. Director, University Department of Orthopædic Surgery, Royal Infirmary, Manchester, England.

of our patients, a sailor, the most inaccessible nerve in the neck; the cervical sympathetic, was divided in this way, the assailant's weapon being a small penknife.

Complications of Cut Throat

1. **Loss of Blood.**—If the hæmorrhage has been severe, dextran, plasma, or blood transfusion is indicated.

2. **Air Embolus.**—In cases encountered in medico-legal practice the cause of death is frequently venous air embolism.

3. **Infection of the wound** is not very frequent, but these wounds should always be drained as they have been inflicted with a potentially infected instrument. Cellulitis sometimes supervenes, and this may spread to the mediastinum.

4. **Pneumonia.**—In spite of antibiotic therapy, pneumonia is a relatively common complication, especially in those cases where the air passages have been opened.

5. **Aerial Fistula.**—A persistent communication between the air passages and the exterior is likely to occur when there has been actual loss of substance of the larynx or trachea. In suitable cases a plastic operation may be undertaken.

6. **Stenosis of the Larynx or Trachea.**—Due to cicatrisation; rarely it necessitates permanent tracheostomy.

7. **Œsophageal Fistula.**—Œsophageal or pharyngeal fistula is a very rare occurrence, and it tends to heal spontaneously.

8. **Surgical emphysema** is another rare complication, and it usually occurs when a tracheostomy tube has been omitted in the treatment of the case.

9. **Aphonia or dysphonia** may follow injury to the vocal cords or division of a recurrent laryngeal nerve.

WOUNDS OF THE CERVICAL PORTION OF THE THORACIC DUCT

Wounds of the thoracic duct are rare, and usually occur during dissection of lymph nodes in the left supraclavicular fossa. When the accident is not recognised at the time, chyle pours from the wound—as much as 1 to 1·5 litre in twenty-four hours—and, as a result, the patient wastes rapidly.

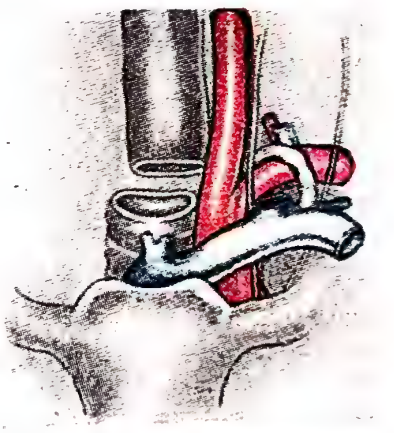

FIG. 626.—The termination of the thoracic duct.

Treatment.—Should the accident be recognised during an operation, the proximal end of the duct must be ligated with fine silk. Ligation of the duct is not harmful, for there are a number of anastomotic channels between the lymphatic and the venous systems in the neighbourhood. Usually the first intimation of a severed thoracic duct is a copious chylous discharge from the wound on the day following the operation. That the fluid *is* chyle is substantiated if it has a specific gravity of over 1·012 and if fat can be extracted from it with ether. Firm pressure by a pad and bandage should be applied, but this simple expedient may not be successful. More often the wound must be reopened. If the patient is given cream to drink an hour before the operation, more especially if the cream is coloured with confectioners' green dye (D-C 6), there is seldom any difficulty in locating a cut thoracic duct, which is about the size of a straw and an immediate external relation of the last 3·75 cm. of the left internal jugular vein (fig. 626). If the duct is found, it should be ligated, but in any case the wound should be packed firmly and allowed to heal by granulation. Thanks to subsidiary anastomotic channels, these measures are regularly satisfactory.

INFLAMMATORY CONDITIONS

Acute cellulitis is either superficial or deep to the deep cervical fascia.

Superficial cellulitis is common, and methods of treating it follow that of cellulitis elsewhere. When, however, it occurs above the level of the hyoid

bone it is especially dangerous, because sudden asphyxia from œdema of the glottis is an ever-present possibility.

Deep cellulitis in the lower third of the neck, on the other hand, is free from this danger. Consequently, it can be treated by antibiotic therapy with every confidence, and should an abscess develop, it is opened.

FIG. 627.—Ludwig's angina. The brawny swelling beneath the mandible and the œdema of the floor of the mouth are characteristic.

Ludwig's Angina.—Ludwig described a clinical entity characterised by a brawny swelling of the submandibular region combined with inflammatory œdema of the mouth. It is the *combined* cervical and intrabuccal signs that constitute the characteristic feature of the lesion (fig. 627). The cause is a virulent (usually streptococcal) infection of the cellular tissues surrounding the submandibular salivary gland. It may be a complication of advanced carcinoma of the floor of the mouth.

Clinical Course.—Unless the infection is controlled, these cases may rapidly assume a grave aspect. The swollen tongue is pushed towards the palate and forwards through the open mouth, while the cellulitis extends down the neck in that most dangerous plane—deep to the deep fascia.

Ludwig's angina is an infection of a closed fascial space, and, untreated, the inflammatory exudate often passes via the tunnel occupied by the stylohyoid to the submucosa of the glottis, in which event the patient is in imminent danger of death from œdema of the glottis (p. 679).

Treatment.—When the condition is diagnosed early, the results of antibiotic therapy are sometimes dramatic. In cases where the swelling, both cervical and intrabuccal, does not subside rapidly with such treatment, a curved incision beneath the jaw, as is shown in fig. 628, is made. The incision is deepened, and after displacing the superficial lobe of the submandibular salivary gland, the mylohyoid muscles are divided. This decompresses the closed fascial space referred to. The wound is lightly sutured and drained. The operation can be conducted with the greatest safety under local anæsthesia. Thiopentone anæsthesia usually precipitates laryngeal spasm and asphyxia.

Infection of the Pharyngo-maxillary Space (*Parapharyngeal Abscess*). — The pharyngo-maxillary space is a potential cone-shaped space, base uppermost. The base is formed by the base of the skull; the apex abuts the great cornu of the hyoid bone; the medial wall consists of the superior constrictor muscle; the lateral wall, from above downwards, is composed of the fascia covering the internal pterygoid muscle, the mandible about its angle, and the submandibular salivary gland, below which the apex of the space becomes relatively superficial. Usually infection of this space originates in the tonsil, and may occur after tonsillectomy, especially when the operation has been performed under local anæsthesia.

FIG. 628.—Incision for decompressing thoroughly the space beneath the mylohyoid muscle.

Clinical Features.—Every posterior, peritonsillar abscess is a potential pharyngomaxillary space infection, the general reaction of which is greater than that accompanying peritonsillar abscess. There is often *slight* trismus, and swelling over the lower part of the parotid gland; this is never present in quinsy. Tenderness, and later swelling below the angle of the mandible, appears when the apex of the space is involved. As the carotid sheath runs through the space, the dreaded complications of thrombophlebitis of the internal jugular vein and/or erosion of an artery, usually the internal carotid, may occur if the space is not adequately drained. Sometimes the abscess

Wilhelm von Ludwig, 1790–1865. Professor of Surgery and Midwifery, Tübingen, Germany.

bursts spontaneously between the cartilaginous plates of the external auditory canal, but obviously such an eventuality is a fortunate escape from death, for which the patient's medical advisers can take no credit.

Treatment.—As soon as the diagnosis is strongly suspected an incision should be made below and behind the angle of the mandible, on a line towards the hyoid bone. A finger is passed upwards, medial to the mandible and the distended space is entered by rupturing its wall. The space is drained with a large soft wick drain.

CERVICAL LYMPHADENITIS

There are approximately 800 lymph nodes in the body; no fewer than 300 of them lie in the neck (fig. 629). Inflammation of the lymph nodes of the neck is exceedingly common. Infection occurs from the oral and nasal cavities, the ear, the scalp, and face. The source of infection must be sought for systematically.

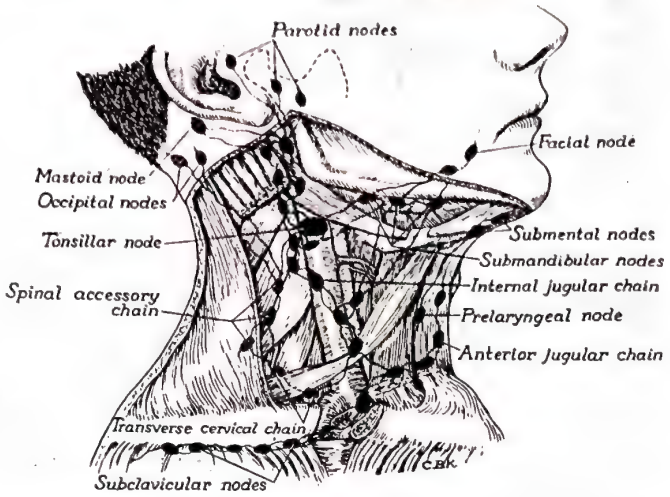

FIG. 629.—The lymphatics of the facio-cervical region. (*After Murry M. Copeland.*)

Acute Lymphadenitis.—The affected lymph nodes are enlarged and tender, and there is a varying degree of pyrexia. The treatment, in the first instance, is directed to the general condition and to the focus of infection, the neck itself being simply protected by a bandage over wool. If, in spite of antibiotic therapy, pain continues or certain lymph nodes appear to be getting larger, fomentations are applied locally. Abscess formation calls for adequate drainage.

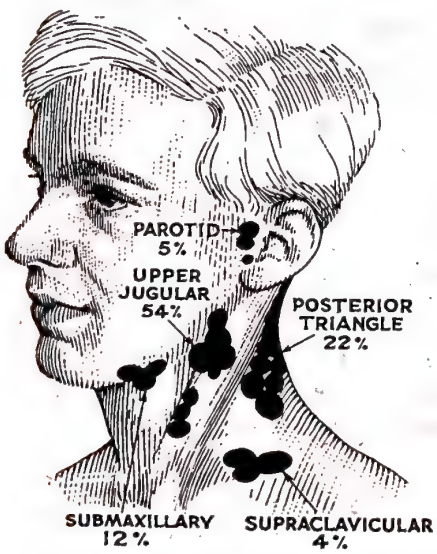

FIG. 630.—Groups of cervical lymph nodes infected by tuberculosis, founded on 372 consecutive cases. The 3 per cent. not labelled are divided between the mid-jugular group (shown) and the submental group (not shown).

Chronic Lymphadenitis.—In the early stages it is extremely difficult to distinguish tuberculous adenitis from chronic non-tuberculous adenitis, but clinical experience shows that chronically inflamed lymph nodes which do not resolve in the space of three or four weeks are nearly always tuberculous.

Tuberculous adenitis (p. 177).

The majority of patients affected are children or young adults, but the condition can occur for the first time at any age. Usually one group of cervical nodes is first infected (fig. 630), most frequently those of the upper jugular chain. More rarely there is widespread cervical lymphadenitis, and in these cases especially, periadenitis or matting of the lymph nodes is evident.

Source of Infection.—In the majority of instances tubercle bacilli gain entrance through the tonsil of the corresponding side. The frequency (22 per cent.) with which

the nodes of the posterior triangle are infected is more difficult to explain. Seeing that some of the lymphatic vessels from the adenoid area pass directly to the lymph nodes of the posterior triangle, it is probable that airborne infection reaches them through this often-diseased filter.

Contrary to what is believed generally, it is the human,[1] and not the bovine, bacillus that is responsible for tuberculous cervical adenitis in about 70 per cent. of cases. In fully 80 per cent. of cases the tuberculous process is virtually limited to the clinically affected group of lymph nodes; nevertheless, especially in widespread adenitis and in that occurring in the supraclavicular fossæ, a primary focus in the lungs must be suspected. Renal tuberculosis may co-exist and the urine should be examined for this organism.

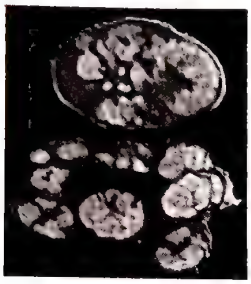

FIG. 631.—Caseating tuberculous lymph nodes.

In the event of the patient developing a natural resistance to the infection or (more often) as a result of appropriate general treatment, fibrosis or calcification may occur. In other circumstances the caseating material (fig. 631) liquefies, breaks through the capsules of the lymph nodes, and a 'cold abscess' forms. The pus is at first confined by the *deep* cervical fascia. In a few weeks this dense sheet becomes eroded at one point, and the pus flows through the small opening into that more commodious space beneath the *superficial* fascia. The process has now reached the well-known stage of collar-stud abscess (fig. 632 and p. 178). The superficial abscess enlarges steadily, and unless suitable treatment is adopted, the skin will soon become reddened over the centre of the fluctuating swelling, and before long a discharging sinus, with its attendant evils, is at hand[2].

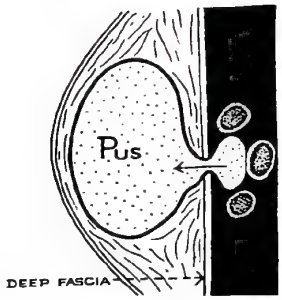

FIG. 632.—Showing the abscess and the source of the pus beneath the deep fascia.

DIFFERENTIAL DIAGNOSIS

When the swelling is solid, from:
- Chronic non-tuberculous lymphadenitis
- Hodgkin's disease (p. 180).
- Reticulo-sarcoma.
- Secondary malignant disease.

When the swelling is cystic, from:
- Branchial cyst.
- Extension of an abscess connected with a tuberculous cervical vertebra.

When a sinus or sinuses have formed, from:
- Actinomycosis.
- An acquired branchial fistula.

TREATMENT OF TUBERCULOUS LYMPHADENITIS

General Treatment.—The patient should be treated by general measures and appropriate chemotherapy (p. 32). If an abscess is present it should be

[1] The human bacillus is responsible for 100 per cent. of cases among the Bantu-speaking urban population of South Africa (Keen).

[2] For 600 years the King's touch was believed to cure this prevalent disease. Charles II touched on an average 10,000 sufferers a year. In addition, he presented each with half a sovereign. The condition was known as the King's Evil.

Paul Keen, Contemporary. Formerly Senior Surgeon, Non-European Hospital, Johannesburg, South Africa.

aspirated and an attempt should be made to grow the tubercle bacillus and find out its sensitivity to the anti-tuberculous drugs (p. 32).

Contraindications to Operative Treatment.—When there is active tuberculosis of another system, e.g. pulmonary tuberculosis, removal of tuberculous lymph nodes of the neck is, of course, illogical. In cases where enlarged lymph nodes are not confined to one region in the neck, where there is much periadenitis, or any discharging sinuses, operative treatment is best avoided, at any rate for several months, during which time sanatorium treatment is advised. Repeated aspiration of a collar-stud abscess cannot be recommended unless the patient is under constant supervision in a sanatorium, because so frequently this predisposes to sinus formation and secondary infection.

Operative Treatment.—When the patient's general condition has improved any lymph node thought to be caseating should be removed. In the majority of cases the tuberculous process is limited to one group of lymph nodes. For this type, extirpation of the affected nodes through an oblique incision (fig. 618), conforming with the skin creases, gives rapid and eminently satisfactory results.

If the nodes are related to the internal jugular vein this structure should be identified first and then the nodes can be dissected away from it.

To minimise unnecessary injury to large veins, no tissue should be divided when stretched taut. Should the internal jugular vein prove to be involved to such an extent that freeing it is difficult or impossible, this great vessel can be ligated, or a portion of it can be resected, without any untoward effect at any age (cf. block dissection of the neck, p. 584).

There is no contraindication to dividing the sternomastoid muscle if, as is frequently the case, such a step facilitates access to the diseased nodes and enables the operator to visualise the spinal accessory nerve more easily. The divided muscle is subsequently reunited.

During the dissection of cervical lymph nodes no effort should be spared to preserve: the spinal accessory nerve; the mandibular branch of the facial nerve; the hypoglossal nerve; which are the nerves most likely to be injured.

Operation for collar-stud abscess.—After mopping away the pus in the superficial compartment of the abscess the hole in the deep fascia is enlarged to admit a small curette. The caseating lymph node beneath is scraped out and the cavity packed with iodoform ribbon gauze, brought out at the edge of the wound which is closed by careful primary suture.

A full excision of the matted lymph-nodes may be required later but this depends upon the result of chemotherapy.

Actinomycosis of the Neck (See p. 34).

PRIMARY MALIGNANT TUMOURS OF THE NECK

Carotid Body Tumour ('Potato' Tumour).—The carotid body, which is situated at the bifurcation of the carotid artery, is the most important moiety of the chemoreceptor system (fig. 633). The cells of this system are sensitive to changes in the hydrogen ion concentration and temperature of the blood.

Pathology.—Histologically a non-chromaffin paraganglioma, a carotid body tumour is now classified as a chemodectoma. The former belief that this tumour is benign has been dissipated. Although, as a rule, the tumour remains localised for years,

eventually regional metastases occur in about 20 per cent. of cases, and distant metastases somewhat less frequently.

Clinical Features.—A carotid body tumour is considered difficult to diagnose because, contrary to expectation, it often exhibits less transmitted pulsation than the solid lumps from which it has to be differentiated. Usually unilateral, the tumour first becomes apparent in middle life, and increases in size very slowly; indeed, it behaves like a mixed parotid tumour (p. 564). Unfortunately, as a rule the lump is at least the size of a plum before the patient seeks advice. The diagnosis is suggested by a long history, a mass at the carotid bifurcation which moves from side to side but not vertically and, usually, a pulsating vessel (external carotid) over its outer surface (Westbury).

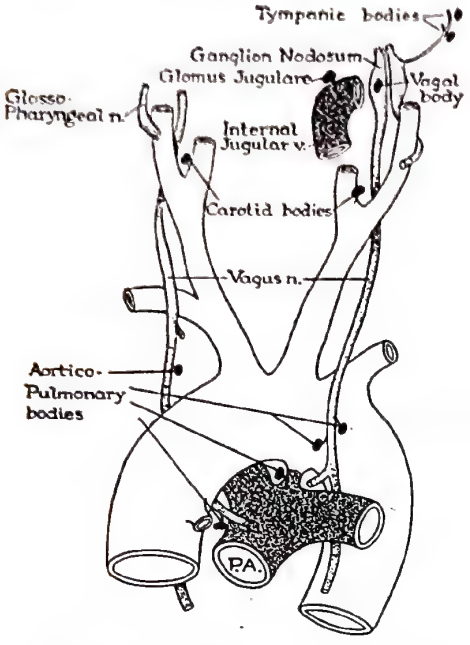

FIG. 633.—Sites where chemodectomas are known to occur. In addition, they have been found in the orbit, along the course of the inferior alveolar artery, and in proximity to the femoral artery. (*After S. O. Burman.*)

The Special Danger of Excision of a Carotid Body Tumour.—While recurrence after complete excision is most unusual it is important to realise that if the tumour is large it is probably so blended with the carotid tree that removal is impossible without resecting the fork of the carotid artery (fig. 634), and unless special precautions are taken (see below), ligation of the internal carotid artery is followed by death or hemiplegia in 33 per cent. of cases (Lahey).

Arteriography is valuable and usually shows the carotid fork to be splayed and a mass of abnormal tumour vessels are outlined. Confirmation by *open biopsy* may be necessary as the operation carries the risk of carotid artery damage.

Treatment.—Hardly any of these tumours are radiosensitive. Extirpation should therefore be carried out in all cases except in the old and enfeebled, in whom it may be decided that it is best to let Nature take her course. The tumour is explored through an ample incision:

1. In some cases it can be separated from the fork of the carotid artery by blunt and sharp dissection, and so removed.

2. In some cases excision can sometimes be effected in the manner shown in fig. 635. Should an artery be wounded in the process it can, on occasions, be repaired, but a temporary bypass, using silastic tubing, may be required.

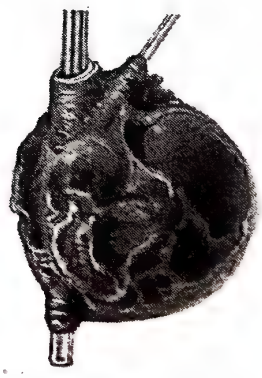

FIG. 634.—Carotid body tumour removed successfully.

3. When the tumour is large and inseparable from the fork of the carotid artery, resection with the arteries, as is shown in fig. 634, must be carried out. It is essential to maintain the blood supply to the brain and a graft—autogenous vein—between the common and internal carotid will be required. A temporary by-pass is necessary while the graft is being inserted, and hypothermia 29–30°C. may be helpful as it reduces the oxygen requirements of the brain.

Frank Howard Lahey, 1880–1953. Professor of Surgery, Harvard University, and Founder of the Lahey Clinic, Boston, Massachusetts, U.S.A.

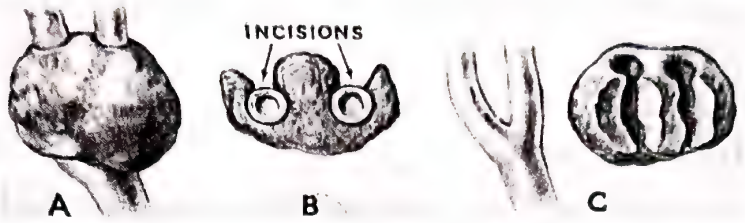

FIG. 635.—The tumour is split in the manner shown, so that it can be dissected from the arteries it envelops.
(*After T. Farrar et al.*)

Hodgkin's Disease (syn. Lymphadenoma in neck), see p. 180.

Reticulosarcoma (including Lymphosarcoma in neck) see p. 179.

SECONDARY CARCINOMA OF THE NECK

Secondary carcinomatous infiltration of the cervical lymph nodes is only too common. When a patient presents with enlargement of cervical lymph nodes that are suspiciously indurated, search for a primary growth is imperative and must be made *before* a node is removed for biopsy. Often the primary growth lies within the buccal cavity; when this is not the case, the search must continue. Among the sites that are prone to be overlooked are the nasopharynx, pharynx and cervical œsophagus, the paranasal sinuses, external auditory meatus, the bronchi, the breast, the stomach, and the testes.

Management.—In so far as cervical lymph nodes are concerned, patients with oral, laryngeal, or facial carcinoma can be categorised as follows:

Stage 1.—*Those without clinical evidence of metastases.* These patients are kept under careful (bi-monthly) observation, dissection of the neck being withheld unless the nodes become palpable. Exceptions to this rule are (1) melanoma, (2) papilliferous carcinoma of the thyroid, and (3) possibly cases of carcinoma of the tongue (see remarks under (*e*), p. 554).

Stage 2.—*Those with palpable cervical lymph nodes where the primary growth is operable,* or can be destroyed with radium. It should be noted carefully that lymph node enlargement, especially when the primary growth is foul, is not necessarily carcinomatous. After removal of the primary neoplasm a period of non-intervention and antibiotic therapy will determine whether or not the enlargement subsides. In the latter event block dissection of the neck is indicated, provided, of course, there is no clinical or X-ray evidence of distant metastases, and the involved cervical nodes have not progressed to a stage where it seems unlikely that they can be encompassed. Adherence to the mandible, or to the larynx, or to the skin, should not be regarded as constituting inoperability, for each of these structures can be sacrificed, provided the patient's general condition is such as to be able to withstand either of these procedures, which are extremely formidable.

Stage 3.—*Those in whom the primary growth is inoperable* or otherwise incurable, and/or the cervical metastases are fixed to deeper structures, and/or distant metastases are present. Palliative deep X-ray treatment is sometimes indicated, or the malignant swelling can be treated by insertion of radioactive gold seeds. The latter course gives minimum discomfort to the

patient and, although only palliative, can effectively reduce the size of the tumour and relieve pain. There is always the risk that high dosage of irradiation will cause necrosis of the mandible or the laryngeal cartilages.

Block dissections of the neck

1. **Crile's block dissection** is conducted through the wide display afforded by specially placed skin incisions (fig. 636).

The skin flaps having been dissected up, the sternomastoid is divided about 2·5 cm above the clavicle. The muscle is freed and retracted upwards. Next, the internal jugular vein is divided between ligatures low down in the neck. The dissection proceeds upwards methodically and the muscle, fascia, fat, lymph nodes, the internal jugular vein, together with the submaxillary salivary gland, are dissected and removed *en bloc*. Attention must be directed to clearing the space between the parotid and the great vessels, and also the submental triangle between the hyoglossi,

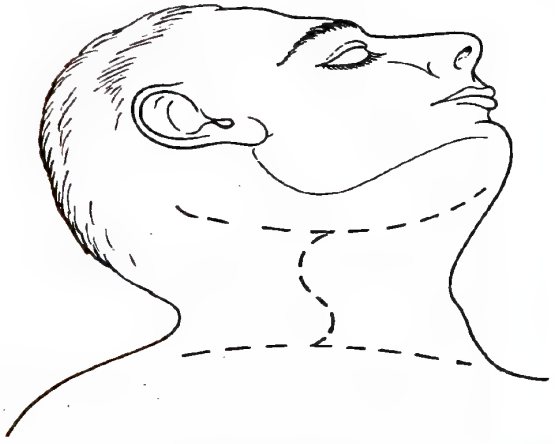

FIG. 636.—An incision for block dissection of the neck.

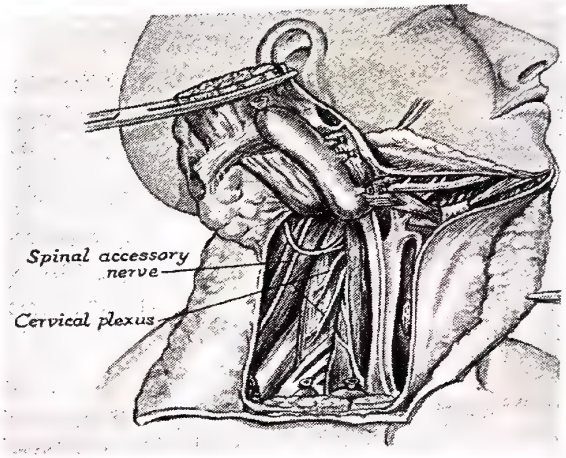

FIG. 637.—Crile's block dissection of the neck nearing completion. (*After W. W. Carroll.*)

for it is in these areas that a lymph node can easily be overlooked. Bleeding vessels are ligated as they occur; finally the upper end of the internal jugular vein is ligated by transfixion, and divided. When the dissection has been completed, the carotid artery is laid bare, and lying with it is the vagus nerve, which has been carefully preserved. The operation aims at removing the whole of the lymphatic-bearing tissues on the affected side of the neck (fig. 637). The skin flaps are approximated and the wound drained. Surprisingly little deformity follows this extensive dissection, but the neck is stiff and there is drooping of the corner of the mouth. (The cervical branch of the facial nerve is severed.) When *bilateral* block dissection is required it must be undertaken, not simultaneously, but consecutively with an interval of about three weeks. Experience has shown that removal of both internal jugular veins is not attended by as much obstructed cerebral circulation as was previously conjectured.

2. **Suprahyoid block dissection** of the neck is indicated in cases of carcinoma of the lower lip, early cases of carcinoma of the tip of the tongue, and carcinoma of the floor of the mouth. Its advantage is that both sides of the neck can be attended to at one operation. Sometimes a unilateral suprahyoid block dissection is indicated combined with a Crile's block dissection of the opposite side.

George Washington Crile, 1864–1943. Professor of Surgery, Western Reserve University, and one of the Founders of the Cleveland Clinic, Cleveland, Ohio, U.S.A.

During these operations it is advisable to transfuse an amount of blood proportional to the estimated loss. Usually tracheostomy is required only when a monobloc (commando, p. 554) operation is to be performed; in other circumstances tracheostomy should be avoided when possible, because it heightens the incidence of wound infection. Should it be necessary to keep the bronchial tree free from accumulating secretions during the post-operative period, this contraindication must be over-ridden.

Post-operative Treatment.—Suction-drainage of the wound for two or three days is best, for it reduces to a minimum the possibility of accumulated blood and blood-clot pressing on the larynx and trachea. Blood transfusion is continued for as long as is deemed necessary, and antibiotic therapy is given as a routine prophylactic measure.

The mortality of cervical-block dissection is, with modern anæsthesia which has done so much to facilitate it, about 3 per cent. The over-all five-year survival rate is 35 per cent.

CHAPTER 33

THE THYROID GLAND AND THE THYROGLOSSAL TRACT

SURGICAL ANATOMY AND PHYSIOLOGY

Embryology.—The thyroid gland is developed from the median bud of the pharynx (the thyroglossal duct) which passes from the foramen cæcum at the base of the tongue to the isthmus of the thyroid. The ultimo-branchial body which arises from a diverticulum of the fourth pharyngeal pouch of each side amalgamates with the corresponding lateral lobe, and parafollicular cells (C-cells) are derived from this bud. It is doubtful whether the branchial apparatus contributes to the thyroid follicular cells.

Surgical Anatomy.—The normal gland weighs 20–25 g. The functioning unit is the lobule supplied by a single arteriole and consisting of 20–40 follicles which are lined by cubical epithelium. The resting follicle contains colloid in which thyroglobulin is

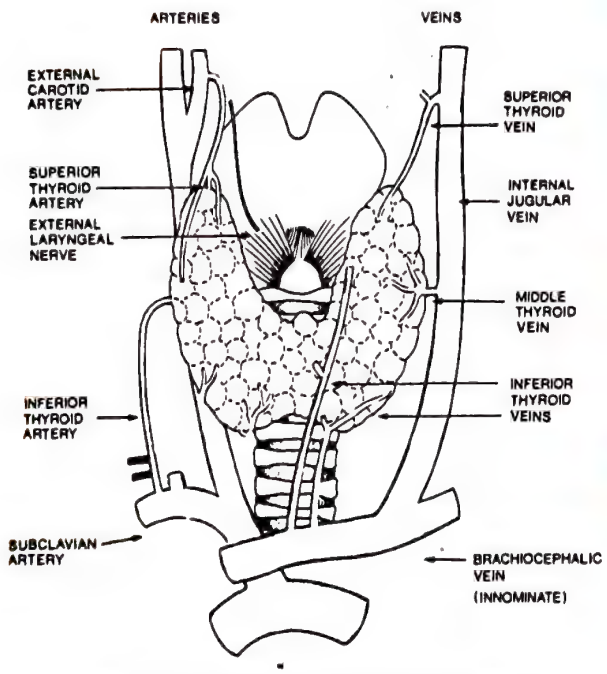

FIG. 638.—The thyroid gland from the front.

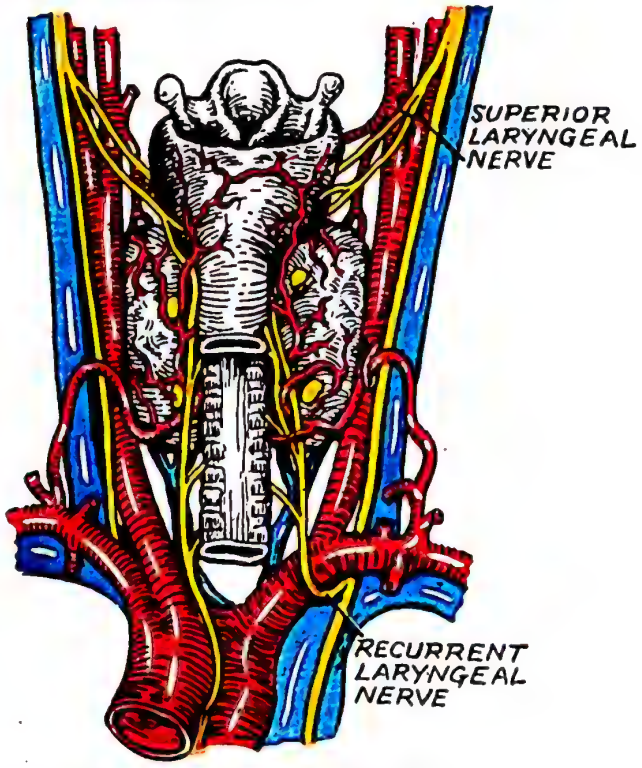

FIG. 639.—The thyroid gland from behind, showing the laryngeal nerves and the four parathyroids. (*After Martin Norland.*)

stored. The arterial supply is rich, and extensive anastomoses occur between the main thyroid arteries and branches of tracheal and œsophageal arteries (figs 638 and 639). There is an extensive lymphatic network within the gland. Although some lymph channels pass directly to the deep cervical nodes, the subcapsular plexus drains principally to the juxtathyroid nodes—i.e. pretracheal (Delphic)[1] and paratracheal

[1] Pythia, the snake-woman oracle of Delphi, sat on her tripod, clutching the ribbons of the monolithic ' omphalos ' of the world. She inhaled sulphurous fumes and laurel, and uttered a meaningless jargon which was interpreted equivocally by the attendant priests for those who came to consult her. Formerly, the meaning of these lymph nodes was uncertain and they were therefore called ' Delphic '.

nodes, and nodes on the superior and inferior thyroid veins, and thence to the deep cervical and mediastinal group of nodes.

Physiology.—The hormones tri-iodo-thyronine (T^3) and thyroxine (T^4)[1, 2] are bound to thyroglobulin within the colloid. Synthesis within the thyroglobulin complex is controlled by several enzymes, in distinct steps: (1) Trapping of inorganic iodide from the blood. (2) Oxidation of iodide to iodine, and binding of iodine with tyrosine to form iodotyrosines. (3) Coupling of mono-iodotyrosines and di-iodotyrosines to form T^3 and T^4. (4) When hormones are required thyroglobulin is broken down; T^3 and T^4 are liberated and enter the blood where they are bound to serum proteins. A small amount of hormone remains free in the serum in equilibrium with the protein bound hormone and is biologically active. T^3 is quick acting (within a few hours) whilst T^4 acts more slowly (4–14 days). T^3 is the more important physiological hormone.

Thyrocalcitonin (see calcitonin, p. 619).

The Pituitary Thyroid Axis (fig. 640)

Synthesis and liberation of thyroid hormones from the thyroid is controlled by thyroid stimulating hormone (T.S.H.) from the anterior pituitary. Secretion of T.S.H. depends upon the level of circulating thyroid hormones. In hyperthyroidism, where hormone levels in the blood are high, T.S.H. production is suppressed, whilst in hypothyroidism it is stimulated.

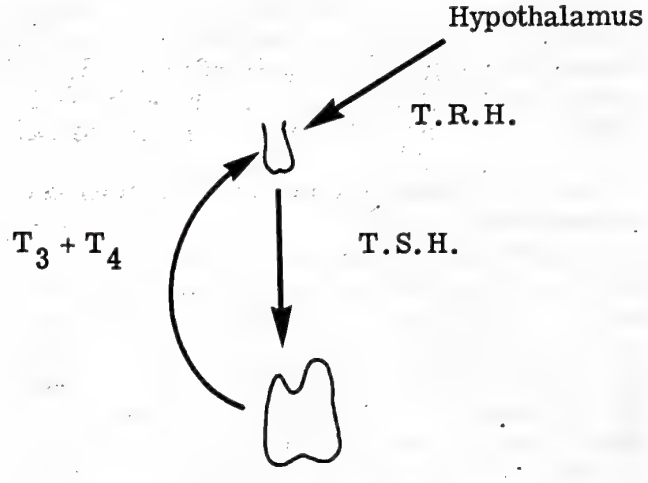

FIG. 640.—The pituitary-thyroid feedback mechanism. Thyrotrophin releasing hormone (T.R.H.) from the hypothalamus, stimulates secretion of T.S.H. by the anterior pituitary, but its precise role in the feedback mechanism is, as yet, uncertain.

Long-acting Thyroid Stimulator (L.A.T.S.)

This is an IgG immunoglobulin which acts as an antibody to certain particulate thyroid antigens. Its action on thyroid cells is similar to T.S.H. but the duration of the stimulus is more prolonged and it is estimated to produce its maximum effect after 16–24 hours as compared with 1·5 to 3 hours for T.S.H. It is measured by a mouse bioassay system and can be detected in the sera of many hyperthyroid patients (figures vary from 14% to 76%). At least one other abnormal thyroid stimulator has been identified which is specific for human thyroid tissue and hence not detected by the previously used mouse bioassay. This is L.A.T.S.—protector—, also called Human Specific Thyroid Stimulator. Other abnormal stimulators probably exist.

These Thyroid Stimulating Immunoglobulins—as they have been called—are now thought to be responsible for all cases of hyperthyroidism not due to autonomous toxic nodules.

TESTS OF THYROID FUNCTION

The principal value of these tests is in assessing the thyroid status when the clinical picture is equivocal. However, even if the clinical diagnosis appears quite certain, it is valuable to have confirmatory evidence to look back upon should doubt as to the diagnosis arise at a later date. Several parameters[3] should be obtained because no single test is conclusive.

---

[1] Extracted by E. C. Kendall in 1916.

[2] Therapeutic Notes—L-thyroxine (T^4) is the official name; trade name Eltroxin; tablet size 0·1 mg. and 0·05 mg. Tri-iodothyronine (T^3), official name lio-thyronine, trade names, Cynomel, Tertroxin. Tablet size 20 μg.

[3] A parameter is any yard-stick or independent variable.

Edward Calvin Kendall, 1886–1972. Professor of Physiological Chemistry, Mayo Clinic, Rochester, Minnesota, U.S.A.

1. Measurement of Thyroid Hormones in the Serum

(a) Serum Protein Bound Iodine (P.B.I.).
(b) Total Serum Thyroxin (T^4).
(c) Total serum Tri-iodo-thyronine (T^3).
(d) Free Serum Thyroxin (T^4).

The iodine containing hormones T^3 and T^4 are transported in the plasma mainly by specific binding proteins, Thyroxine binding globulin (T.B.G.), and by Thyroxine binding prealbumin. As only a small amount of T^3 and T^4 are free in the blood the P.B.I. effectively represents total circulating Thyroid hormones. The euthyroid[1] range is 3·5–8 μg per 100 ml (280–640 nmol/l). False low results are due to lowering of T.B.G. hereditary, androgens or nephrotic syndrome. False high results are due to iodine contamination, e.g. X-ray contrast media and expectorants containing potassium iodide: also to pregnancy and oral contraceptives, when thyroid binding proteins in the serum are increased.

The Total Serum T^4 (normal range 3·0–7·5 μg per 100 ml (60–160 nmol/l)) is not subject to the inaccuracies of the Serum P.B.I., but measurement is more difficult. It will eventually replace the Serum P.B.I. The Total Serum T^3 and the Free Serum T^4 (both measured by radio-immuno assay) are available only in special laboratories, but they will eventually become routine tests, for two reasons—(i) Some cases of hyperthyroidism (T^3—toxicosis) are due to excessive production of T^3 without any accompanying rise in the level of the serum P.B.I. or the serum T^4. (ii) The T^4 that is free in the serum—and not protein bound—is far more representative of the level of hormone available to the individual thyroid cell than is the total serum T^4.

2. Measurement of free (unoccupied) binding sites for thyroid hormones in the blood

In the T^3 uptake test radio-active T^3 is incubated with the patient's serum so that it becomes fixed to any thyroid binding protein not already carrying T^3 or T^4. The amount so fixed can be measured and from this can be estimated the number of binding sites in the serum which are unoccupied. In hyperthyroidism the number of free binding sites is low because few are not already carrying hormone. In hypothyroidism and myxœdema, however, the number of free sites is high. Using the Thyopac method and taking 100 per cent. as the mean normal value for free binding sites, a figure of 85 per cent. or less suggests hyperthyroidism and a figure of 120 per cent. or more suggests hypothyroidism. This is not a very accurate test in itself, but in conjunction with the Total Serum T^4, or the Serum P.B.I., the Free Thyroxin Index (F.T.I.) can be calculated from the formula F.T.I. = Serum T^4 (or P.B.I.) $\times$ $^{100}/T^3$ uptake per cent. The euthyroid range of the F.T.I. is from 2·25–7·0. The F.T.I. gives a close approximation to the Free Serum T^4 and is probably the best single parameter of thyroid function which is generally available at present.

3. *In vivo* tests of uptake and discharge of ^{131}I by the thyroid gland

(*a*) *Radioactive iodine uptake test* (fig. 641). The thyroid treats radio-active isotopes of iodine exactly as it treats inorganic iodine (^{127}I). When a tracer dose of ^{131}I is given (5 microcuries[2] is the usual dose) it is rapidly absorbed from the small bowel into the blood, and the thyroid and the kidneys compete for it. In hyperthyroidism the thyroid uptake is rapid and little is excreted in the urine. Ultimately the isotope—now incorporated into the T^3 and T^4 molecules—passes back into the serum and can be measured as protein bound ^{131}I (P.B. ^{131}I). A rapid uptake of ^{131}I (high counting rate over the thyroid at four hours) and a rapid turnover (high serum P.B.I. ^{131} at 24 or 48 hours) are typical of hyperthyroidism. This can, however, occur when the mass of functioning thyroid tissue has been reduced so that radio-iodine studies after surgery or radio-iodine therapy must be interpreted with caution. ^{132}I may also be used as a diagnostic tracer but only for thyrotoxicosis as it has a short life (2·3 hours as opposed to the 8 days of ^{131}I). Because the radio-active dose is low it can be used on children, for serial tests and in pregnancy.

[1] Euthyroid—Euthyroidism = the state of normal thyroid function.
[2] Microcurie—a millionth part of a Curie (abbreviation μCi). Millicurie—a thousandth part of a Curie (abbreviation mCi).

Pierre Curie, 1859–1906, and Marie Sklodowska Curie, 1867–1934. Co-discoverers of radium. Madame Curie succeeded her husband as Professor of Physics at the Sorbonne, Paris.

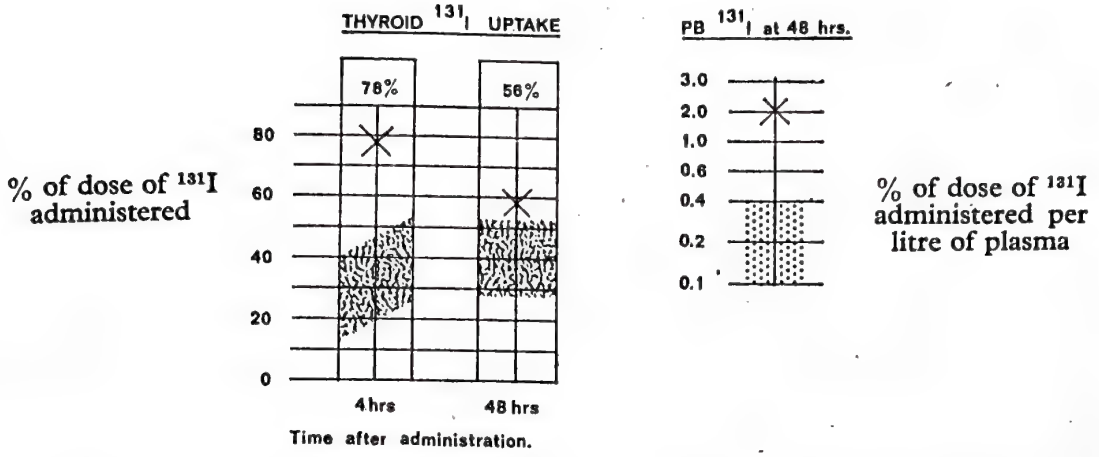

FIG. 641.—Radio-iodine uptake test. Thyroid uptake at 4 hours and 48 hours after administration of ^{131}I and serum protein bound ^{131}I at 48 hours in a typical case of diffuse toxic goitre. Stippled areas represent the euthyroid range.

(*b*) *T^3 Suppression Test* (*Werner*) (fig. 642). An iodine avid goitre, e.g. due to iodine deficiency in endemic areas, has a rapid ^{131} I uptake. However, a simple goitre, as opposed to a toxic goitre, is under T.S.H. control so that uptake can be diminished by suppressing T.S.H. production. This is done by giving 40 μg of tri-iodothyroinine (T^3) 8 hourly for 7 days. ^{131}I uptake curves are compared before and after T^3

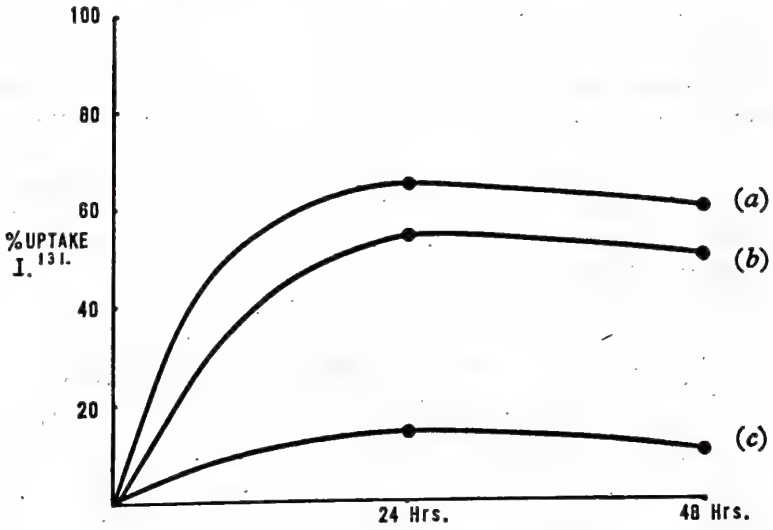

FIG. 642.—T^3 suppression test

(*a*) hyperthyroid or normal —represents a doubtful hyperthyroid uptake curve.
(*b*) non-suppressed — would confirm hyperthyroidism.
(*c*) suppressed—would confirm a euthyroid state.

suppression when a toxic goitre may show up to 10–20 per cent. reduction in uptake whilst a simple goitre will show 50–80 per cent. reduction.[1] This test is useful—(1) In the diagnosis of thyrotoxicosis in difficult cases.—(2) In the assessment of ophthalmic Graves' disease—where the patient may be euthyroid but uptake of radio-iodine is not suppressed.—(3) In checking the response to the treatment of thyrotoxicosis with antithyroid drugs.

(*c*) *Thyroid Scanning* (fig. 643). Scanning of the thyroid after a tracer dose of ^{131}I shows which parts of the gland are functioning or functionless (hot or cold).[2] Whilst scanning is sometimes helpful in cases of thyroid carcinoma, its principal value is in the diagnosis of an autonomous toxic nodule—either as a solitary toxic nodule or as part of a toxic multinodular goitre.

Whole body scanning can also be used to demonstrate metastases but the patient must have no normal functioning thyroid tissue when the isotope is given because thyroid cancer can only very rarely compete with normal thyroid tissue in the uptake of iodine.

[1] Failure to suppress is strong but not conclusive evidence of hyperthyroidism. Suppression rules out hyperthyroidism absolutely.

[2] Technitium ($^{99}Tc^{m}$), taken up exactly like ^{131}I is also used for scanning.

Sidney Charles Werner, Contemporary. Professor of Clinical Medicine, Columbia University College of Physicians and Surgeons, New York, U.S.A.

4. Miscellaneous Tests

These comprise the B.M.R., E.C.G., serum cholesterol and measurement of tendon reflexes. The B.M.R. and measurement of tendon reflexes are occasionally useful in the diagnosis of hypothyroidism but all these tests are otherwise of little practical value.

Routine Tests of the Future

The Serum T^3 and the Serum Free T^4 have already been discussed. The measurement of T.S.H. levels is at present available only in special centres, but will eventually become a routine test. The estimation of the T.S.H. levels after thyroidectomy for simple nodular goitre should indicate whether or not post-operative T^4 is necessary, and if so should help to assess the exact dose to be given. Similarly, in the follow-up of thyrotoxic patients treated with radio-iodine or by surgery, a rise in T.S.H. levels should give early warning of developing thyroid insufficiency. T.S.H. level at 20 and 60 minutes after the administration of T.R.H.[1] is a test of thyroid function that is likely to be used extensively in the future. The measurement of L.A.T.S. and of other abnormal thyroid stimulators may provide valuable information in the ætiology of thyrotoxicosis, but these are unlikely to become routine tests.

HYPOTHYROIDISM

CLASSIFICATION OF HYPOTHYROIDISM

1. **Failure of Thyroid Development**—(*a*) Complete (Sporadic Cretinism), (*b*) Partial.

FIG. 644.—An infant cretin. (*The late Professor de Quervain, Berne.*)

2. **Endemic Cretinism** (often goitrous).

3. **Iatrogenic**—(*a*) After thyroidectomy, (*b*) After radio-iodine therapy, (*c*) After pituitary ablation, (*d*) Drug induced.[2]

4. **Auto-immune thyroiditis**—(*a*) Non-goitrous (Primary myxœdema), (*b*) Goitrous (Lymphadenoid goitre).

5. **Dyshormonogenesis** (p. 592).

6. **Goitrogens** (p. 592).

7. **Vascular damage to anterior pituitary.**

Cretinism (Foetal or Infantile Hypothyroidism). Sporadic cretinism is due to complete or near complete failure of thyroid development (partial failure causes juvenile myxœdema): the parents and other children may be perfectly normal. In endemic areas goitrous cretinism is common, and is due to maternal and fœtal iodine deficiency. Fig. 644 depicts the infant cretin, potbellied with umbilical hernia, protruding tongue and pale puffy face. In adolescence and adult life

[1] T.R.H. = Thyrotrophic releasing hormone secreted by the Hypothalamus.
[2] Antithyroid drugs, P.A.S., and iodides in excess.

(fig. 645) the cretin is mentally and physically retarded with dry wrinkled skin and supraclavicular pads of fat. Immediate diagnosis and treatment with thyroxine within a few days of birth are essential if physical and mental development are to be normal, or if further deterioration is to be prevented when damage has already occurred *in utero*.

Adult Hypothyroidism

Myxœdema is a very advanced form of adult hypothyroidism and this term should never be applied to the milder degree seen much more frequently after thyroidectomy and ^{131}I therapy, and with lymphadenoid goitre. Significant early symptoms are tiredness, mental lethargy, cold intolerance, increase in weight, constipation, menstrual disturbance and a carpal tunnel syndrome due to increased tissue fluid deep to the flexor retinaculum (Hubble). Significant physical signs are a slow pulse rate, dry skin and hair, cold extremities, periorbital puffiness, hoarse voice, slow movements and slow relaxation of the ankle jerks. Comparison of the facial appearance with a previous photograph is helpful.

FIG. 645.—A cretin girl aged twenty-two.

Tests of Thyroid Function.—The serum T^4 is below 3·0 μg per 100 ml. (60 nmol/l). Radio-iodine studies show reduced thyroid uptake[1] and increased renal excretion. In an E.C.G. the voltage is reduced and the T wave flattened or even inverted. Serum T.S.H. values are raised and in doubtful cases a T.R.H. test will be helpful. A therapeutic trial of thyroxine is also helpful.

Treatment.—Dried thyroid extract is unstable, difficult to assay, and should not be used. It has been replaced by l-thyroxine—which is no more expensive. A full replacement dose is 0·3–0·4 mg. a day and, because of its slow action, it can be given in a single dose. In the elderly or those with myocardial insufficiency, the initial dose must be as low as 0·05 mg. a day and

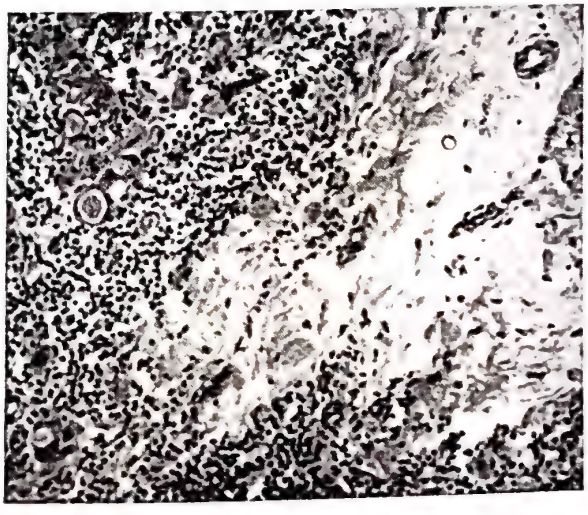

FIG. 646.—Myxœdema. Histology × 100. Gross fibrosis, lymphocytic infiltration and atrophy of acini. Compare with normal histology fig. 652. *(Dr. Bernard Fox, London.)*

FIG. 647.—Myxœdema : note the bloated look, the pouting lips, and the dull expression. *(Dr. V. K. Summers, Liverpool.)*

[1] Thyroid ^{131}I uptake of less than 12% at 24 hours is diagnostic.

Sir Douglas Vernon Hubble, Contemporary. Dean, Faculty of Medicine, Haile Sellassie I University, Addis Ababa, Ethiopia.

Sir William Withey Gull, 1816–1890. Physician Guy's Hospital, London. Wrote the first account of Myxœdema in 1873.

cautiously increased. If a rapid or short-lived response is essential tri-iodothyronine is used.

Myxœdema.—The signs and symptoms of hypothyroidism are accentuated. The facial appearance (fig. 647) is typical, and there is often supraclavicular puffiness, a malar flush, and a yellow tinge to the skin. Myxœdema coma occurs in neglected cases and carries a high mortality: the body temperature is low and the patient must be warmed slowly: 1 g of intravenous hydrocortisone should be given daily, and intravenous tri-iodo-thyronine in slowly increasing doses.

Auto-immune Thyroiditis.—The so-called primary or atrophic myxœdema is now considered an autoimmune disease similar to lymphadenoid goitre but without goitre formation from T.S.H. stimulation. Because of the delay in diagnosis the hypothyroidism is usually much more severe than in goitrous auto-immune thyroiditis.

Dyshormogenesis and Goitrogens.—Genetically determined deficiencies in the enzymes controlling the synthesis of thyroid hormones, if severe, are responsible for goitre formation with hypothyroidism. If of moderate degree, a simple (euthyroid) goitre results.[1, 2] Similarly goitrogens may produce a goitre with, or without, hypothyroidism.

GOITRES

A goitre[3] is an enlarged thyroid gland.

CLASSIFICATION OF GOITRES

Simple Goitre (Endemic[4] or sporadic[5]) (Euthyroid)	Diffuse hyperplastic goitre. Nodular goitre.
Toxic Goitre	Diffuse toxic goitre (Graves' disease). Toxic nodular goitre. Toxic nodule.
Neoplastic Goitre	Benign. Malignant.
Thyroiditis	Granulomatous thyroiditis. Auto-immune thyroiditis. Riedel's thyroiditis.
Other Rare Goitres	Acute bacterial thyroiditis. Chronic bacterial thyroiditis (Tuberculosis and Syphilis). Amyloid Goitre.

[1] A number of non-endemic goitrous cretins have been born to a group of itinerant tinkers living in Scotland who intermarry (Hutchison). This was due to a deficiency of the enzyme dehalogenase.

Another classical example is Pendred's syndrome, where goitre is associated with congenital deafness. This is due to deficiency of peroxidase, the enzyme responsible for organification of trapped iodides (page 587).

[2] When thyroglobulin is broken down, uncoupled iodotyrosines are liberated as well as T^3 and T^4. They are broken down by the enzyme dehalogenase and the iodine retained within the thyroid.

If dehalogenase is deficient, iodotyrosines pass into the blood, are excreted in the urine, and this may result in iodine deficiency and goitre formation.

[3] Goitre—Latin, *guttur* = the throat.

[4] Endemic = prevalent in a people or a district.

[5] Sporadic = haphazard occurrence.

James Holmes Hutchison, Contemporary. Professor of Child Health, Glasgow, Scotland.
Vaughan Pendred, 1869–1946. General Practitioner, East Sheen, Surrey, England. Described this Syndrome in 1896.

SIMPLE GOITRE

Simple goitre is due to stimulation of the thyroid gland by the anterior pituitary, i.e. by increased levels of circulating T.S.H. T.S.H. secretion is increased by low levels of circulating thyroid hormones. Any factor, therefore, that maintains a persistently low level of circulating thyroid hormones can be responsible for a simple goitre. The most important factor is iodine deficiency, but defects in hormone synthesis may be responsible.

1. **Iodine Deficiency.** The daily requirement of iodine is about 100–125 μg. In nearly all districts where simple goitre is endemic there is a very low iodide content in the water and food. Endemic areas are in the mountainous ranges, such as the Rocky Mountains, the Alps, the Andes and the Himalayas. In Great Britain endemic goitre is found in the Mendips, Chilterns, Cotswolds and the Pennine Chain of Derbyshire and Yorkshire. Endemic goitre is also found in lowland areas where the soil lacks iodide or the water supply comes from far away mountain ranges, e.g. the Great Lakes of North America, the Plains of Lombardy, the Struma Valley,[1] the Nile Valley and the Congo. Calcium is also goitrogenic and goitre is common in low iodine areas on chalk or limestone, e.g. Derbyshire and Southern Ireland. Although iodides in food and water may be adequate, failure of intestinal absorption may produce iodine deficiency (McCarrison).

2. **Defects in Synthesis of Thyroid Hormones.** (*a*) Enzyme deficiency within the thyroid gland (p. 587). (*b*) Goitrogens.

It is probable that enzyme deficiencies of varying degree of severity are responsible for many sporadic goitres, (i.e. in non-endemic areas), and there is often a family history of goitre in these cases suggesting a genetic defect. If the iodine intake is very high an enzyme deficiency may be overcome, e.g. in Iceland where goitre is practically unknown. Enzyme deficiency is often associated with a low iodine intake, e.g. a dislike of sea-fish.

Well known goitrogens are vegetables of the brassica family (cabbage, kale and rape) which contain thiocyanate, drugs such as P.A.S. and, of course, the antithyroid drugs.[2]

Surprisingly enough, iodides in large quantities are goitrogenic as they inhibit the organic binding of iodine and give an iodide goitre.[3]

The Natural History of Simple Goitre. This is investigated by autoradiographs of slices of goitre from patients to whom a pre-operative tracer dose of I^{131} has been given. Blackening of the X-ray film takes place in areas where colloid contains iodine, and the autoradiographs are compared with histological sections of the same slice. In any single lobule all follicles behave uniformly. Active follicles are small, lined by tall cells and their colloid contains iodine. Inactive follicles are three times larger, lined by flattened cells and contain colloid without iodine (Taylor).

Stages in goitre formation are:

1. Persistent T.S.H. stimulation causes diffuse hyperplasia; all lobules are composed of active follicles and iodine uptake is uniform. This is a diffuse hyperplastic goitre which may persist for a long time but is reversible if T.S.H. stimulation ceases.
2. Later, as a result of fluctuating T.S.H. levels, a mixed pattern develops with areas of active lobules and areas of inactive lobules.
3. Active lobules become more vascular and hyperplastic until hæmorrhage occurs causing central necrosis and leaving only a surrounding rind of active follicles.
4. Necrotic lobules coalesce to form nodules filled either with iodine-free colloid or a mass of new but inactive follicles.
5. Continual repetition of this process results in a nodular goitre. Most nodules are inactive and active follicles are present only in the internodular tissue.

---

[1] Struma. In the mountains of Bulgaria arises the River Struma that flows into the Aegean Sea. Along its banks, and those of its tributaries, dwell persons of several nationalities among whom endemic goitre has long been prevalent. Struma is a continental term for a goitre.

[2] Antithyroid drugs—Thiocyanates and perchlorates interfere with iodide trapping, Carbimazole, Thiouracil Compounds and Resorcinol interfere with the oxidation of iodide and the binding of iodine to tyrosin (p. 587).

[3] Iodide goitre is usually seen in asthmatics who have taken proprietary preparations containing iodides (e.g. Felsol) over a prolonged period.

Sir Robert McCarrison, 1878–1960. Indian Medical Service. Director of the Nutrition Research Laboratories, Coonoor, Madras, India.

Selwyn Francis Taylor, Contemporary. Surgeon, Royal Postgraduate Medical School, London.

CLINICAL TYPES OF SIMPLE GOITRE

1. Diffuse Hyperplastic Goitre

Diffuse hyperplasia corresponds to the first stages of the natural history. The goitre appears in childhood in endemic areas but in sporadic cases it usually occurs at puberty when metabolic demands are high—Puberty Goitre (fig. 648). If T.S.H. stimulation ceases the goitre may regress, but tends to recur later at times of stress such as pregnancy. The goitre is soft, diffuse and may become large enough to cause discomfort. A colloid goitre is a late stage of diffuse hyperplasia when T.S.H. stimulation has fallen off and when many follicles are inactive and full of colloid (fig. 649).

FIG. 648.—Physiological hyperplasia of the thyroid gland (goitre of puberty).

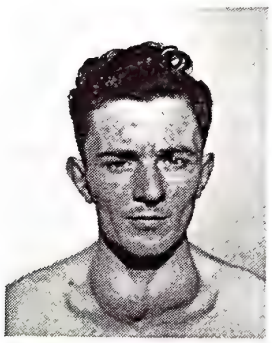

FIG. 649. — Colloid goitre.

2. Nodular Goitre

Persistent fluctuating T.S.H. stimulation results inevitably in progressive nodule formation. Nodules are usually multiple, forming a multinodular goitre. Occasionally, only one macroscopic nodule is found, but microscopic changes will be present throughout the gland: this is one form of a clinically solitary nodule (p. 596). Nodules may be colloid or cellular, and cystic degeneration and hæmorrhage are common, as is subsequent calcification. Nodules appear early in endemic goitre and later (between 20 and 30) in sporadic goitre, although the patient herself may be unaware of the goitre until the late forties or fifties. All types of simple goitre are far more common in the female than in the male.

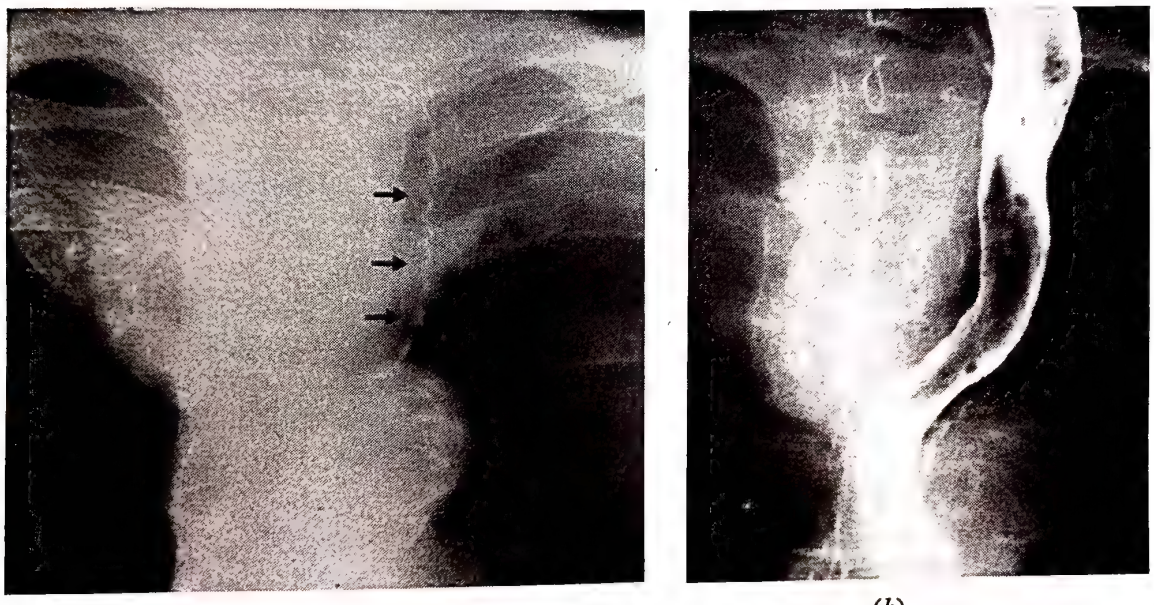
Diagnosis is usually straightforward. The patient is euthyroid; the nodules are palpable and often visible; they are smooth, usually firm and not hard, and the goitre is painless and moves freely on swallowing. Hardness and irregularity, due to calcification, may simulate carcinoma. A painful nodule, sudden appearance, or rapid enlargement of a nodule, raises suspicion of carcinoma, but is usually due to hæmorrhage into a simple nodule. Differential diagnosis from a lymphadenoid goitre in a euthyroid patient is often difficult.

Investigations.—Tests of thyroid function may be necessary to exclude mild hyperthyroidism, and the estimation of titres of thyroid antibodies to

differentiate from lymphadenoid goitre. Plain X-rays may show calcification and tracheal deviation or compression (fig. 650).

Complications.—(i). *Tracheal obstruction*—due to gross lateral displacement, or compression in a lateral or antero-posterior plane. Acute respiratory obstruction may follow hæmorrhage into a nodule impacted in the thoracic inlet.

(ii). *Secondary Thyrotoxicosis*—many patients with nodular goitres develop



(*a*) (*b*)

FIG. 650.—Retrosternal goitre causing (*a*) deviation of the trachea and (*b*) œsophagus, by barium swallow.

hyperthyroidism sooner or later. The incidence is difficult to estimate, but figures as high as 30% have been suggested.

(iii). *Carcinoma*—which is usually of follicular pattern. It is uncommon—an incidence of 5–8% has been suggested—but an increased incidence has been reported from endemic areas.

Prevention and Treatment of Simple Goitre.—All table salt should be iodised (potassium iodide 1 part in 10,000). In endemic areas (e.g. Switzerland, parts of the U.S.A. and Argentine) the incidence of goitre has been strikingly reduced by this prophylactic measure.

In the early stages a hyperplastic goitre is reversible if l-thyroxine is given in maximum doses—0·3 mg. a day for several months—and then very slowly tailed off to 0·1 mg. a day which should be continued for many years. If regression does not occur, thyroidectomy may be indicated for cosmetic reasons or pressure symptoms.

The nodular stage of simple goitre is irreversible. A multinodular goitre is often uncomfortable and unsightly and, in view of the possible complications, subtotal thyroidectomy is advisable unless the expectation of life is short. Resection aims at removing nodules and leaving up to 8 g. of relatively normal tissue in each remnant. The technique is essentially the same as described for toxic goitre (p. 605) as are the post-operative complications.

In many cases the causative factors persist and recurrence is likely, particularly in the younger patient, unless further T.S.H. stimulation is prevented. 0·1 mg. of l-thyroxine a day should be given post-operatively to all patients until after the menopause. Some clinicians give 0·2 mg. a day and consider that it should be given indefinitely. If one thyroid lobe appears normal in size and consistency at operation, it is justifiable not to resect it, but post-operative thyroxine is more than ever essential.

3. The Problem of the Clinically Solitary Nodule

The clinically solitary nodule may be defined as 'A goitre which, on clinical examination, appears to be a single nodule in an otherwise normal gland'.

Clinically solitary nodules fall into two categories. In the first are those in which there is a certainty or grave suspicion of malignancy; in these exploration is essential. In the second and far larger category, there is a smooth, firm, mobile nodule which is probably benign but carries a small but significant risk of being a carcinoma. In this category about 50% prove to be simple multinodular goitres when explored.

The thyroid status of these patients must be established by clinical examination and by laboratory tests, and the nodule should be scanned. This should divide the patients into three categories:

(i) Hyperthyroid with a hot (overactive) nodule.[1]
(ii) Euthyroid with a warm (active) nodule.[2]
(iii) Euthyroid with a cold (inactive) nodule.[3]

The solitary toxic nodule is never malignant, it is a toxic adenoma: it is treated by excision or radio-iodine.

The euthyroid warm nodule is a functioning adenoma or a simple nodule with some active thyroid tissue in it. Very rarely, a well differentiated carcinoma will take up isotope. For this reason, and because a functioning adenoma may develop into an overactive adenoma, it should be excised.

The euthyroid cold nodule is suspect, because a carcinoma so rarely takes up isotope if normal thyroid tissue is present. It should be excised.

Resection entails taking a wide margin of healthy thyroid tissue—preferably a lobectomy. Incisional biopsy is absolutely contraindicated. It could result in seeding of malignant cells.

Other investigations which may be undertaken are:

(i) *Needle biopsy.*—This is of little value in the diagnosis of a well differentiated thyroid carcinoma. It should differentiate a solid from a cystic nodule.

(ii) *Ultrasound.*—This should differentiate between solid and cystic nodules and will often detect other impalpable nodules, i.e. demonstrate that the goitre is multinodular.

---

[1] A hot nodule is one that takes up isotope, whilst the surrounding thyroid tissue does not. Here the surrounding thyroid tissue is inactive because the nodule is producing such high levels of thyroid hormones that T.S.H. secretion is suppressed.
[2] A warm nodule takes up isotope and so does normal thyroid tissue about it.
[3] A cold nodule takes up no isotope.

(iii) *Selenium Scan.*—A highly cellular tumour, synthesising protein, will show up well on a radioactive selenium scan. It should, therefore, distinguish between a benign cold nodule and a malignant cold nodule. Unfortunately, many well differentiated carcinomas are of such low cellular activity that they do not take up selenium.

Note.—The clinically solitary nodule presents a diagnostic problem when the nodule is smooth, firm and mobile in a euthyroid patients. Scanning, needle biopsy and ultrasound may increase or decrease the suspicion of malignancy, but there is only one certain diagnostic procedure and that is excisional biopsy.

4. Retrosternal Goitre

A very few retrosternal goitres arise from ectopic thyroid tissue, but most arise from the lower pole of a nodular goitre. If the neck is short and the pretracheal muscles are strong, as in men, the negative intrathoracic pressure tends to draw these nodules into the superior mediastinum. The degree of descent varies accounting for—(*a*) *Substernal type*—when the nodule is palpable. (*b*) *Plunging type*—when an intrathoracic goitre is occasionally forced into the neck by increased intrathoracic pressure. (*c*) *Intrathoracic goitre.*

Clinical Features.—A history of a previous cervical goitre which has disappeared is not uncommon. A retrosternal goitre may be symptomless or produce severe obstructive symptoms: (*a*) Dyspnœa, particularly at night, cough and stridor.[4] (*b*) Engorgement of neck veins and, in severe cases, of superficial veins on the chest wall. (*c*) Dysphagia is rare, as is recurrent nerve paralysis. It may also be malignant or toxic.

X-rays show a soft tissue shadow in the superior mediastinum—sometimes with calcification—and often causing deviation and compression of the trachea (fig. 650). An ^{131}I scan may help to distinguish a retrosternal goitre from a mediastinal tumour.

Treatment.—If obstructive symptoms are present it is unwise to treat a retrosternal goitre with antithyroid drugs or radio-iodine, as these may enlarge the goitre. Resection can almost always be carried out from the neck and a sternal split is hardly ever necessary. The cervical part of the goitre should first be mobilised by ligation and division of the superior thyroid vessels, and by ligature and division of the middle thyroid veins and of the inferior thyroid artery. The retrosternal goitre can then be delivered by traction and finger mobilisation. If carcinoma can definitely be excluded, an impacted goitre can be broken up and removed piecemeal. Hæmorrhage is rarely a problem because the goitre takes its blood supply with it from the neck. The recurrent nerve should be identified if possible before delivering the restrosternal goitre, as it is particularly vulnerable to injury from traction or tearing.

TOXIC GOITRE

Thyrotoxicosis (Hyperthyroidism)

The term thyrotoxicosis is retained because hyperthyroidism, i.e. symptoms due to a raised level of circulating thyroid hormones, is not responsible for all manifestations of the disease.

[4] Stridor = harsh sound on inspiration.

Clinical Types. 1. Diffuse toxic goitre. (Graves' disease).[1] 2. Toxic nodular goitre. 3. Toxic nodule. 4. Hyperthyroidism due to rarer causes.

FIG. 651.—Primary toxic goitre.
(Professor E. J. Wayne, Glasgow.)

1. **Diffuse Toxic Goitre.**—Graves' disease—a diffuse vascular goitre appearing at the same time as the hyperthyroidism, usually in the younger woman and frequently associated with eye signs. The syndrome is that of primary thyrotoxicosis (fig. 651). The whole of the functioning thyroid tissue is involved, and the hypertrophy and hyperplasia are due to abnormal thyroid stimulators such as L.A.T.S.

2. **Toxic Nodular Goitre.**—A simple nodular goitre is present for a long time before the hyperthyroidism, usually in the middle aged or elderly and very infrequently associated with severe eye signs. The syndrome is that of secondary thyrotoxicosis.

In many cases of toxic nodular goitre, the nodules are inactive, and it is the internodular thyroid tissue that is overactive. Here the hyperthyroidism is due to abnormal thyroid stimulators such as L.A.T.S. However, in some toxic nodular goitres one or more nodules are overactive and here the hyperthyroidism is due to autonomous thyroid tissue as in the toxic nodule.

3. **Toxic Nodule.**—A solitary overactive nodule. It is autonomous and its hypertrophy and hyperplasia are not due to L.A.T.S. Because T.S.H. secretion is suppressed by the high level of circulating thyroid hormones, the normal thyroid tissue surrounding the nodule is itself suppressed and inactive.

Histology. The normal thyroid gland (fig. 652) consists of acini lined by flattened cuboidal epithelium and filled with homogenous colloid. In hyperthyroidism (fig. 653) there is hyperplasia of acini which are lined by high columnar epithelium. Many of them are empty, and others contain vacuolated colloid.

Symptomatology.—Thyrotoxicosis is 8 times commoner in females than in males. It may occur at any age. Wayne's clinical diagnostic index (p. 599) gives all the important symptoms and signs of thyrotoxicosis and indicates by their score the relative importance of each. The most significant symptoms are loss of weight in spite of a good appetite, a recent preference for cold, and palpitations. The most significant signs are the excitability of the patient, the presence of a goitre, exophthalmos, and tachycardia or cardiac arrhythmia.

---

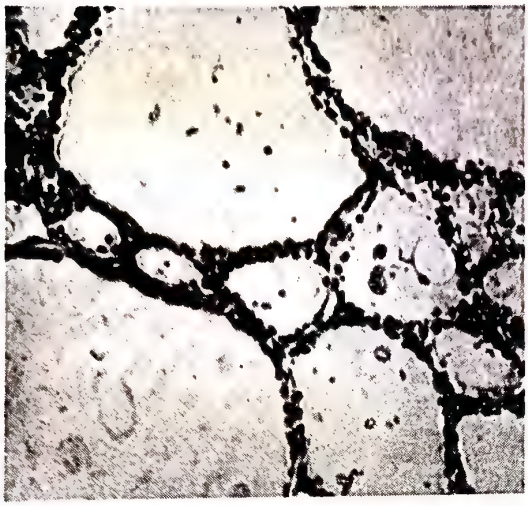

FIG. 652.—Normal thyroid (see text). × 100.

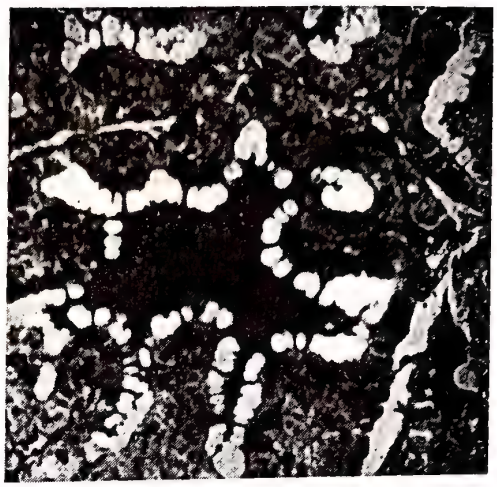

FIG. 653.—Thyrotoxicosis (see text). × 100. (*Dr. Bernard Fox, London.*)

The goitre in primary thyrotoxicosis is diffuse and vascular, it may be large or small, firm or soft, and a thrill and a bruit may be present, usually at the upper poles over the superior thyroid arteries. The onset is abrupt, but remissions and exacerbations are not infrequent. Hyperthyroidism is usually more severe than in secondary thyrotoxicosis but cardiac failure is rare. Manifestations of thyrotoxicosis not due to hyperthyroidism *per se*, e.g. orbital proptosis, ophthalmoplegia and pretibial myxœdema may occur in primary thyrotoxicosis.

In secondary thyrotoxicosis the goitre is nodular. The onset is insidious and may present with cardiac failure or atrial fibrillation. It is characteristic

that the hyperthyroidism is not severe. Eye signs other than lid lag and lid spasm (due to hyperthyroidism) are very rare.

Cardiac rhythm.—A fast heart rate, which persists during sleep, is characteristic. Cardiac arrhythmias are superimposed on the sinus tachycardia as the disease progresses, and they are commoner in older patients with thyrotoxicosis because of the prevalence of coincidental heart disease. Stages of development of thyrotoxic arrythmias are:—

(1) Multiple extrasystoles. (2) Paroxysmal atrial tachycardia. (3) Paroxysmal atrial fibrillation. (4) Persistent atrial fibrillation, not responsive to digoxin.

Myopathy.—Weakness of the proximal limb muscles is commonly found if looked for. Severe muscular weakness (Thyrotoxic myopathy) resembling myæsthenia gravis, occurs occasionally. Recovery occurs as hyperthyroidism is controlled.

Exophthalmos.—Some degree of exophthalmos is common. It may be unilateral. True exophthalmos is a proptosis of the eye, caused by infiltration of the retrobulbar tissues with fluid and round cells, with a varying degree of retraction or spasm[1] of the upper eyelid. This results in

(*a*) (*b*)

FIG. 654.—(*a*) Prior to sub-total thyroidectomy following preparation with carbimazole and potassium iodide; note lid retraction, which is more marked on the right. (*b*) Relapse of thyrotoxicosis. Weight loss; a bilateral partial tarsorrhaphy has been performed because of early exposure keratitis. *(Dr. Bruce Fowler, London.)*

widening of the palpebral fissure (the inner and outer canthus) so that the sclera can be seen clearly above the upper margin of the iris and cornea (above the ' limbus ').

Spasm and retraction usually disappear when the hyperthyroidism is controlled. They may be improved by β-adrenergic blocking drugs, e.g. Guanethidine eye drops. The condition is aggravated by compression of the ophthalmic veins.

[1] Lid spasm occurs because the levator palpebræ superioris muscle is partly innervated by sympathetic fibres.

The proptosis can be measured with an exophthalmometer.[1] Œdema of the eyelids, conjunctival injection and chemosis are aggravated by compression of the ophthalmic veins. Weakness of the extra-ocular muscles, particularly the elevators, results in diplopia. In severe cases papillœdema and corneal ulceration occur. When severe and progressive it is known as malignant exophthalmos (fig. 655) and the eye may be destroyed. It has

FIG. 655.—Progressive exophthalmos, with chemosis and exophthalmic ophthalmoplegia. (*The Lahey Clinic, Boston, Mass., U.S.A.*)

been postulated that the syndrome of infiltrative ophthalmopathy is due to a pituitary hormone E.P.S. (Exophthalmos Producing Substance).

Exophthalmos is usually self-limiting and may even regress a little. Sleeping propped up and lateral tarsorrhaphy will help to protect the eye but will not prevent progression. Hypothyroidism increases proptosis by a few millimetres and must be avoided.

Improvement has been reported with massive doses of prednisone and with metronidazole. Intra-orbital injection of steroids is dangerous because of the venous congestion, and total thyroid ablation has not proved effective. When the eye is in danger, orbital decompression may be required.

Pretibial Myxœdema (fig. 656) is a thickening of the skin by a mucin-like deposit, nearly always associated with true exophthalmos, past or present hyperthyroidism, and high levels of L.A.T.S. It is usually symmetrical, and minor degrees are not uncommon but are easily missed. The earliest stage is a shiny red plaque of thickened skin with coarse hair, which may be cyanotic when cold. In severe cases the skin of the whole leg below the knee is involved, together with that of the foot and ankle and there may be clubbing of the fingers and toes. (Thyroid Acropachy.)

FIG. 656.—Pretibial myxœdema in hyperthyroidism.

Diagnosis of Thyrotoxicosis. — Most cases are diagnosed clinically and the Wayne diagnostic index (p. 599) is an excellent

[1] Exophthalmometry. In a person with normal vision a reading of 19 mm. or above is abnormal. In the short-sighted however, the bulb is elongated and each −3 diopters correction represents an increase of 1 mm.

discipline. Difficulty is most likely to arise in the differentiation of mild hyperthyroidism from an anxiety state when a goitre is present. In these cases the thyroid status is determined by the diagnostic tests described on page 587. If there is still doubt after a routine Thyroid Profile—(Serum T^4, T^3 uptake percentage—and F.T.I.) and a radio-iodine uptake test—then a T^3 suppression test should be done.

T^3 thyrotoxicosis is diagnosed by estimating the serum T^3. It should be suspected if the clinical picture is suggestive, but routine tests of thyroid function are within the normal range. A thyroid scan is essential in the diagnosis of an autonomous toxic nodule.

Thyrotoxicosis should always be considered in : (*a*) children with a growth spurt, behaviour problems or myopathy. (*b*) Tachycardia or arrhythmia in the elderly. (*c*) Unexplained diarrhœa. (*d*) Loss of weight.

Principles of the Treatment of Thyrotoxicosis.—Non-specific measures are rest and sedation, and in established thyrotoxicosis should be used only in conjunction with specific measures which are the use of antithyroid drugs, surgery and radio-iodine.

Antithyroid Drugs.—Those in common use are Carbimazole and Propyl-Thiouracil. Potassium perchlorate and Thiouracil[1] are infrequently used these days and iodides should only be used as immediate pre-operative drugs. Antithyroid drugs are used to restore the patient to a euthyroid state and to maintain this for a prolonged period in the hope that a permanent remission will occur (i.e. that production of L.A.T.S. will diminish or cease).

Advantages.—No surgery and no use of radio-active materials.

Disadvantages:—

(*a*) Treatment is prolonged and the failure rate after a course of 1½ to 2 years is at least 50%.

(*b*) It is impossible to predict which patient is likely to go into a remission.[2]

(*c*) Some goitres enlarge and become very vascular during treatment[3]—even if thyroxine is given at the same time.

(*d*) Very rarely there is a dangerous drug reaction, e.g. agranulocytosis[4] or aplastic anæmia.

Initially, 10 mg. of Carbimazole[5] are given three or four times a day, and there is a latent interval of 7–14 days before any clinical improvement is apparent. It is most important to maintain a high concentration of the drug throughout the 24 hours by spacing the doses at 8 or 6 hourly intervals. When the patient becomes euthyroid a maintenance dose of 5 mg. two or three

---

[1] In 1943 Astwood first treated thyrotoxicosis successfully with thiourea.

[2] It has been suggested that drug responsive patients can be identified after 6 months treatment by a positive response to a T^3 suppression test. The 20 minute uptake of intravenous ^{132}iodine is measured so that treatment with Carbimazole need not be discontinued. This test has not yet been fully evaluated.

[3] This is probably due to L.A.T.S. stimulation during the prolonged course of treatment and not a direct effect of the drug.

[4] Agranulocytosis—The patient should be instructed to discontinue treatment if she develops a sore throat until the white cell count has been checked.

[5] Carbimazole = proprietary name Neomercazole, 5 mg. tablets.

Edwin Bennett Astwood, Contemporary. Physician, New England Center Hospital, Boston, Mass., U.S.A.

times a day is given for another 12–18 months. If Tri-iodo-thyronine—20 μg 2 to 4 times daily, or Thyroxine—0·2 mg daily, are given in conjunction with antithyroid drugs, there is less danger of producing iatrogenic thyroid insufficiency or an increase in the size of the goitre.

Surgery. (p. 605).—In diffuse toxic goitre and toxic nodular goitre with overactive internodular tissue, surgery cures by reducing the mass of overactive tissue. It seems that a cure is probable if the thyroid tissue can be reduced below a critical mass.[1] In the autonomous toxic nodule, and in toxic nodular goitre with overactive autonomous toxic nodules, surgery cures by removing all the overactive thyroid tissue: this allows the suppressed normal tissue to function again.

Advantages.—The goitre is removed, the cure is rapid, and the cure rate is high if surgery has been adequate.

Disadvantages.—A recurrence of thyrotoxicosis occurs in about 5 per cent. of cases. Every operation carries a morbidity and mortality. However, with suitable preparation and an experienced surgeon the mortality is negligible. Although post-operative thyroid insufficiency occurs in 15–20 per cent of cases this is rarely due to the operation itself (p. 607). The only significant complication due to the operation is parathyroid insufficiency (p. 608).

Radio-iodine.—Radio-iodine[2] destroys thyroid cells and, as in thyroidectomy, reduces the mass of functioning thyroid tissue to below a critical level.

Advantages.—No surgery and no prolonged drug therapy.

Disadvantages.—(*a*) Isotope facilities must be available. (*b*) There is a high and progressive incidence of thyroid insufficiency which may reach 75–80 per cent. after 10 years.[3] (*c*) An indefinite follow-up is essential.

There is no convincing evidence that radio-iodine has been responsible for genetic damage, leukæmia, damage to the fœtus if given inadvertently in early pregnancy, or carcinoma in the adult. In some North American Clinics radio-iodine is given to almost all patients over the age of 25—when development is complete. In this country, on account of the real and potential risks, most clinicians are unwilling to advise it under the age of 45. The dose of radio-iodine varies with the size of the goitre, and a suggested dosage is 160 μCi per 1 g of thyroid tissue. Thus, for a gland estimated at 60 g, between 9 and 10 mCi would be prescribed.[4] Response is slow, but a substantial improvement is to be expected in 8 to 12 weeks. Accurate dosage is difficult and, should there be no clinical improvement after 12 weeks,

---

[1] This may result in a reduction of L.A.T.S. production, or it may be that the circulating L.A.T.S., however high its level, can only produce limited hypertrophy and hyperplasia when the mass of thyroid tissue is small.

[2] Radio-active iodine was first used in the treatment of thyrotoxicosis by Hertz and Roberts in 1942. Isotope—Greek, *isos* = equal, *topos* = place.

[3] This is due to sublethal damage to those cells not actually destroyed by the initial treatment and this eventually causes failure of cellular reproduction.

[4] A more sophisticated method is to give a dose of 7,500 rad, calculated from the peak uptake of ^{131}I in the thyroid and the length of time the ^{131}I remains in the gland.

Saul Hertz, Contemporary. Director of Radioactive Isotope Research Institute, Boston, Mass., U.S.A.
A. Roberts, Contemporary. Isotope Department, Massachusetts Institute of Technology, Boston, Mass., U.S.A.

a further dose is given (Macgregor). Two or more doses are necessary in 20–30 per cent. of cases.

The Choice of Therapeutic Agent.—Each case must be considered individually. Below are listed guiding principles as to the most satisfactory treatment for a particular toxic goitre at a particular age: these must however be modified according to the facilities available and the personality, intelligence and wishes of the individual patient, her business or family commitments and any other co-existent medical or surgical condition.

1. *Diffuse Toxic Goitre.*—Over 45—Radio-iodine.
Under 45—Surgery for the large goitre—Antithyroid drugs for the small goitre.

Large goitres are uncomfortable and remission with antithyroid drugs is less likely than in the small goitre.

2. *Toxic Nodular Goitre.*—Surgery.

Toxic nodular goitre does not respond as well or as rapidly to radio-iodine or antithyroid drugs as does a diffuse toxic goitre, and the goitre itself is often large and uncomfortable.

3. *Toxic Nodule.*—Surgery or Radio-iodine.

Resection is easy, certain and without morbidity. Radio-iodine is, however, the treatment of choice over the age of 45 because the suppressed thyroid tissue does not take up iodine and there is thus no risk of delayed thyroid insufficiency.

4. *Recurrent Thyrotoxicosis after adequate surgery*—over 45 radio-iodine,—under 45 antithyroid drugs.

5. *Failure of previous treatment with antithyroid drugs or radio-iodine.*—Surgery or thyroid ablation with ^{131}I.

In advising treatment, the age of 45 must not be taken as a rigid dividing line. Intelligence is important: unintelligent patients cannot be trusted to take drugs regularly if they feel well, and are unlikely to attend follow-up clinics indefinitely, which is essential after radio-iodine therapy.

Special Problems in Treatment

1. **Pregnancy.**—Radio-iodine is absolutely contraindicated because of the risk to the fœtus. The danger of surgery is miscarriage; and that of antithyroid drugs is of inducing thyroid insufficiency in the mother, and because both T.S.H. and antithyroid drugs cross the placenta, of the baby being born goitrous (fig. 657) and hypothyroid. The risk of either surgery or antithyroid drugs in competent hands is very small and the choice is exactly as in an uncomplicated case.

FIG. 657.—Transmitted thiouracil goitre.[1]

2. **Children.**—Radio-iodine is absolutely contraindicated because of the risk of inducing thyroid carcinoma. There is an increased risk of recurrence after thyroidectomy because thyroid cells are highly active in the young. It is probably best to treat children and adolescents with antithyroid drugs until the late teens. If thyroidectomy is to be undertaken it must be very radical.

3. **The Thyro-cardiac.**—This is a patient with severe cardiac damage due wholly or partly to hyperthyroidism. The patient is usually middle aged or elderly with secondary thyrotoxicosis and the hyperthyroidism is not very severe. The cardiac condition is far more significant than the hyperthyroidism, but this must be rapidly controlled to prevent further cardiac damage.

[1] This does not occur if T^3 is given with antithyroid drugs as it too crosses the placenta.

Alastair Goold Macgregor, 1919–1972. Regius Professor of Materia Medica and Therapeutics, Aberdeen, Scotland.

Thyroidectomy is the treatment of choice after control of the cardiac condition. In the elderly, however, or when the operative risk is unacceptable, radio-iodine is given, and treatment with antithyroid drugs is started 48 hours later and continued until the radio-iodine has had effect.

4. **High Pre-operative Titres of Thyroid Antibodies.**—Their presence indicates lymphatic infiltration of the goitre—i.e. a diffuse or focal thyroiditis—and a liability to thyroid insufficiency after thyroidectomy. These patients are best treated conservatively unless the goitre is large, vascular and uncomfortable.

5. **Proptosis of Recent onset.**—It is considered unwise to terminate thyrotoxicosis abruptly by thyroidectomy or radio-iodine if proptosis is recent, because malignant exophthalmos may be induced. There is no real proof of this, but it is advisable to treat these patients with antithyroid drugs, until the proptosis has been static for six months.

Hyperthyroidism due to other causes

1. *Thyrotoxicosis factitia.*[1] Hyperthyroidism can be induced by taking l-thyroxine, but only if the dosage exceeds the normal requirements of 0·3–0·4 mg. a day. Doses below the normal requirements simply suppress normal hormone production by the thyroid.

2. *Jod-Basedow.*[2] *Thyrotoxicosis.* Large doses of iodide given to a hyperplastic endemic goitre which is iodine avid may produce temporary hyperthyroidism, and very occasionally a persistent hyperthyroidism.

3. *In subacute or acute forms of lymphadenoid thyroiditis or of de Quervain's thyroiditis* (p. 613), mild hyperthyroidism may occur in the early stages due to liberation of thyroid hormones from damaged tissue.

4. *A large mass of secondary carcinoma* will rarely produce sufficient hormone to induce mild hyperthyroidism.

5. *Neonatal thyrotoxicosis* occurs in babies born to hyperthyroid mothers or to euthyroid mothers who have had thyrotoxicosis. High L.A.T.S. titres are present in both mother and child because L.A.T.S., being an immunoglobulin, can cross the placental barrier. The hyperthyroidism gradually subsides in 3 to 4 weeks' time as the L.A.T.S. titres fall in the baby's serum.

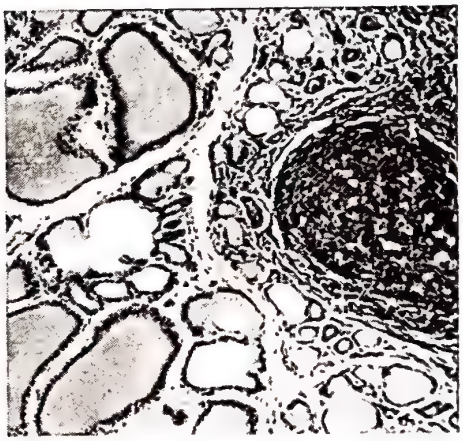

FIG. 658.—'Prepared' thyrotoxicosis. The acini are lined by low cuboidal epithelium and contain more colloid. Compare with figs. 652 and 653. Note the lymphocytic infiltration with lymph follicle formation, which is a feature of the thyrotoxic gland. × 100. *(Dr. Bernard Fox, London.)*

Surgery for Thyrotoxicosis

Pre-operative Preparation (fig. 658).—The patient must be euthyroid or near euthyroid at operation. The thyroid state is determined by clinical assessment, i.e. by improvement in previous symptoms and in objective signs such as gain in weight and lowering of the sleeping pulse. Serial estimations of the thyroid profile (serum T^4—T^3 uptake percentage—and F.T.I.) are helpful in difficult cases.

Preparation is as an outpatient and only rarely is admission to hospital necessary on account of severe symptoms at presentation, or failure to control the hyperthyroidism. Failure to control with antithyroid drugs is unusual but may be due to uneven dosage—i.e. not taking the drug at 6 or 8 hourly intervals.

---

[1] Usually seen in health cranks or those given thyroid extract as 'a tonic'.

[2] Jod—German for iodine + Basedow. In European countries Diffuse Toxic Goitre is often called Basedow's disease.

Carl Adolph von Basedow, 1799–1854. General Practitioner, Merseburg, Germany. Published his account of exophthalmic goitre in 1840.

Carbimazole[1] 30–40 mg a day is the drug of choice for preparation. When euthyroid—after 8–12 weeks—the dose is reduced to 5 mg 8 hourly : it is unwise to stop Carbimazole completely prior to operation. Iodides[2] are now very rarely used alone because, if the patient needs pre-operative treatment, a more effective drug should be given. Iodides may be given with Carbimazole for 2–3 weeks immediately prior to operation, but their use is of doubtful value and has been given up in many centres.

Propranolol is used by some surgeons to prepare less severe cases. Because it acts on the target organs and not on the thyroid gland itself, it does not interfere with the synthesis of thyroid hormones, so that hormone levels remain high during treatment and for some days after thyroidectomy. It is, therefore, important to continue to give the drug for 7 days post-operatively.

Propranolol controls symptoms very rapidly so that its principal value is in combination with Carbimazole in the immediate treatment of patients with very severe hyperthyroidism.

Subtotal Thyroidectomy.—Pre-operative investigations to be carried out and recorded are—(*a*) Indirect laryngoscopy—a symptomless cord paralysis is present in 3 per cent. of cases, without any previous thyroid surgery. (*b*) Thyroid antibodies (p. 613). (*c*) Photograph—full face. (*d*) A scan prior to pre-operative preparation is essential in patients with toxic nodular goitre. The surgeon should know which nodules, if any, are autonomous and active in order to ensure their resection. A scan is of no value in diffuse toxic goitre when uptake, for practical purposes, is uniform. The diagnosis of a single toxic nodule can only be made by demonstrating that the nodule is active and the remaining thyroid tissue suppressed.

Technique.—General anæsthesia is administered by an endotracheal tube; local anæsthesia is rarely advisable. A crease incision is made, and flaps of skin, subcutaneous tissue and platysma are raised upwards to the superior thyroid notch and downwards to the suprasternal notch. Adequate exposure entails mobilisation of the sterno-mastoid muscles by incising the fascia along their medial border, midline incision of the cervical fascia, and transverse division of the pretracheal muscles to the carotid sheath. If the pretracheal muscles are not divided, safe ligation of the superior thyroid arteries may be difficult. The thyroid lobes are mobilised by division between ligatures of the middle thyroid veins, the superior thyroid vessels, and inferior thyroid veins. The inferior thyroid arteries are ligated in continuity or divided between ligatures. The recurrent laryngeal nerve should be identified in its course in the operative field. It should first be sought below the level of the inferior thyroid artery as it passes obliquely upwards and forwards. This course (fig. 659), oblique to the trachea and œsophagus is accentuated by mobilisation of the thyroid lobe: only rarely does the nerve lie in the groove between the trachea and œsophagus. The nerve often lies between the branches of the inferior thyroid artery so that identification is helped by traction on a ligature on the trunk of the artery, and if not seen it can frequently be palpated as a taut strand. The nerve passes into the larynx immediately behind the inferior cornu of

[1] Potassium perchlorate—200 mg. 6 hourly may be used pre-operatively but Lugol's iodine cannot be used with it, as perchlorate interferes with the trapping of iodide. To stop potassium perchlorate and give iodides is highly dangerous and may promote thyroid crisis at operation.

[2] Lugol's Iodine—Dose 30 ml t.d.s. It is helpful to the patient to prescribe in the old-fashioned minims as one minim = 1 drop. The value of iodide is to reduce the vascularity of the goitre and make it softer and easier to handle. Potassium iodide tablets N.F. 60 mg. t.d.s. may be used instead of Lugol's iodine.

Jean Guillaume Auguste Lugol, 1786–1851. Physician, Hôpital Saint-Louis, Paris. Henry Stanley Plummer, 1874–1937, Physician, Mayo Clinic, Rochester, U.S.A. was the first to use iodine for preparing thyrotoxic patients for operation.

the thyroid cartilage which is therefore a very important landmark. If the right nerve cannot be found in its usual course, an anomalous nerve, present in 1% of cases, should be suspected: this arises from the vagus trunk and usually passes from behind the carotid sheath curving medially, forwards, and upwards and may be mistaken for the inferior thyroid artery. The parathyroid glands are protected by careful inspection of the goitre before resection and by avoiding ligatures and sutures close to the hilum of identified glands. Subtotal resection of each lobe is carried out leaving a remnant of 4 to 5 g on each side.[1] Absolute hæmostasis is secured by ligation of individual vessels and by suture of the thyroid remnants to the tracheal fascia (fig. 660). The pretracheal muscles and cervical fascia are sutured and the wound closed with suction drainage to the deep cervical space.

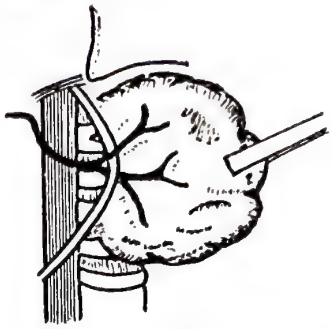

FIG. 659.—Identification of the recurrent laryngeal nerve (see text).

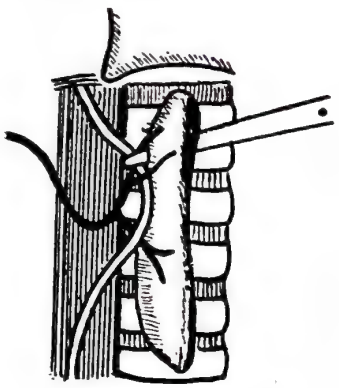

FIG. 660.—On obtaining hæmostasis special care should be exercised on the medial side of the thyroid remnant as the nerve can easily be damaged.

Post-operative Complications

1. **Hæmorrhage.** — A tension hæmatoma deep to the cervical fascia (fig. 661), is usually due to slipping of a ligature on the superior thyroid artery: occasionally hæmorrhage from a thyroid remnant or a thyroid vein may be responsible. It causes severe shock and it is often necessary to open the wound in the ward in order to relieve tension before taking the patient to theatre to evacuate the hæmatoma and to tie off a bleeding vessel if one can be found. A small subcutaneous hæmatoma or collection of serum may form and should be evacuated or aspirated.

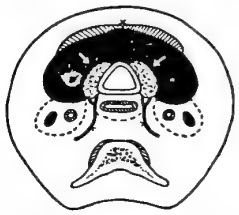

FIG. 661.—Tension haematoma deep to the pretracheal muscles. *(After V. H. Riddell, F.R.C.S., London.)*

2. **Respiratory Obstruction.** —Is very rarely due to collapse or kinking of the trachea. Most cases are due to laryngeal œdema. The most important cause of laryngeal œdema is a tension hæmatoma. However, trauma to the larynx by anæsthetic intubation, and surgical manipulation are important contributory factors—particularly if the goitre is very vascular—and may cause laryngeal œdema without a tension hæmatoma. Unilateral or bilateral recurrent nerve paralysis will not cause immediate postoperative respiratory obstruction unless laryngeal œdema is also present, but they will aggravate the obstruction.

If releasing the tension hæmatoma does not immediately relieve airway obstruction, the trachea should be intubated at once. An endotracheal tube can be left in place for several days; steroids are given to reduce œdema and a tracheostomy is rarely necessary. Intubation in the presence of laryngeal œdema may be very difficult and should be carried out by an experienced anæsthetist; repeated unsuccessful attempts may increase obstruction and cause serious cerebral anoxia.

3. **Recurrent Laryngeal Nerve Paralysis** may be unilateral or bilateral, transient or permanent (p. 683). Transient paralysis occurs in about 3% of nerves at risk and recovers in 3 weeks to 3 months. Permanent paralysis is extremely rare if the nerve has been identified at operation.

4. **Thyroid Insufficiency** (p. 590).—This usually occurs within two years, but it is sometimes delayed for 5 years or more. It is often very insidious and difficult to recognise. The incidence is considerably higher than used to be thought and figures of up to 20 per cent. have been reported. It represents a change in the auto-immune response from stimulation to destruction of thyroid cells, and is only rarely a result of operative removal of too much thyroid tissue.

---

[1] The critical mass for the thyroid remnant is arbitrarily estimated at one-third of the size of a normal thyroid gland (20–25 g).

5. **Parathyroid Insufficiency**[1] (p. 619). Most cases present dramatically 2–5 days after operation but, very rarely, the onset is delayed for 2–3 weeks or a patient with marked hypocalcæmia is asymptomatic.

6. **Thyrotoxic Crisis (Storm)** is an acute exacerbation of hyperthyroidism. It occurs if a thyrotoxic patient has been inadequately prepared for thyroidectomy, and is now extremely rare.[2] Symptomatic treatment is for dehydration, hyperpyrexia and restlessness. Specific treatment is by Propranalol (β adrenergic blocking drug) 20 mg 6 hourly. Iodides and antithyroid drugs are slow acting and therefore of no immediate value.

7. **Wound Infection.**—A subcutaneous or deep cervical abscess should be drained.

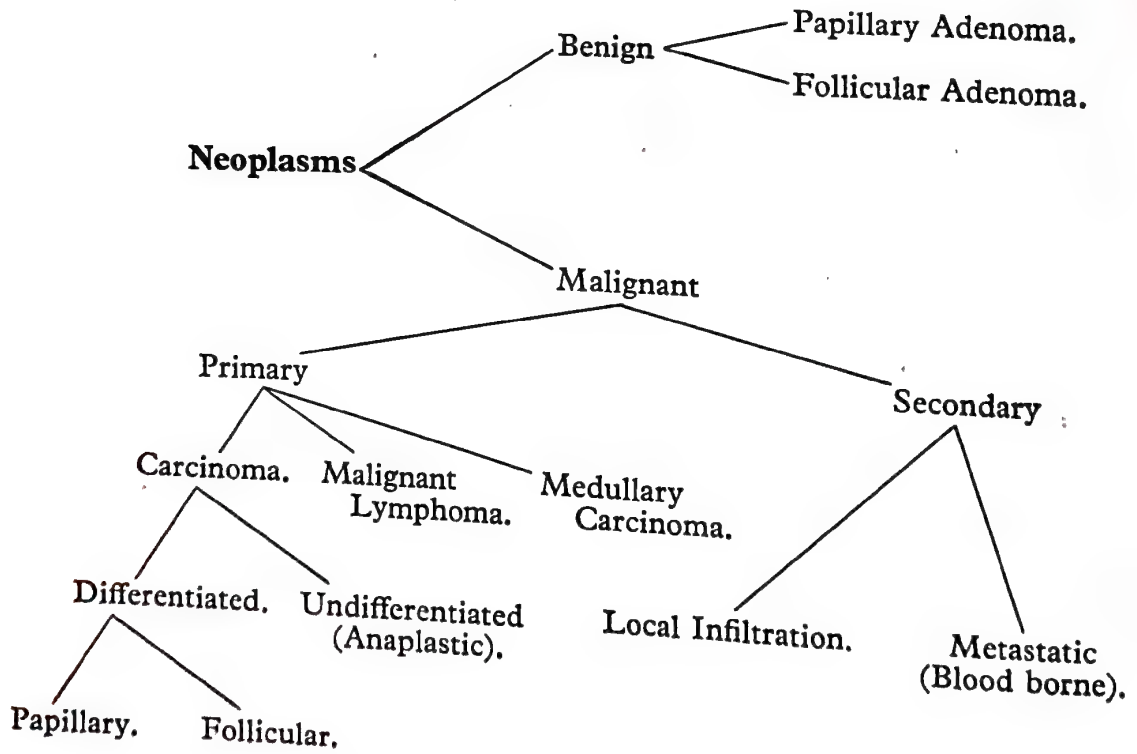
8. **Keloid Scar** is more likely to form if the incision overlies the sternum. Intradermal injections of corticosteroid should be given at once and repeated monthly if necessary.

Post-operative Follow-up.

(1) Indirect laryngoscopy should be carried out routinely before leaving hospital.
(2) Screening for parathyroid insufficiency by serum calcium estimation at 6 weeks.
(3) Observation at 6 monthly and then yearly intervals for recurrence of hyperthyroidism—which occurs in 5–10 per cent. of cases.
(4) Observation at 6 monthly and then yearly intervals for delayed thyroid insufficiency, particularly if the resected goitre showed lymphocytic infiltration or if pre-operative thyroid antibody titres were high. Follow up should be for at least 5 years and, ideally, for ever.

NEOPLASMS OF THE THYROID

Classification of Thyroid Neoplasms



Benign Tumours.—Adenomas present as clinically solitary nodules and their treatment has already been discussed. It is impossible to differentiate

[1] Parathyroid insufficiency is due to removal of parathyroid glands, or infarction through damage to the parathyroid end-artery: often both factors occur together. Vascular injury probably far more important than inadvertent removal.

[2] Very rarely a thyrotoxic patient presents in a crisis and this may follow an unrelated operation.

with absolute certainty between a follicular adenoma and a follicular carcinoma showing no evidence of capsular penetration or invasion of blood vessels, and it is doubtful if there is such an entity as a papillary adenoma. After excision of an adenoma, the patient should be followed up with care.

Malignant Tumours.—Secondary growths are rare. Blood borne metastases occur from primary carcinomas of breast, colon, kidney and from melanomas. The vast majority of primary growths are carcinomas (fig. 662). Dunhill classified them histologically as differentiated and un-

Relative Incidence	(%)
Papillary Carcinoma	60
Follicular Carcinoma	17
Anaplastic Carcinoma	13
Medullary Carcinoma	6
Malignant Lymphoma	4

FIG. 662.—Relative incidence of primary malignant tumours of the thyroid gland.

differentiated : we now subdivide the differentiated carcinomas into follicular and papillary. Clinico-pathological studies have demonstrated a pattern of behaviour according to histological type, which has an important bearing on treatment.

Papillary Carcinoma.—Most papillary tumours contain a mixture of papillary and colloid filled-follicles, and in some the follicular structure predominates. Nevertheless, if any papillary structure is present, the tumour will behave in a predictable fashion as a papillary carcinoma.

Woolner has divided papillary tumours into three subgroups according to their size and extent (fig. 663). Multiple foci may occur in the same lobe as the primary tumour or, less commonly, in both lobes. They are probably due to lymphatic spread in the rich intrathyroidal lymph plexus, rather than to multicentric growth. Spread to the lymph nodes is common and in all groups the tumour tends to be T.S.H. dependent.

CLASSIFICATION BY SIZE AND INFILTRATION.

	A *Occult < 1·5 cm*	*B* *Intrathyroidal*	*C* *Extrathyroidal*
Incidence	31%	53%	15%
Encapsulation	Rare	—	—
Lymph spread	33%	55%	60%
Blood spread	—	—	Late
Death due to growth	Nil/240	9/354	10/68

FIG. 663.—Subgroups of papillary carcinoma and their behaviour. *(after Woolner)*

The primary aim of treatment is to eradicate the growth. The secondary aim is to prevent local recurrence, because a long and comfortable life is possible, even when metastases are present, provided the trachea and larynx are not involved. Because of the high incidence of multiple foci, a total thyroidectomy should be carried out and, in the extrathyroidal tumours, this may entail resection of part of the trachea or a laryngectomy. Because of the

Sir Thomas Peel Dunhill, 1876–1957. Surgeon, St. Bartholomew's Hospital, London.
Lewis B. Woolner, Contemporary. Pathologist, The Mayo Clinic, Rochester, Minnesota, U.S.A.

high incidence of lymph metastases, even in occult tumours, the pretracheal and paratracheal nodes should be resected : any other involved nodes should be removed individually and only rarely is any form of block dissection necessary. After operation T.S.H. production must be suppressed by full doses of thyroxin—0·3–0·4 mg. daily.

If properly treated, prognosis is extremely good. The presence of lymphatic metastases is of no significance and only in the extrathyroidal tumours, and in those which present over the age of 40, is the expectation of life lower than in a control group.

Follicular Carcinoma.—These appear to be macroscopically encapsulated but microscopically there is invasion of the capsule and of the vascular spaces in the capsular region. Follicular tumours in which invasion is minimal are termed ' non-invasive ' and those in which invasion is moderate or marked are termed ' invasive ' (fig. 664). The prognosis depends on the

	A *Non-invasive*	*B* *Invasive*
Incidence	50%	50%
Apparent encapsulation	All	Most
Lymph spread	V. rare	Uncommon
Blood spread	Uncommon	Common
Death due to growth within 6 years	3/104	51/104

FIG. 664.—Subgroups of follicular carcinoma and their behaviour. (*after Woolner*)

histological picture. ' Non-invasive ' cases have as good a prognosis as the intrathyroidal papillary tumours. On the other hand, 50 per cent of patients with ' invasive ' tumours develop a local recurrence or secondaries in bone or lung, and have a mean survival time after surgery of six years.

Because multiple foci are rare, wide excision, as by lobectomy, is good treatment, and the advantage of total thyroidectomy over lobectomy is very slight. Lymph nodes rarely require excision and, although not particularly hormone dependent, full doses of thyroxin should be given post-operatively.

Isolated secondaries may be irradiated directly, but ^{131}I therapy offers the only prospect of success when metastases are multiple. All normal thyroid tissue must have been ablated by surgery or by radio-iodine and the patient must be hypothyroid when the isotope is given.

Anaplastic Carcinoma.—Local infiltration is an early feature of these tumours with spread by lymphatics and by the blood stream. They are extremely lethal tumours and survival for more than four years after presentation is most unusual. In most cases death occurs within months rather than within years. An attempt at curative resection is only justified if there is no infiltration through the thyroid capsule and no evidence of metastases. Radiotherapy should be given in all cases and may provide a worthwhile period of palliation.

Medullary Carcinoma.—These are tumours of the parafollicular (C) cells which are derived from the ultimo-branchial body, and not from the cells of the thyroid follicle as are other primary thyroid carcinomas. The cells are

not unlike those of a carcinoid tumour and there is a characteristic amyloid stroma. High levels of serum calcitonin are produced by many medullary tumours. These levels fall after resection of a tumour and may rise again if the tumour recurs. Diarrhœa is a feature in 30 per cent. of cases and this may be due to 5HT or prostaglandins produced by the tumour cells. The tumour presents usually in the 50–70 age group, but there is a younger group which presents in childhood, or before the age of 30, with a family history of medullary carcinoma. These young patients are more likely to have associated phæochromatocytomata, parathyroid tumours, pigmented areas in the skin and neuromas in the skin, tongue, and mucosa of the lip and cheek. Involvement of lymph nodes occurs in 50–60 per cent. of cases and blood borne metastases are not uncommon. As would be expected, the tumours are not hormone dependent and do not take up radio-iodine. Treatment is by total thyroidectomy and resection of involved lymph nodes. Prognosis depends principally upon the presence or absence of lymph metastases. In one series, there were two deaths due to the growth in 36 cases without involved nodes, and 19 deaths out of 41 cases with involved nodes.

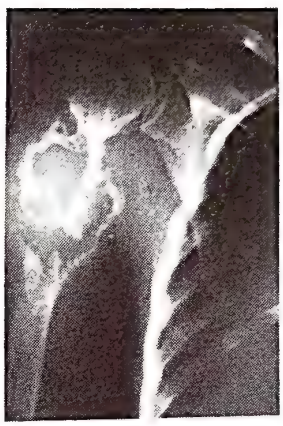


FIG. 665.—Metastasis from a carcinoma of the thyroid in a humerus. *(Dr. S. Devadatta, Vellore, South India.)*

Malignant Lymphoma.—May be difficult to differentiate from a small celled anaplastic carcinoma. Good palliation may follow total thyroidectomy and irradiation.

Ætiology of Malignant Thyroid Tumours.—Papillary carcinoma has frequently followed accidental irradiation of the thyroid in childhood—never in the adult. The incidence of follicular carcinoma is high in endemic goitrous areas, possibly due to T.S.H. stimulation. Malignant lymphomas sometimes develop in auto-immune thyroiditis so that the lymphocytic infiltration in the auto-immune process may be an ætiological factor.

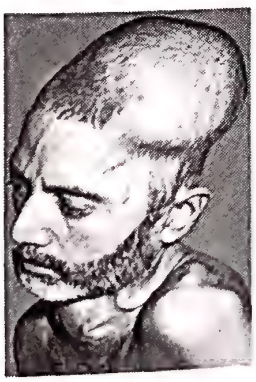

FIG. 666.—Metastasis in the left parietal bone from a carcinoma of the thyroid. *(Professor A. K. Toufeeq, Lahore, Pakistan.)*

Clinical Features.—The annual incidence is about 20 per million of the population[1] and the sex ratio 3 females to 1 male. The commonest presenting symptom is a goitre and a 5-year history is far from uncommon in differentiated growths. Recurrent nerve paralysis, enlarged cervical lymph nodes, pathological fractures (fig. 665), or a pulsating bone tumour (fig. 666), may also be the presenting feature.

Anaplastic growths are usually hard, irregular and infiltrating. A differentiated carcinoma is usually suspiciously firm and irregular, but may resemble a simple nodule. Small papillary tumours may be impalpable—

[1] In the Annual Report of the Chief Medical Officer, Ministry of Health (1965), thyroid carcinoma accounted for 298 female and 86 male deaths. As a registered cause of death the incidence is approximately that of carcinoma of the tongue and of ulcerative colitis.

even when lymph metastases are present.[1] Pain, often referred to the ear, is frequent in infiltrating growths.

Diagnosis.—Diagnosis is obvious on clinical examination in most cases of anaplastic carcinoma, although Riedel's thyroiditis (p. 614) is almost indistinguishable. The localised forms of granulomatous thyroiditis and lymphadenoid goitre may simulate carcinoma. It is not always easy to exclude a carcinoma in a multinodular goitre, and solitary nodules, particularly in the young male, are always suspect. Failure to take up radio-iodine is characteristic of almost all thyroid carcinomas,[2] but occurs also in degenerating nodules and all forms of thyroiditis. Thyroid antibody titres are often raised in carcinoma. Thus, no diagnostic test is certain, and exploration with excisional biopsy and frozen section is essential when in doubt. Incisional biopsy may cause seeding of cells and local recurrence, and is most inadvisable in a resectable carcinoma. In an anaplastic and obviously irremovable carcinoma, however, incisional or needle biopsy is justified.

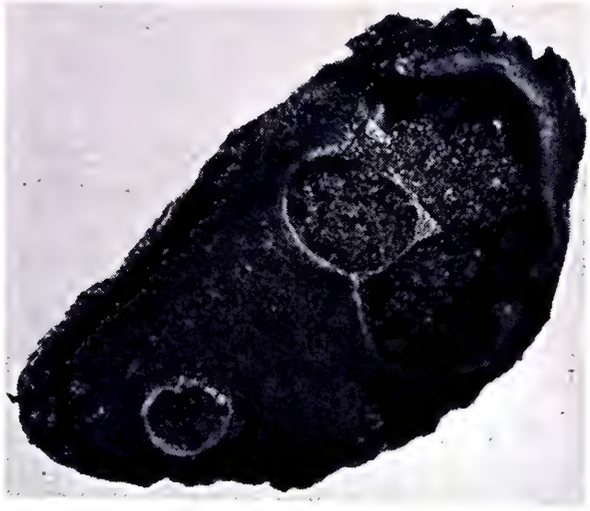

FIG. 667.—Papilliferous carcinoma of the thyroid, showing an intra-glandular seedling. This specimen demonstrates how necessary it is to remove the whole lobe, if not the whole gland. (*F. F. Rundle, F.R.C.S., Sydney, Australia.*)

Histological Surprise.—Not infrequently a differentiated carcinoma of the thyroid is unsuspected until the histological report on a nodule is received—several days after thyroidectomy. In follicular carcinoma further surgery is rarely necessary if the growth has been excised with a healthy margin of thyroid tissue. In papillary carcinoma, however, re-exploration with total thyroidectomy and excision of juxta-thyroid nodes is essential if multiple foci are present, as these indicate lymphatic spread: if the growth is solitary, conservative treatment as for a follicular growth is justified, as the risk of local recurrence can be accepted provided that a careful follow-up is carried out. In all cases, long term observation and full replacement dosage of thyroxine are essential.

Local Recurrence of Differentiated Carcinoma

This may be due to—1. Tumour foci in the thyroid remnant if total thyroidectomy was not performed. 2. Tumour in affected juxta-thyroid nodes not cleared at the initial operation. 3. Spillage of cells from an ill-advised incisional biopsy.

Recurrence may occur 10 or more years after the initial operation.

Total Thyroidectomy

Near-total is a better term than total thyroidectomy, because surgical removal of all thyroid tissue is almost impossible and a little thyroid tissue may have to be left to protect the parathyroid artery. At least one parathyroid gland should be identified and preserved: this is usually the superior gland on the side opposite to the primary growth. The risks of post-operative complications—recurrent nerve injury and parathyroid insufficiency—have been exaggerated, and do not contraindicate total thyroidectomy when it is advisable.

[1] So called Lateral Aberrant Thyroid (p. 615).

[2] Only very rarely will differentiated carcinoma (primary or secondary) take up ^{131}I in the presence of normal thyroid tissue.

THYROIDITIS

1. Granulomatous Thyroiditis. 2. Auto-immune Thyroiditis. 3. Riedel's Thyroiditis.

1. **Granulomatous Thyroiditis** (Subacute Thyroiditis—de Quervain's Thyroiditis). This is due to a virus infection.[1] In a typical subacute presentation there is pain in the neck, fever, malaise and a firm, irregular enlargement of one or both thyroid lobes. There is a raised E.S.R., absent thyroid antibodies, the serum T^4 is a high normal or slightly raised, and the ^{131}I uptake of the gland is low. The condition is self-limiting and in a few months the goitre has subsided: subsequent hypothyroidism is rare. In 10% of cases the onset is acute, the goitre very painful and tender and there may be symptoms of hyperthyroidism. 35% of cases are asymptomatic but for the presence of the goitre. If diagnosis is in doubt, it can be confirmed by the rapid symptomatic response to prednisone: but if symptomless a biopsy may be necessary. The specific treatment for the acute case with severe pain is to give prednisone—10 to 20 mg. daily—for seven days and the dose is then gradually reduced over the next month.

2. **Auto-immune Thyroiditis.**—This is much more common than was previously thought. It is usually associated with raised titres of thyroid antibodies (see table) and not infrequently there is a family history of other auto-immune diseases, e.g. pernicious anæmia, auto-immune gastritis and thyrotoxicosis.

Classification.—1. Focal thyroiditis. 2. Diffuse non-goitrous thyroiditis (Primary Myxœdema p. 592). 3. Diffuse goitrous thyroiditis (Lymphadenoid goitre—Hashimoto's disease).[2]

Focal Thyroiditis is commonly seen on histological examination in association with other thyroid disease—notably toxic goitre. Its presence is a warning that post-operative hypothyroidism is likely.

Diffuse Goitrous Thyroiditis.—The histological picture is of interfollicular plasma cell and lymphocytic infiltration, lymph follicles, a varied epithelial change—ranging from destruction to hyperplasia, and a tendency to eventual fibrosis.

THYROID ANTIBODIES

Site of Antigen	*Antibody*	*Test*	*Significant Titres*
Thyroid Cytoplasm	Microsomal Antibody	1. Complement Fixation Test (C.F.T.)	1 in 64
		2. Immunofluorescent.	
Thyroid Colloid	1. Thyroglobulin Antibody	1. Precipitin	+VE ≡ 1:25,000
		2. Tanned Red Cell (T.R.C.)	T.R.C. 1:2,500
	2. Second Colloid Antibody.	Immunofluorescent	

Thyroid antibodies may be present in normal persons and in those with goitres of all varieties. Low titres are not diagnostic of auto-immune disease. Tests normally available are C.F.T., T.R.C. and Precipitin.

Clinical Features.—There is no typical Hashimoto's disease. As might be expected from the varied histological picture, the onset, the thyroid status and the type of goitre vary profoundly from case to case. The onset may be

[1] An epidemic reported from Israel was due to a mumps virus.

[2] The concept of Hashimoto's disease as an auto-immune thyroiditis was first defined by Roitt and his co-workers in 1956.

Fritz de Quervain, 1868–1940. Professor of Surgery, Berne, Switzerland. Described this form of thyroiditis in 1902.
Hakaru Hashimoto, 1881–1934. Director of the Hoshimoto Hospital, Mie, Japan. Described this disease in 1912.
Ivan Maurice Roitt, Contemporary. Professor of Immunology, Middlesex Hospital, London.

insidious and asymptomatic, or so sudden and painful that it resembles the acute form of granulomatous thyroiditis. Mild hyperthyroidism may be present initially, but hypothyroidism is inevitable and may develop rapidly or extremely slowly. The goitre is usually lobulated, and may be diffuse or localised to one lobe. It may be large or small, and soft, rubbery or firm in consistency—depending upon the cellularity and the degree of fibrosis. The disease is commonest in women at the menopause, but may occur at any age. Papillary carcinoma and malignant lymphoma are very occasionally associated with lymphadenoid goitre.

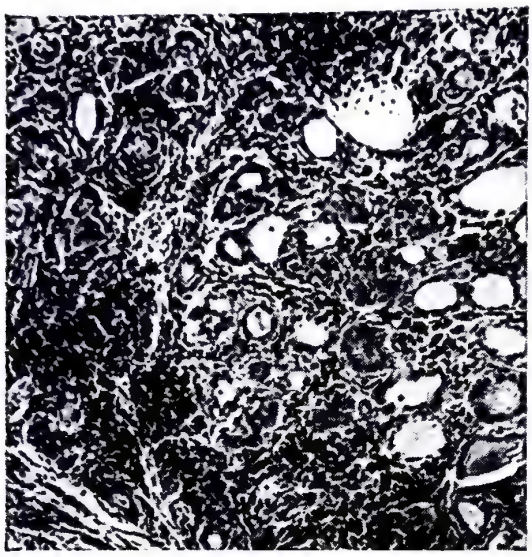

FIG. 668. — Hashimoto's disease (struma lymphomatosa). × 100. Intense lymphocytic-plasma cell infiltration, acinar destruction, and fibrosis. Compare with the normal histology (fig. 652). *(Dr. Bernard Fox, London.)*

Diagnosis. — Chemical tests of thyroid function vary with the thyroid status and are of diagnostic value only if hypothyroidism is present. A radio-active iodine uptake test is often helpful.[1] Significantly raised titres of one or more thyroid antibodies are present in over 85 per cent of cases. Nevertheless, differential diagnosis from nodular goitre, carcinoma and malignant lymphoma of the thyroid is not always easy and needle or open biopsy may be necessary (fig. 668).

Treatment. — Full replacement dosage of thyroxine should be given in every case, because eventual hypothyroidism is inevitable, and because some early lymphadenoid goitres (under T.S.H. stimulation) may subside with hormone therapy. Subtotal thyroidectomy may be necessary if the goitre is large and causes discomfort.

3. Riedel's Thyroiditis

This is very rare, accounting for 0·05% of goitres. Thyroid tissue is replaced by cellular fibrous tissue which infiltrates through the capsule into adjacent muscles, paratracheal connective tissue and carotid sheath. It may occur in association with retroperitoneal and mediastinal fibrosis and is most probably a collagen disease. The goitre may be unilateral or bilateral and is very hard and fixed. A serum P.B.I. and radio-iodine uptake are within normal limits and the scan shows no uptake over the tumour. The differential diagnosis from anaplastic carcinoma can only be made with certainty by biopsy when a wedge of the isthmus should also be removed to free the trachea. If unilateral, the other lobe is usually involved later and subsequent hypothyroidism is common.

ECTOPIC THYROID AND ANOMALIES OF THE THYROGLOSSAL TRACT

Ectopic and Aberrant Tissue

Some residual thyroid tissue along the course of the thyroglossal tract is not uncommon, and may be lingual, cervical or intra-thoracic. Very rarely the whole gland is ectopic.

[1] A high 48 hour PB ^{131}I in the absence of a previous thyroidectomy or treatment with radio-active iodine is very suggestive.

Bernhard Moritz Carl Ludwig Riedel, 1846–1916. Professor of Surgery, Jena, Germany. Described this form of thyroiditis in 1896.

Lingual Thyroid.—Forms a rounded swelling at the back of the tongue at the foramen cæcum (fig. 669) and it may represent the only thyroid tissue present. It may cause dysphagia, impairment of speech, respiratory obstruction or hæmorrhage. It is best treated by full replacement with l-thyroxin when it should get smaller, but excision or ablation with radio-iodine is sometimes necessary.

FIG. 669.—Lingual thyroid.
(H. Wapshaw, F.R.C.S., Glasgow.)

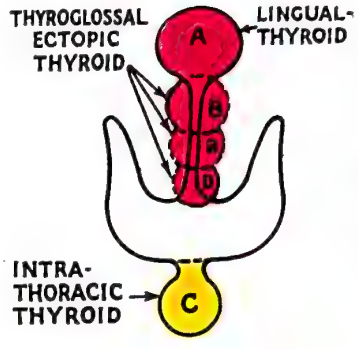

FIG. 670.—Ectopic and aberrant thyroids. A and B are ectopic thyroids, C intrathoracic aberrant thyroid (nearly always acquired).

Median (Thyro-glossal) Ectopic Thyroid.—Forms a swelling in the upper part of the neck (fig. 670B) and is usually mistaken for a thyroglossal cyst. Again, this may be the only normal thyroid tissue present.

Lateral Aberrant Thyroid.—There is no evidence that aberrant thyroid tissue ever occurs in a lateral position (Willis). 'Normal Thyroid Tissue' found laterally, separate from the thyroid gland, must be considered and treated as a metastasis in a cervical lymph node from an occult thyroid carcinoma, almost invariably of papillary type.

Struma Ovarii.—Is not ectopic thyroid tissue, but part of an ovarian teratoma. Very rarely carcinogenic change occurs or hyperthyroidism develops.

Anomalies of the Thyroglossal Tract

Thyroglossal Cyst.—May be present in any part of the thyroglossal tract (fig. 671). The common situations, in order of frequency, are beneath

FIG. 671.—Possible sites of a thyroglossal cyst: (1) Beneath the foramen cæcum. (2) In the floor of the mouth. (3) Suprahyoid. (4) Subhyoid. (5) On the thyroid cartilage. (6) At the level of the cricoid cartilage.

Rupert Allan Willis, Contemporary. Formerly Professor of Pathology, Royal College of Surgeons of England, London.

the hyoid (fig. 672), in the region of the thyroid cartilage (fig. 673), and above the hyoid bone (fig. 674). Such a cyst occupies the middle line, except in

FIG. 672. — Subhyoid thyroglossal cyst. The commonest variety.

FIG. 673.—Thyroglossal cyst in relation to the thyroid cartilage.

FIG. 674.—Suprahyoid thyroglossal cyst.

the region of the thyroid cartilage, where the thyroglossal tract is pushed to one side, usually to the left.

A thyroglossal cyst should be excised because infection is inevitable (fig. 675) due to the fact that the wall contains nodules of lymphatic tissue which

FIG. 675.—Inflamed thyroglossal cyst.

FIG. 676.—A long-standing thyroglossal fistula. The semilunar fold is characteristic.

communicate by lymphatics with the lymph nodes of the neck. An infected cyst is often mistaken for an abscess and incised, which is one way in which a thyroglossal fistula arises.

Thyroglossal Fistula.—Is never congenital: it follows infection or inadequate removal of a thyroglossal cyst. Long-standing fistulæ are inclined to be situated low down in the neck, and fig. 676 shows an example that had been present for twenty years. The hood of skin, with its concavity downwards (due to uneven rates of growth of the neck as a whole and that of the thyroglossal tract), is characteristic. A thyroglossal fistula is lined by

columnar epithelium, discharges mucus, and is the seat of recurrent attacks of inflammation.

FIG. 677.—Complete extirpation of the thyroglossal tract. A portion of the body of the hyoid bone has been removed, and the dissection is proceeding towards the foramen cæcum.

Treatment.—Because the thyroglossal tract is so closely related to the body of the hyoid bone, this must be excised, together with the cyst or fistula, or recurrence is certain. If the thyroglossal tract can be traced upwards towards the foramen cæcum, it must be excised with a central core of lingual muscle (Sistrunk's operation) (fig. 677).

Walter Ellis Sistrunk, Jr., 1880–1933. Professor of Clinical Surgery, Baylor University College of Medicine, Dallas, Texas, U.S.A.

CHAPTER 34

THE PARATHYROID AND ADRENAL GLANDS

THE PARATHYROID GLANDS

Anatomy and Physiology.—The parathyroid glands, 4 in number are small, oval in shape, about 0·5 to 1·0 cm in size, yellowish-brown in colour and arranged in pairs —closely applied to the thyroid gland, but outside its capsule. The upper pair are fairly constant in position and found on the posterolateral border of the thyroid immediately above the point of entry of the inferior thyroid artery. The lower pair, more variable in position, are usually found at the lower pole of the thyroid, but may be found anywhere along a line from this situation downwards to the upper pole of

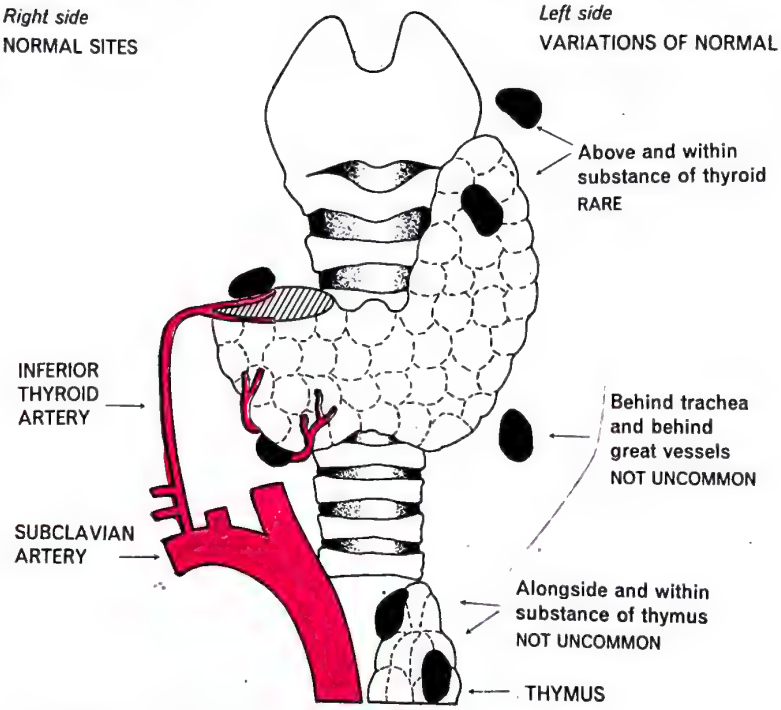

FIG 678.—Parathyroid gland. Normal and abnormal sites.

the thymus (fig. 678). Approximately 5% of parathyroid glands are found within the upper anterior mediastinum. Each gland has a smooth capsule and is supplied by a single leash of blood vessels which can be clearly seen running in the subcapsular plane (fig. 679).

Histology.—The stroma consists of a rich sinusoidal capillary network with islands of secretory cells interspersed with fat cells. The glandular cells are of two types. The 'chief' or 'principal' cells are small with vesicular nuclei and poorly staining cytoplasm. 'Water-clear' cells, derived from the chief cells, are found in the hyperplastic and neoplastic glands. The 'oxyphil' cells are less numerous and larger, with granular cytoplasm and deeply staining nuclei.

Function.—The chief cells of the parathyroids produce parathormone, the hormone being released directly into the blood-stream. The circulating level of parathormone can be measured by radio-immuno-assay, but the method is not generally available at present. It is sufficiently reliable to distinguish between high and low levels.

Parathormone.—(i) Stimulates osteoclastic activity, thereby increasing bone resorption by mobilizing calcium and phosphate.

(ii) Increases the re-absorption of calcium by the renal tubules, thus reducing the urinary excretion of calcium.

(iii) Augments the absorption of calcium from the gut.

(iv) Reduces the renal tubular re-absorption of phosphate, thus promoting phosphaturia.

Calcitonin (Copp), was once thought to be the second parathyroid hormone, but is now known to be secreted by the thyroid (Thyrocalcitonin). It lowers the serum calcium and effects calcium storage in bones; quite the opposite action to parathormone.

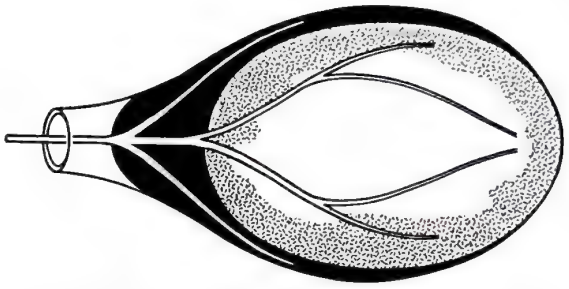

FIG. 679.—The blood supply of a parathyroid gland.

HYPOPARATHYROIDISM

Parathyroid tetany is a rare complication of subtotal thyroidectomy (less than 1%). At this operation some of the parathyroid glands may be removed or have their blood supply temporarily embarrassed. Symptoms usually appear on the second or third postoperative day, and are temporary. Milder forms of hypoparathyroidism have been described in the follow-up of thyroidectomised patients. Permanent hypoparathyroidism, most commonly encountered following radical thyroidectomy for cancer, requires constant supervision and treatment. Tetany in the new-born may occur within the first few days of life in the child born of a mother with undiagnosed hypoparathyroidism.

Clinical Features.—The first symptoms are tingling and numbness in the face, fingers and toes. In extreme cases cramps in the hands and feet are very painful; the extended fingers are flexed at their metacarpophalangeal joints, with the thumb strongly adducted. The toes are plantar flexed and the ankle joints extended—the so-called carpopedal spasm. Spasm of the muscles of respiration not only result in pain and stridor, but dread of suffocation. In infancy, the symptoms of tetany may be mistaken for epilepsy, though there is no loss of consciousness.

Latent tetany may be demonstrated by:

(i) *Chvostek's sign.*—Tapping over the branches of the facial nerve at the angle of the jaw will produce twitching at the corner of the mouth, the ala of the nose and the eyelids.

FIG. 680.—The 'obstetrician's hand' seen in parathyroid tetany.

(ii) *Trousseau's sign.*—A sphygmomanometer cuff applied to the arm and inflated above the systolic blood pressure for not more than two minutes will produce carpal spasm (fig. 680).

Treatment.—In acute cases the symptoms can be quickly and effectively relieved by the slow intravenous injection of 10–20 ml of a 10% solution of calcium gluconate, and this may be repeated as required until the patient's circulating calcium level has been stabilised. Absorption of calcium is encouraged by the oral administration of Calciferol (vitamin D_2), and calcium lactate. An initial dose of 400,000 units of Calciferol may be followed by 100,000 units daily for

Douglas Harold Copp, Contemporary. Professor of Physiology, University of British Columbia, Vancouver, B.C., Canada.
Frantisek Chvostek, 1835–1884. Physician, Josefsakademie, Vienna.
Armand Trousseau, 1801–1867. Physician Hôtel Dieu, Paris.

several days, according to the patient's need. The only reliable guide to dosage is the level of the serum calcium, which should be estimated daily.

HYPERPARATHYROIDISM

Symptoms of overactivity of the parathyroid glands may result from single or multiple adenomas, hyperplasia of all 4 glands, or carcinoma. A single adenoma is the commonest finding (multiple in 6%). The whole gland is usually considerably enlarged, darker in colour, firmer and more vascular than normal; in some a rim of normal parathyroid tissue can be seen surrounding the adenoma. The histological appearances are the same as in hyperplasia, with a predominance of chief and water-clear cells. Carcinoma of the parathyroids is extremely rare, less than 5%. It tends to invade locally and recur after operation. Blood-borne metastases have been described.

Clinical Features.—Hyperparathyroidism, rarely found in the first decade of life, is commoner in women than men, and most commonly found between the ages of 20 and 60 years. The clinical features vary enormously, even when the biochemical changes are similar. The disease has been described as one of *bones, stones, abdominal groans and psychic moans.*

Bone Disease.—There may be generalised decalcification of the skeleton, as in osteitis fibrosa cystica (von Recklinghausen's disease), single or multiple cysts, or pseudotumours of any bone. The latter are particularly common in the jaw bones. Early X-ray changes first appear in the skull and in the phalanges, with loss of density and subperiosteal erosions. Many patients presenting with vague pains in the bones and joints are mistakenly diagnosed as rheumatism.

Renal Stones.—The formation of renal stones is much the commonest result of hyperparathyroidism, and this diagnosis must be considered in every patient presenting with renal tract stone or nephrocalcinosis (fig. 681), and even in those cases of renal colic where no stone can be demonstrated.

Dyspeptic Cases.—Patients with nausea, vomiting and anorexia are relatively common. Peptic ulcer and pancreatitis are not infrequently found in association with hyperparathyroidism, but the relationship is not as yet fully understood.

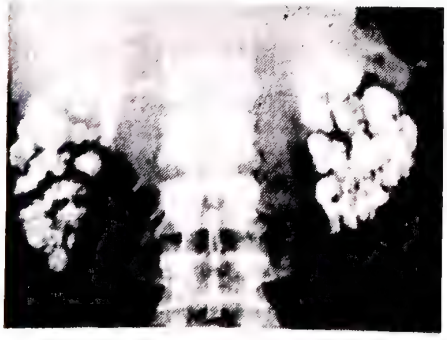

FIG. 681.—Nephrocalcinosis.

Psychiatric Cases.—Are not uncommon; women, complaining of tiredness, listlessness and with obvious personality changes, are often wrongly labelled 'neurotic' or 'menopausal'. Patients have been admitted to mental institutions because of irrational behaviour.

Acute Hyperparathyroidism.—This diagnosis is difficult and only too often made after death. Nausea and abdominal pain is followed by severe vomiting, dehydration, oliguria, and finally coma. The serum calcium is very high, up to 17 mg/100 ml (4·2 mmol/l) or more. Treatment is urgent.

Friedrich Daniel von Recklinghausen, 1833–1910. Professor of Pathology, Strasbourg, France.

Asymptomatic Cases.—Since the advent of routine biochemical screening of all patients attending hospital, more and more cases of hyperparathyroidism fall into this group.

Clinical Examination and Investigation.—Except in severe bone cases with skeletal deformities, swellings or pathological fractures, clinical examination is usually negative. A parathyroid tumour is rarely palpable in the neck. The diagnosis is confirmed with the following biochemical findings:

(i) Elevation of serum calcium (upper limit of normal 10·9 mg/100 ml (2·6 mmol/l)).

(ii) Diminution of serum phosphorus (lower limit of normal 3·0 mg/100 ml (0·8 mmol/l)).

(iii) Increased excretion of calcium in the urine (upper limit of normal 250 mg (6·2 mmol) per 24 hours for females, 300 mg (7·5 mmol) for males).

(iv) Elevation of the serum alkaline phosphatase in bone cases.

Differential Diagnosis.—Other cases of hypercalcæmia must be remembered and excluded. They are:

(i) Secondary cancer in bone (breast, prostate, bronchus, kidney and thyroid).

(ii) Carcinoma with endocrine secretion (bronchus, kidney and ovary).

(iii) Multiple myeloma.

(iv) Vitamin D intoxication.

(v) Sarcoidosis.

(vi) Thyrotoxicosis.

Treatment.—The only corrective treatment is surgical removal of the overactive gland or glands.

Pre-operative treatment is not usually necessary. In acute cases, rapid correction of dehydration and electrolyte imbalance is necessary, with a careful daily check on the serum calcium. Where there is extensive skeletal decalcification, the patient should be given one tablet of calcium lactate and 500 international units of vitamin D daily for a few days prior to operation, and for several weeks afterwards to prevent postoperative tetany.

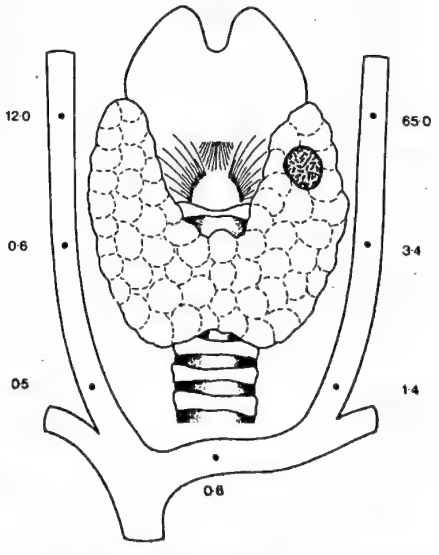

FIG. 682.—Selective venous sampling of parathormone levels to detect site of tumour.

As there is no pre-operative method for determining the likely pathology, the surgeon at operation must identify all 4 glands, study each carefully, both macroscopically, and, if need be, microscopically after biopsy. Adenomas, single or multiple, are removed; in hyperplasia three glands should be removed with half of the fourth; in carcinoma, a radical local resection is required.

In approximately 10% of cases even the most experienced surgeon in this field may find difficulty in locating a parathyroid adenoma. Selective venous

sampling with estimation of parathyroid hormone levels at these points is of great help to the surgeon in locating the tumour, especially after a first neck exploration has failed (fig. 682).

Prognosis.—With successful surgery, bones will recalcify and pseudo-tumours resolve. Renal stones will not disappear, but the incidence of recurrence after surgical removal is reduced, and deterioration in renal function is prevented. Psychiatric patients show an early, and often remarkable, recovery. In a small minority of cases hyperparathyroidism recurs after several years, and may warrant further surgery.

Secondary Hyperparathyroidism.—In patients with a low serum calcium, such as one finds in *chronic renal failure* and *malabsorption syndromes*, there is a compensatory parathyroid hypertrophy affecting all 4 glands. Few of these will require surgical treatment and only when bone pain and skeletal decalcification is severe.

THE ADRENAL GLANDS

Surgical Anatomy.—At birth, the adrenal glands have attained nearly adult proportions. Fully developed, each weighs about 4 g, but the left is a little larger than the right. A deeper yellow colour and a firmer consistency enables the gland to be distinguished from the adjacent fat. Each rests on the superior, anterior, and medial aspects of the superior pole of the corresponding kidney, and presents the appearance of a French Liberty cap worn at a rakish angle.

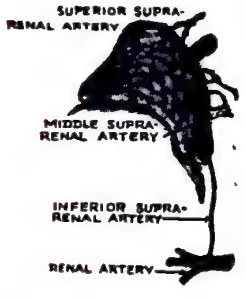

FIG. 683.—Right adrenal gland, viewed from in front.

The intimate anatomical relationship of the cortex to the medulla of an adrenal gland is the only good reason for considering the two portions of the gland as one and the same structure. Embryologically, histologically, pathologically and functionally, the adrenal cortex and the adrenal medulla are separate internal secretory glands.

The adrenal glands are supplied by several adrenal arteries (fig. 683), rendering them remarkably vascular, but only one vein drains each gland. On the right side the adrenal vein is short and enters the inferior vena cava just distal to the hepatic vein, while on the left it empties into the left renal vein (which communicates through the azygos vein with the left intercostal, internal mammary, and vertebral veins (Anson)). The dissimilarity of the right and left venous flow determines, to some extent, the location of metastases from malignant tumours of these glands (p. 630).

Radiography of the Adrenal Glands

Delineation of an Adrenal Tumour.—Because of their protected position, very few adrenal tumours are palpable. In some cases urography shows a deformity of the upper calyx of the corresponding kidney but this is sometimes impossible to distinguish from a renal neoplasm.

Paracoccygeal injection of oxygen into the retroperitoneal tissues is not as helpful as was first thought, even when combined with intravenous urography. Selective aortography is now employed.

Calcification in an adrenal gland is difficult to interpret in a radiograph. It is liable to be confused with a renal calculus. Areas of calcification in the adrenal glands may be present in Addison's disease (p. 625).

THE ADRENAL CORTEX

The adrenal cortex is made up of the following layers from without inwards; the zona glomerulosa, the zona fasciculata, and the zona reticularis.

Physiology.—At least fifty steroid compounds have been isolated from the adrenal cortex. These hormones exhibit various types of activity which, for practical purposes, can be arranged in three groups.

Barry J. Anson, Contemporary. Research Professor, Department of Otolaryngology and Maxillofacial Surgery College of Medicine, University of Iowa, Iowa City, U.S.A.

1. **Salt Regulating Hormones** which are concerned in the maintenance of water and electrolytic balance. A deficiency of these hormones produces sodium diuresis, potassium retention and dehydration; an excess results in hypertension, œdema, cardiac dilatation, and hypopotassæmia. **Aldosterone** is the most important of these ' salt regulating ' hormones (see Conn's syndrome, p. 628).

2. **The cortisones** are concerned with the metabolism of proteins and carbohydrates, favouring the formation of the latter from the body's storehouse of the former. This conversion is known as gluconeogenesis. Consequently hormones belonging to this group are called glucocorticoids. The best known of these are **hydrocortisone** (also known as **cortisol**), and **cortisone** (which is converted in the body to hydrocortisone). The therapeutic application of these hormones falls into two headings:

(*a*) *In Endocrine Deficiencies.*—Cortisone is the logical need in adrenocortical insufficiency (p. 599) and after bilateral adrenalectomy (p. 629).

(*b*) *In Non-endocrine Disease.*—Cortisone is used in the treatment of a diversity of diseases, including allergic conditions, granulomatous disorders, blood diseases and the collagenoses. Hydrocortisone is used in the treatment of hypocorticism and shock (p. 79) and is an effective anti-allergic agent in a number of skin diseases and eye conditions.

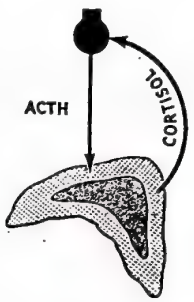

FIG. 684.—Pituitary ACTH stimulates the adrenals. Cortisol of the adrenals inhibits the output of ACTH.

3. **Sex Hormones.**—Both androgenic and œstrogenic hormones are produced by the adrenal cortex. Excessive secretion of androgens causes virilism in females, while on rare occasions excessive secretion of œstrogens brings about effeminacy in males.

Inter-hormonic Action.—The anterior lobe of the pituitary gland secretes adrenocorticotropic hormone (ACTH) which stimulates the adrenal cortex, whereas the cortisol of the adrenal cortex inhibits the secretion of ACTH (fig. 684).

Tests of Adrenal Cortical Activity

(i) *Estimation of the 24-hour output of urinary steroids (cortisol metabolites).*—The 17-oxogenic steroid and the 17-oxosteroid excretions are similar—10–20 mg/h (35–70 μmol/24h)[1] for men, 5–15 mg (17–42 μmol/24h)[1] for women, and 2–4mg (7–14 μmol/24h) for a child of six to eleven years. Adult levels are reached at about eighteen years. The average excretion is lower in coloured than in white males. After the age of forty, urinary steroid excretion gradually falls and at seventy is approximately halved.

(ii) *Plasma cortisol level.*—Normally 8–28 μg/100 ml (220–780 nmol/l).

(iii) *ACTH stimulation test.*—An intramuscular injection of corticotrophin gel (40 units twice daily)[2] stimulates the adrenal cortex, and so the urinary steroid levels are increased. Patients with adrenal hyperplasia are said to be very responsive and may give a level of 20–60 mg/24h (70–210 μmol/24h) above the prestimulation control levels of the two urinary steroids mentioned in (i).

(iv) *Adrenal Suppression.*—Injections of cortisol or dexamethasone will suppress adrenal function (fig. 684), as shown by the depression of the urinary steroids, especially in patients with adrenal hyperplasia. Adrenal tumours, however, are *autonomous*, so the excretion of urinary steroids in these cases is not suppressed.

It must be remembered that, as a rule, the result of each test alone is not a clear indication of the state of the adrenals, and therefore any conclusions must be drawn from the results of all the tests.

Disorders of adrenocortical function

The two most common disorders of adrenocortical function are chronic insufficiency (Addison's disease, p. 625) and chronic over-activity (Cushing's syndrome, p. 626).

[1] Estimated as dehydro-epianorosterone.

[2] A single injection of 250 microgrammes of a synthetic corticotropin (Synacthen) may be used instead. Normally this will double the plasma cortisol level in the space of thirty minutes.

Acute Hypocorticism:

1. **Adrenal Apoplexy in the Newborn.**—Extensive hæmorrhage into one (fig. 685) or both adrenals can be a cause of death in infants within the first few days of birth. The condition may occur after long and difficult labour, and particularly when resuscitative procedures have to be employed to combat asphyxia neonatorum. The hæmorrhage into the adrenels follows necrosis of the innermost layer of the cortex, which always occurs at birth, possibly as a result of sudden withdrawal of the female sex hormone (œstrogen). Adrenal crisis in the newborn produce signs of profound shock. A mass may be palpable in one or both renal regions. Intravenous fluid therapy with hydrocortisone, or, failing the latter, cortisone intramuscularly, offers the only hope.

FIG. 685.—Kidney and adrenal of a newly born infant showing hæmorrhage into the adrenal gland.

2. **Waterhouse-Friderichsen Syndrome.**—Massive bilateral adrenal cortical hæmorrhage, occurs in cases of fulminating meningococcal septicæmia and in some cases streptococcal, staphylococcal, or pneumococcal septicæmia. Most of cases occur in infants and young children, but it can happen in adults. The onset is catastrophic, with rigors, hyperpyrexia, cyanosis, and vomiting. Petechial hæmorrhages into the skin which coalesce rapidly into purpuric blotches are a constant feature. Profound shock follows, and before long the patient passes into coma. The condition is one of overwhelming sepsis that pursues a galloping course, death occurring in most cases within forty-eight hours of the onset of symptoms unless correct treatment is given without delay.

Unilateral hæmorrhage causing a lesser degree of systemic upset and not associated with infections has been described. This type of case resembles a perinephric abscess or other upper abdominal acute condition.

Confirming the Diagnosis.—It is futile to await the result of a blood culture. Bilateral tenderness 5 cm. below the costal margin, clear urine (oliguria is often present), and an absence of signs in the lungs help to call attention to the adrenal glands. In meningococcal infection the diplococcus can be demonstrated by smears obtained from a punctured petechial spot in the skin.

Treatment.—Antibiotic therapy must be given intensively by the intravenous route. In addition, an intravenous infusion of dextrose-saline solution containing hydrocortisone 100 to 200 mg. per litre is given. In the absence of hydrocortisone, cortisone can be given intramuscularly, but its action is slower and less certain. Oxygen should also be administered. Following such treatment, improvement often sets in within three hours, and a number of patients have recovered.

3. **Crises of Infantile Hypercorticism** (p. 626).

4. **Following Bilateral Adrenalectomy.**—If precautions are taken (p. 628), acute hypocorticism is unusual in the post-operative period. In the months that follow, crisis may occur if the correct dose of cortisone replacement is not given. The treatment is to support the blood pressure with D.O.C.A. (desoxycorticosterone acetate, 5 to 20 mg. intramuscularly), and then administer 3 litres of dextrose-saline solution per twenty-four hours, 50 to 200 mg. of hydrocortisone being added to each flask. Failing hydrocortisone, give cortisone intramuscularly.

5. **Postoperative Adrenal Hæmorrhage.**—Adrenal hæmorrhage can be an unexpected cause of deterioration and sudden death in the postoperative period. In some cases the left adrenal gland is damaged during radical gastrectomy for carcinoma (Fox). In other cases when adrenal hæmorrhage is bilateral, there is no evidence of operative injury, they are usually associated with intra-abdominal sepsis, pneumonia, coagulation defects and cancer. Thrombosis of the adrenal veins is the cause of infarction of the glands.

The diagnosis of postoperative adrenal hæmorrhage is difficult. It should be suspected when there is sudden collapse, with hypotension, particularly if associated with upper abdominal pain and tenderness. Other evidence of acute adrenal failure

Rupert Waterhouse, 1873–1958. Clinical Pathologist and Physician, Royal United Hospital, Bath, England. Described this syndrome in 1911.
Carl Friderichsen, Contemporary. Formerly Medical Superintendent, Children's Department, Sundby Hospital, Copenhagen. Wrote his account of this syndrome in 1918.
Bernard Fox, Contemporary. Pathologist, Charing Cross Hospital, London.

are vomiting, diarrhœa and mental confusion. The most useful laboratory finding is a low plasma cortisol, although unexplained blood eosinophilia is very suggestive of adrenal failure. The classical changes of hyperkalæmia and hyponatræmia often take several days to appear and may be obscured by intravenous therapy. If the diagnosis is suspected, then treatment should not be withheld for lack of laboratory confirmation.

Treatment.—A therapeutic trial of at least 100 mg of intravenous hydrocortisone hemisuccinate in 500 ml of isotonic saline as quickly as possible, and repeated in about an hour, is indicated. If there is a positive response then hydrocortisone (50 mg every 6 hours) should be given. When the patient's condition has sufficiently improved, then treatment with a synthetic oral steroid should be substituted. Occasionally there may be a deficiency in mineral corticoids so that treatment with fludrocortisone is necessary. Adrenal hæmorrhage may result in chronic adrenal insufficiency (see below).

Chronic Hypocorticism

Addison's disease is due to adreno-cortical insufficiency consequent upon progressive destruction of the zona reticularis, the zona fasciculata, the zona glomerulosa, and the medulla of the adrenal glands, in that order. Tuberculosis accounts for 50 per cent. of cases, the remainder being due to atrophy, amyloidosis, and other lesions that destroy the cortex. The medulla, which may or may not be implicated, appears to play no part in the clinical disturbance.

Clinical Features.—Addison's disease usually commences in the third or fourth decade. Sometimes it is the terminal event in cases of adrenogenital hyperplasia. The sex distribution is about equal. The leading features are muscular weakness and a low blood pressure. Irregular dusky pigmentation of the skin, due to deposits of melanin, appears at points of pressure (e.g. garter, belt) and in the flexion creases. Pigmentation of mucous membranes, particularly of the mouth, is often striking. When fully established, the course of the disease is punctuated by crises of acute adrenocortical insufficiency (see above).

Confirmatory Diagnostic test.—The 24-hour urinary excretion of the 17-hydroxycorticosteroids by a patient with Addison's disease are usually less than 5 mg./24 hrs if the patient is a man and less than 1 mg./24 hrs in the case of a woman. The excretion fails to increase after ACTH administration (p. 623).

Especially during a crisis, the plasma sodium is decreased, the chlorides low, and the potassium elevated above 5 mEq (mmol)/litre.

Treatment is medical, using cortisone, and relevant cases should include chemotherapy for tuberculosis.

Prognosis.—By the use of cortisone, the expectation of life of a patient suffering from Addison's disease has been extended from up to three years to at least seven years.

Hypercorticism

The various forms of adrenal cortical hyperfunction are classified according to the age of onset. (1) Infantile. (2) Pre-pubertal. (3) Adult, otherwise known as Cushing's syndrome—the commonest type. (4) Post-menopausal. (5) Primary aldosteronism (Conn's syndrome) can occur at any age (p. 628.)

Thomas Addison, 1793–1860. Physician, Guy's Hospital, London. Described the effects of disease of the suprarenal capsules in 1849.

1. **Infantile Hypercorticism.**—Androgenic excess during intrauterine life is one form of pseudo-hermaphrodism in the *female child.* The condition is present at birth; sometimes the enlarged clitoris and a varying degree of hypospadias make it difficult to determine the infant's sex. The 17-ketosteroid content of the urine may be sufficiently elevated to substantiate a diagnosis of a female with adrenal hyperfunction. If this is not the case, it is justifiable to perform sex determination by a skin biopsy before the age of one year. Female pseudohermaphrodism with virilism is invariably associated with disease of the adrenal cortex, usually bilateral hyperplasia of the cortex. Hormonal studies have shown that there is a congenital failure of the adrenal glands to synthesise gluco-corticoids, mainly compound F. Due to this lack, these infants are liable to acute phases of adrenal insufficiency during stress or infection, or to suffer from periodic hypoglycæmic attacks. They need cortisone, not only in the emergency, but as long-term therapy, thereby inhibiting the secretion of excessive androgens. In the absence of such treatment the epiphyses join early, the patients are dwarfed, menstruation does not occur, and the breasts do not develop. These tendencies are corrected by cortisone given orally, 25 mg. or more daily, the dose being determined by 17-ketosteroid estimations (Leonard Simpson). Hirsutism is moderated, but not necessarily abolished. The treatment should be commenced early if good results are to be obtained.

2. **Pre-pubertal Hypercorticism.**—There is never any doubt as to the sex of the infant at birth, and during the very early years of life the child is normal. The symptoms commence about the age of five or six years.

In the Female.—Pubic and axillary hair appear, but there is no gross enlargement of the clitoris. The child is short in stature, the legs being especially stunted, but she looks much older than she is. Puberty is often precocious, menstruation, if it occurs, being scanty. There is a deepening of the voice at this time.

In the Male.—The term ' infant Hercules ' is descriptive. He is extremely short, muscular, and hirsute. The genitalia assume adult proportions, and spermatozoa are often present in the seminal fluid.

In both sexes, 17-ketosteroid content of the urine is increased. A very high reading supports the diagnosis of an adrenocortical tumour, which must always be excluded. In both males and females, with a later onset or the passage of time, the features of Cushing's syndrome become super-added.

Treatment.—This is identical with that of Cushing's syndrome.

3. **Post-pubertal or Adult Hypercorticism (Cushing's syndrome)** is due to an excessive production of glucocorticoids, mainly hydrocortisone (compound F). It is the commonest type of hypercorticism. In 35 per cent. of cases an adrenal neoplasm is present; in half of these the tumour is malignant. In 60 per cent. of cases the patient has bilateral adrenal hyperplasia; in one-third of these a basophilic tumour of the anterior pituitary gland—often microscopic in size—is present. In 5 per cent. of cases there is no discernible structural alteration in the adrenal glands, but in a small proportion of these there is a tumour of the pineal gland or the thymus.

In its most typical form, Cushing's syndrome is seen in patients treated with large doses of cortisone over long periods for non-endocrine diseases, particularly rheumatoid arthritis, and in patients receiving transplants.

Clinical Features.—The female : male ratio is at least 3 : 1. The great majority of cases (excluding those induced by cortisone therapy) occur in females between fifteen and thirty years of age, in whom it produces highly characteristic features. Although the patient's weight is not necessarily increased, there is a deposition of fat in certain situations. The face becomes rubicund, rounded like a full moon, and the lips are pursed. The abdomen becomes protuberant the neck thick, the supraclavicular fossæ obliterated, and a roll of fat appears over the region of the vertebra prominens

Samuel Leonard Simpson, Contemporary. Consulting Endocrinologist, St. Mary's Hospital, London.
Hercules, one of the most famous of the heroes of Greek mythology, was noted for his prodigious strength.
Harvey Cushing, 1869–1939. Professor of Surgery, Harvard University, Boston, Mass., U.S.A. (1912–1932), *(see footnote, p. 71).* *Described this syndrome in 1932.*

(buffalo hump). The arms, and especially the legs, are relatively thin, the muscular development is poor, and the patient complains of increasing weakness. As the disease progresses, so the general contour becomes more and more that of a lemon on match-sticks.→ Consequent upon the inhibitory effect of the hypercorticism on fibrous tissue, the skin becomes of tissue-paper consistency, and inelastic. Exceedingly characteristic are purple-red striæ distentiæ, mostly on the abdomen (fig. 686), of a texture that can be likened to an over-stretched garter. Ecchymoses are frequent and bruising occurs on the slightest trauma. Acne is common and there is a low resistance to skin infections. Often there is increased growth of lanugo hair, but hirsutism is usually absent. Amenorrhœa is usual or, in the male, impotence. Due to a negative calcium balance, the matrix of bone becomes thin, and severe osteoporosis results. Pathological fractures, particularly compression fracture of a vertebra, are common, and this is sometimes the first reason for the patient seeking advice. Mild glycosuria is often present. Hypertension is frequent, and eventually congestive heart failure supervenes. In about 60 per cent. of cases various psychoses occur.

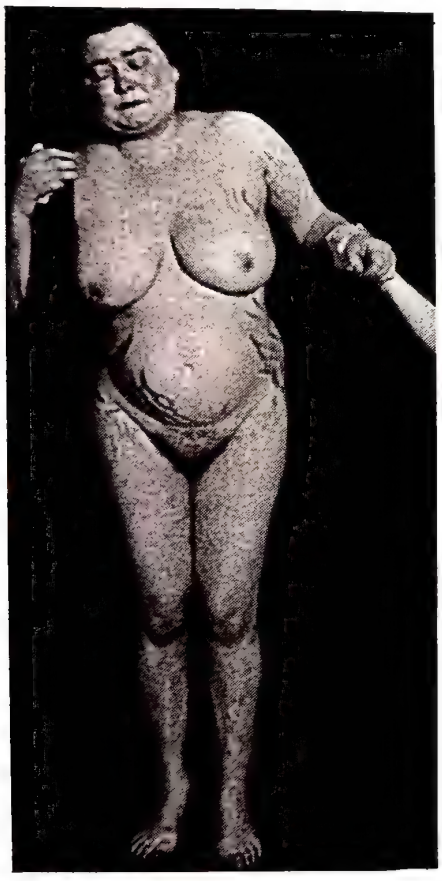

FIG. 686.—Cushing's syndrome in a woman aged twenty-three years. Adrenal hyperplasia. (*Dr. Leonard Simpson, London.*)

Cushing's syndrome is rare in children; when it occurs, the patient is nearly always a female and an adrenal tumour is usually the cause.

A sub-group, probably due to an excessive secretion of adrenal androgens (*adreno-genital syndrome*), commences between the ages of fifteen and twenty-five and is confined to females. One of the first indications of its onset is amenorrhœa or oligo-menorrhœa. There follows an excessive growth of hair on the face (fig. 687), acne, atrophy of the breasts, alteration in bodily contour and muscular development, deepening of the voice, and enlargement of the clitoris. Jewish and Spanish women are more prone to this affliction than those of other races.

FIG. 687.—Adreno-genital syndrome in a woman of twenty-eight. (*Dr. Leonard Simpson, London.*)

Arrhenoblastoma of the ovary.—This rare condition occurs between puberty and the menopause and also causes hirsutism. It may also arise in a suprarenal 'rest'.

Laboratory Findings.—Polycythæmia, lymphopænia, and eosinopænia are common. A fasting

eosinophil count over 30 per ml. of blood is good evidence against the diagnosis. The basal metabolic rate is low and the serum cholesterol is elevated. The dextrose tolerance is impaired, and the insulin tolerance test reveals a resistance to the action of insulin. Urinary 17-ketosteroids are somewhat high, and urinary ketogenic steroids are above normal levels. There is a negative calcium balance and radiography of the skeleton reveals osteoporosis, most marked in the spine and pelvis.

Treatment.—In cases of cortical hyperplasia, total adrenalectomy on one side and resection of seven-eighths of the adrenal gland on the other side (usually after an interval) is the best course. Obviously the only treatment for neoplastic cases is excision of the adrenal gland bearing the tumour.

If a pituitary tumour causes oculomotor symptoms or enlargement of the pituitary fossa as seen on X-ray, it should be removed surgically (p. 439); in other circumstances destruction of the gland by the implantation of pellets of radio-active Yttrium 90 may be performed (Forrest).

Very rarely, the *adreno-genital syndrome* appears in youths and men. Owing to excessive production of œstrogenic hormones by the adrenal cortex, gynæcomastia, atrophy of the testicles, and psychic signs of effeminacy appear (Adrenal Feminism).

4. **Post-menopausal hypercorticism** is usually characterised by the growth of a beard (the bearded woman of the circus), and is often accompanied by mental aberration. A lesser degree of hirsutes is almost a natural accompaniment of the aging process, particularly in dark-haired females, and it is difficult to draw the line between the normal and the pathological. Thus it is that operative treatment is usually disappointing.

Primary aldosteronism (Conn's syndrome) is due to a rare adreno-cortical tumour producing aldosterone (p. 623). Excess of this leads to sodium retention and a fall in serum potassium. The latter causes the typical features of the syndrome, namely episodes of muscular weakness associated with polyuria and polydipsia. The serum sodium is high and the potassium is low, but simple administration of potassium does not relieve the condition. Special, complex urinary tests demonstrate an increase of aldosterone. Effective treatment involves removal of the causative tumour, but there is the usual difficulty in ascertaining on which side it lies (see under operation, p. 629).

ADRENALECTOMY FOR HYPERCORTICISM

It is essential that all patients who are to be subjected to extirpation of adrenal cortical tissue be prepared adequately for the operation, and supported post-operatively by adrenocortical hormone replacement therapy, irrespective of the extent of adrenal resection.

Cortisone Therapy

Pre-operative	Cortisone acetate, 100 mg intramuscularly twice a day for two days. One dose is given two hours before operation.
During the Operation and Immediate Post-operative Period	Hydrocortisone, 100 mg slowly by intravenous drip. Then a similar quantity during the subsequent twelve hours, to be followed by cortisone 50 mg intramuscularly six-hourly. If the blood-pressure remains below 100 systolic, then blood-transfusion and/or noradrenaline is given (p. 630).
Post-operative	**Day 1.**—Cortisone 50 mg intramuscularly six-hourly. **Days 2 and 3.**—Cortisone 50 mg intramuscularly eight-hourly. **Days 4 and 5.**—Cortisone 50 mg intramuscularly every twelve hours. **Days 6 and 7.**—Cortisone 25 mg by mouth every eight hours.

Andrew Patrick McEwen Forrest, Contemporary. Regius Professor of Surgery, Edinburgh.
Jerome W. Conn, Contemporary. Professor of Internal Medicine, University of Michigan, Ann Arbor, Michigan U.S.A.

Thenceforward cortisone by mouth should be reduced slowly to maintenance level in cases of total adrenalectomy, or to zero in subtotal adrenalectomy. Fludrocortisone 0·1 mg daily (replacing aldosterone) may be necessary to regulate fluid and salt balance.

N.B.—If hydrocortisone is not available, 200 mg of cortisone instead of 100 mg should be administered intramuscularly twelve hours before operation. Cortisone is cheaper than hydrocortisone.

After total adrenalectomy the patient should always carry a card stating the dosage of cortisone she is receiving. Any stress (a further operation or infection) is an indication to increase the dosage.

Operation: (*a*) When an adrenal tumour has been demonstrated preoperatively, excision of that adrenal gland alone is carried out. (*b*) If a tumour has not been demonstrated, the patient is prepared for bilateral exploration.

Because the difficulties are usually less on the left than on the right side, exploration of the left adrenal gland is undertaken first. If a tumour is found, adrenalectomy is carried out. If the left gland is found to be atrophic, it is highly probable that there is a tumour on the right side, which should be explored forthwith. Should the gland be hyperplastic or normal, subtotal (90 per cent.) adrenalectomy is indicated. If, after this has been performed, it is apparent that the patient will not tolerate a bilateral operation well, exploration of the contralateral side should be postponed.

Technique.—An ample postero-lateral incision, such as is used for exploration of the kidney (Chap. 54), is commonly employed. After subperiosteal resection of the twelfth rib the lower border of the pleura is defined and protected. The incision is extended through the bed of the twelfth rib to reveal the perinephric fat, within which the adrenal gland is identified, as described below. Sometimes an approach through the bed of the eleventh rib, reflecting the pleura upwards is preferred. (See also the abdominal approach, below).

On the right side the suprarenal vein is short and may be torn from the vena cava if it is not identified and ligated at an early stage of the dissection. By finger and gauze dissection, keeping close to the gland, the gland is freed from below and behind, upwards, ligating and dividing bleeding vessels as they are encountered, until it is suspended only by its main vascular pedicle near its apex. If subtotal adrenalectomy is to be performed, the gland is cut across with scissors so as to leave a small triangular fragment of the apex well supplied with blood-vessels. Bleeding should be controlled by swab pressure, as diathermy coagulation leads to necrosis.

BILATERAL TOTAL ADRENALECTOMY FOR INOPERABLE CARCINOMA OF THE BREAST OR PROSTATE, OR THEIR METASTASES

In somewhat less than 50 per cent. of patients, total adrenalectomy results in a surprising degree of reduction of pain, a feeling of well-being, occasional radiographic evidence of recalcification of osseous metastases, and apparent resorption of metastases in other situations. In the case of carcinoma of the breast, the operation may be combined with removal of both ovaries (p. 660). Hormone therapy is employed before, during, and after adrenalectomy as described above. The majority of patients tolerate a single-stage bilateral adrenalectomy exceedingly well.

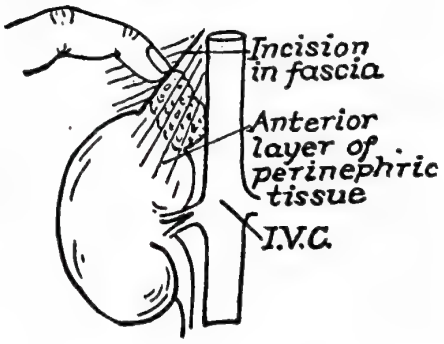

FIG. 688.—Incision in the fascia lateral to the right adrenal gland. Insertion of the finger into the space above the gland prevents its upward displacement. (*After J. C. McKeown and A. Ganguli.*)

Operation.—The anterior route is to be preferred in these cases, and the adrenal glands are approached through a curved transverse incision. The left adrenal gland is approached first by cutting along the lateral leaf of the lieno-renal ligament and then curving downwards and medially, so as to enable a wide peritoneal flap to be reflected. By retracting the spleen downwards and medially, the adrenal gland comes into view. The fascia over its lateral border is incised, and by gauze dissection the blood-vessels of the gland are defined, ligated, and divided, thus freeing the gland, which is removed. The right adrenal gland is more deeply situated. The peritoneum is incised lateral to the duodenum and above the upper pole of the kidney. The flap of peritoneum is raised to expose the anterior surface of the adrenal gland as it lies against the bare surface of the liver. The fascia covering the lateral surface of the gland is incised. A finger can then be inserted above the upper pole of the gland into the space between the two layers of fascia enclosing the gland (fig. 688). This prevents the gland from becoming displaced upwards, which otherwise it is prone to do. The anterior fascial layer is then incised transversely and the gland can be dissected under vision, as on the left side. After removal, each gland should be inspected to check its completeness, and each adrenal bed must be searched for the presence of accessory adrenal tissue, which is present in 32 per cent. of cases. If this important step is omitted, failure of the operation is not unlikely. The abdomen is closed with small drainage tubes passing to the adrenal fossæ on either side.

Alternative Approach.—Some surgeons prefer to perform bilateral adrenalectomy for carcinoma of the breast through two incisions, resecting the twelfth or eleventh ribs.

THE ADRENAL MEDULLA

The medulla of the adrenal glands (chromaffin tissue), which is developed, together with sympathetic nerves, from ectoderm, is grey in colour and connected intimately, both anatomically and functionally, with splanchnic nerves. Chromaffin tissue is so-called because the large polyhedral cells of which it is composed contain granules that stain yellow with chromic acid. These granules are the internal secretion of the adrenal medulla itself, for they can be observed being extruded *in toto* into radicles of the adrenal vein. The secretion consists of adrenaline and noradrenaline. In health, 80 per cent. of the output is adrenaline, and 20 per cent. is noradrenaline. However, in hyperfunctioning medullary tumour (phæochromocytoma) this ratio is completely reversed. Fear, anger, pain, and effort give rise to an increased output in response to the stimuli received via the splanchnic nerves.

It would appear that one of the principal functions of chromaffin tissue is to liberate quickly hormones that permit a more rapid response of the body to noxious stimuli. Noradrenaline causes an over-all vasoconstriction, thereby raising the blood pressure. Its action is short-lived.

TUMOURS OF THE ADRENAL MEDULLA

Neoplasms of the sympathetic neurones
- Ganglioneuroma
- Neuroblastoma (sympatheticoblastoma)

Neoplasm of chromaffin cells = Phæochromocytoma

Those occurring at any age:

A ganglioneuroma is relatively benign. This neoplasm is symptomless, grows to a large size, and constitutes one of the varieties of retroperitoneal 'sarcoma' (Chap. 46). Only 15 per cent. involve the adrenal, the remainder occurring in any position along the sympathetic chain. If removed completely at a comparatively early stage, a cure can be expected.

Those occurring in infants and children:

Neuroblastoma of the adrenal medulla is a reddish-grey tumour that is highly malignant. It soon breaks its confines and invades neighbouring organs, e.g. the kidney and the pancreas, and metastasises by lymphatics, and even more frequently by the blood-stream.

Clinical Features.—Distributed equally between the sexes, 80 per cent. of these comparatively rare tumours occur below the age of five years. Usually the child is

brought on account of an abdominal swelling. Pallor and loss of appetite are frequent accompaniments. The knobbly contour of an adrenal neuroblastoma helps to differentiate it from a Wilms' tumour (Chap. 54), which remains smooth even after it has attained a great size. Although unilateral, the growth, as it enlarges, extends across the middle line. About 60 per cent. of patients have metastases by the time they are seen (fig. 689).

Pepper's type of the disease.—The primary and secondaries are on the right side, with large liver metastases. In *Hutchison's type*, a left-sided primary spreads upwards by lymphatics and deposits are found in the orbit and skull. Metastases in the skull mimic the spicular osteogenic sarcoma; those in the long bones resemble Ewing's tumours. (p. 250)

Investigations should include a complete radiographic examination of the skeleton (skeletal survey).

Treatment.—Unless there are secondary deposits, exploration (before or after radiotherapy) should be undertaken; in comparatively early cases the tumour can be removed completely. When total removal is not feasible, as much as possible of the neoplasm should be excised, followed later by a course of deep radiotherapy.

If complete excision is possible, the prognosis is enhanced, but an extraordinary feature of these cases is that from time to time a patient survives when the tumour is found to be so advanced that only a piece is removed for section, and no treatment of any kind is given; sometimes even secondary deposits disappear. There is some evidence that cases which are histologically borderline between ganglioneuroma and neuroblastoma become converted to the former with high doses of *folic acid* with subsequent betterment of the prognosis. With *operation*, followed by *X-ray therapy*, about 25 per cent. of the patients recover, and if they are free from recurrence by the end of one year, it is almost certain that they are cured permanently (Gross).

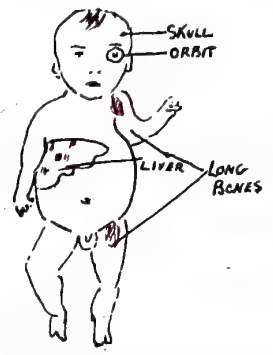

FIG. 689.—The common sites for metastases from neuroblastoma of the adrenal. Bones are involved more frequently than the liver.

Those occurring in adults (rare in children):

Phæochromocytoma is a soft brownish benign tumour, usually less than 5 cm. in diameter, composed of large differentiated sympathetic ganglion cells, and a few fibres enclosed in a delicate capsule. It owes its name to the presence of chromaffin granules. In about 15 per cent. of cases the tumour is bilateral. This tumour, occurs in both sexes, usually during early adult life or middle age. It produces, either intermittently or continuously, an excess of adrenaline, and especially of noradrenaline: the ratio of the latter to the former often being as high as 20:1 causing *hypertension* which is either *paroxysmal* or *persistent*. The latter predominates statistically and probably indicates a late stage of the disease. Consequently all patients under sixty years of age who suffer from sustained arterial hypertension deserve routine tests to confirm or exclude a phæochromocytoma. While not more than 0·5 per cent. of cases of hypertension are caused by a phæochromocytoma, at the Mayo Clinic, where routine diagnostic procedures are undertaken to confirm or exclude the presence of this tumour in all cases of hypertension, the percentage has been stated to be nearly 3 per cent. Untreated, it progresses to a fatal termination.

Clinical Features.—The most common symptoms, in order of frequency, are: headache (55 per cent.), palpitation, vomiting, sweating, dyspnœa,

Robert Edward Gross, Contemporary. Ladd Professor of Children's Surgery, Harvard University, Boston, Massachusetts, U.S.A.
The Mayo Clinic, Rochester, Minnesota, U.S.A. was founded in 1889 by William Worrall Mayo (1819–1911) and his two sons William James Mayo (1861–1939) and Charles Horace Mayo (1865–1939).

weakness, pallor—i.e. the symptoms of adrenaline overdosages. A typical attack is associated with hypertension. When the blood pressure is persistently high the patients are liable to all the complications of hypertension and may present with them. Ten per cent. of the patients have diabetes mellitus.

Radiography.—Urographic examinations sometimes reveal displacement of the upper pole of the kidney. Other radiographic investigations are those described on p. 622, that is, retroperitoneal oxygen insufflation with an intravenous urogram and tomography. Aortography shows a vascular ' blush ' at the site of the tumour. It also reveals the vascular state and size of the kidneys. If a ' blush is not seen and one kidney is diseased, this is the likely explanation of the hypertension.

Laboratory Tests

1. *Colorimetric examination of the urine* for a metabolite of noradrenaline, vanillylmandelic acid, or fluorimetric determination of the catecholamines, can be relied upon to exclude the diagnosis of phæochromocytoma.
2. *Biological assay* (injection of an extract of the urine into an animal, usually a cat) determines accurately if there is a pressor substance excreted in the patient's urine.
3. *Direct Blood Examination.*—Another test is to pass a polythene tube into the inferior vena cava and test samples of blood for their concentration of noradrenaline.
4. The response to a carefully given diagnostic dose of Rogitine[1] is also confirmatory evidence of hypersecretion of chromaffin tissue.

Operation.—Twenty to 40 mg (for an adult) of Rogitine (1 to 2 tablets) should be given after meals t.d.s., while the patient is being prepared for operation. The hazardous phases in the operation are: during the induction of anæsthesia, positioning of the patient on the operating table, when the tumour is manipulated, and immediately after removal of the tumour. Five mg of Rogitine are given intravenously, prior to commencing the anæsthetic. With an intravenous drip infusion of dextrose-saline running, the operation is commenced. If pre-operative investigations have not revealed the side on which the tumour is situated, the procedure detailed on p. 629 is carried out. As some 10 per cent. of phæochromocytomas are ectopic there is something to be said for exploration via the anterior route (p. 630). The blood-pressure rises sharply when the affected adrenal gland is handled, and to counteract this rise another 5 mg of Rogitine is given into the tube of the intravenous drip. Should it be necessary, yet another dose is given. As soon as the adrenal gland has been extirpated, a considerable fall in the blood pressure is to be expected, and is combated by giving an injection of noradrenaline (p. 630), which, during the first week following the operation, should always be at hand for immediate intravenous injection in case of need. With these precautions, the earlier operative mortality has been lowered. If symptoms persist after unilateral adrenalectomy, a tumour in the contralateral gland is highly probable. In this instance the second tumour, which is usually well-defined, must be dissected from the healthy portion of the gland. Some consider this to be the better technique for all cases, particularly because these tumours are almost always benign and the operation is curative.

The excised specimen, when fixed in bichromate solution, stains brown.

Hyperplasia of the adrenal medulla, although often more in evidence on one side than the other, is usually bilateral. Paroxysmal hypertension, clinically identical with that produced by a phæochromocytoma, is present. Unilateral adrenalectomy brings about amelioration, but for a cure of the condition, the remaining adrenal should be removed, after an interval.

[1] Rogitine (Ciba) (phentolamine B.P.), a substance that suppresses temporarily the pressor activity of the secretion of chromaffin tissue.

CHAPTER 35

THE BREAST

Comparative and Surgical Anatomy.—Mammals are distinguished and so-called because they are provided with mammary glands. The cow, sheep, goat, mare and the elephant have an udder surmounted by teats, while other animals are furnished with breasts, the number of pairs of which vary with the species, and is related to the average number of offspring in each litter. Thus the sow has six to nine pairs, rodents six or seven pairs, while, like man, the anthropoid apes, the lioness, the sea-cow and, as John Hunter first noted, the whale, have but a single pair.

In anatomical works the protuberant part of the human breast is generally described as overlying the second to the sixth ribs, and extending from the lateral border of the sternum to the anterior axillary line. Actually a thin layer of mammary tissue extends considerably farther on all sides, viz: to the clavicle above, to the seventh or eighth ribs below, to the mid-line medially, and to the edge of the latissimus dorsi posteriorly. This fact is of importance to a surgeon when he seeks to remove the whole breast. The full extent of the breast is apparent in cases of milk engorgement.

As age advances, the parenchyma of the breast undergoes considerable atrophy and becomes loose in texture, making the detection of lumps within it easier.

The axillary tail of the breast is of considerable surgical importance. In some normal cases it is palpable, and in a few it can be seen in the pre-menstrual phase and during lactation. A well-developed axillary tail is sometimes mistaken for a mass of enlarged lymph nodes or a lipoma.

The lobule is the basic structural unit of the mammary gland. In the human breast the number and size of the lobules vary exceedingly: they are largest and most numerous during early womanhood. From ten to more than a hundred lobules empty by means of ductules into a lactiferous duct, of which there are from fifteen to twenty. Each lactiferous duct is lined by a spiral arrangement of contractile myo-epithelial cells and is provided with a terminal ampulla—a little reservoir for milk or abnormal discharges.

The ligaments of Cooper are hollow conical projections of fibrous tissue filled with breast tissue, the apices of the cones being attached firmly to the superficial fascia and thereby to the skin overlying the breast. These ligaments account for the dimpling of the skin overlying a scirrhous carcinoma, or other lesions of the breast accompanied by fibrosis.

The Areola.—The subcutaneous tissue contains involuntary muscle arranged in concentric rings as well as radially. The areolar epithelium contains numerous glands of three kinds—sweat glands, sebaceous glands, and accessory mammary glands. The sebaceous glands (known as the glands of Montgomery) enlarge strikingly during pregnancy and serve to lubricate the nipple during lactation. The accessory mammary glands are minute, inconstant, and possess ducts that open on the areola.

The Nipple is covered by a thick and rather crinkled skin. Near its apex, and very difficult to see because of the cutaneous corrugations, lie the orifices of the lactiferous ducts. The nipple and the areola of a nullipara are pink; with succeeding pregnancies they become pigmented by deposits of melanin. The nipple contains smooth muscle fibres arranged concentrically and longitudinally; thus it is an erectile structure and, for the convenience of the infant in arms, points forwards and *outwards*.

Lymphatics.—The lymphatic vessels of the breast drain into (1) nodes that lie between the greater and lesser pectoral muscles; (2) the thoracic chain of lymph nodes along the lateral thoracic artery; (3) the subscapular chain that extends from the lateral thoracic wall to the axillary vein, and thence along the axillary vein, most of the lymph nodes being on the caudal aspect of that vessel; (4) the central group, which is the largest, lying at the apex of the axilla. The highest of these lymph

William Fetherston-Haugh Montgomery, 1797–1859. Obstetrician, Dublin.

nodes is sheltered beneath the clavicle; (5) The internal mammary group which lie along the internal mammary vessels.

It is highly important to know that: (*a*) there is free communication between the subclavicular and the supraclavicular lymph nodes which are involved in 33 per cent. of cases in which the axillary lymph nodes are the seat of secondary deposits of carcinoma (Andreassen); (*b*) that the postero-cervical chain of lymph nodes is linked with those of the axilla, and that (*c*) the lymph nodes along the internal mammary artery are involved in about half the cases in which the axillary lymph nodes are implicated (Handley).

Investigation of the Breast.—Although an accurate history and clinical examination are still the most important methods of detecting breast disease there are a number of investigations which can assist in the diagnosis:

Mammography.—Soft tissue X-rays are taken by placing the breast in direct contact with fine-grained film and exposing it to low voltage high amperage X-rays for a prolonged time. The standard views are lateral and supero-inferior. Mammography is a relatively accurate method of demonstrating the soft tissue architecture of the breast, but it should always be combined with clinical examination.

Galactography.—Soft tissue X-rays combined with the injection of radio-opaque material into a major lacteal duct may be used to demonstrate a duct tumour.

Thermography.—A technique by which the heat emission from the surface of the breast in the form of infra-red radiation can be recorded. The information is usually displayed on a photographic plate or a cathode tube comparable to a television screen. The heat intensity varies with the vascularity and metabolism of the tissues and is increased in inflammatory conditions and some cancers. Unfortunately the technique is as yet relatively inaccurate and has little clinical value.

THE NIPPLE

Absence of the nipple is rare, and usually associated with amazia (p. 636).

Supernumerary nipples occasionally occur along a line extending from the anterior fold of the axilla to the fold of the groin. This constitutes the milk line of lower mammals.

Retraction of the nipple is of two exceedingly important varieties: (*a*) that occurring at puberty (remote), and (*b*) that occurring during womanhood (recent).

(*a*) **Retraction occurring at puberty** is due in most instances to a developmental abnormality; the nipple, for some unknown reason, does not develop *pari passu* with the breast. It is possible that in a few instances the retraction is an aftermath of mastitis of infancy. In about one-quarter of the cases the condition is bilateral.

Non-protuberance of the nipple hinders an infant suckling at the breast. Clinical experience shows that a breast with long-standing retraction of its nipple is prone to local excoriation by the retained sebaceous gland secretion and, especially during lactation, to infection and abscess formation.

Treatment.—During and soon after puberty: if the patient draws out the nipple between finger and thumb daily for about three weeks the condition is usually remedied. In somewhat older patients, the regular application of a large warmed test-tube over the nipple may create sufficient suction to rectify the deformity.

(*b*) **Recent Retraction.**—The importance of long-standing retraction of the nipple is dwarfed by the ominous diagnostic significance of recent retraction, which is a frequent accompaniment of scirrhous carcinoma (p. 652).

Mogens Kristian Andreassen, Contemporary. *Professor of Clinical Surgery, University of Copenhagen, Denmark.*
Richard Sampson Handley, Contemporary. *Consulting Surgeon, Middlesex Hospital, London.*

Therefore the all-important question to put to the patient is : ' How long has this nipple been retracted? '

Cracked Nipple.—Want of care in the preparation for lactation and neglect of the hygiene of the nipple during lactation are the chief causes of this not uncommon condition. Its main importance lies in the fact that the crack may be a forerunner of acute infective mastitis.

Prophylaxis.—During the last two months of pregnancy the nipples and their areolæ should be washed, dried, and anointed with a little lanoline each day. The same routine may be continued, with advantage, after suckling.[1]

Treatment.—At the first sign of soreness the nipple is rested for twenty-four to forty-eight hours and the breast emptied with a breast-pump, as necessary. The nipple is washed and a mild antiseptic cream applied. When the soreness ceases, the baby is put to the breast for one minute at first and normal feeding is gradually resumed.

A cracked nipple is rested until healed. The breast is expressed and feeding gradually established as for a sore nipple. Especially if the nipple is partially retracted, the use of a nipple shield will prevent recurrence.

Papilloma of the nipple presents the features of a cutaneous papilloma. Sometimes it grows to the size of a cherry, but the pedicle is always narrow. The treatment is excision together with a tiny disc of the skin from which it grows.

Retention Cyst of a Gland of Montgomery.—These glands, situated in the areola, secrete sebum and, as a result of an orifice of one of the glands becoming blocked, a sebaceous cyst forms.

Chancre of the Nipple.—The majority of chancres of the nipple occur by infection from a syphilitic buccal mucous patch in the mouth of a member of the opposite sex. Although wet-nurses are now seldom, if ever, employed in this country, when this form of infant feeding was used the nipple was sometimes infected from the mouth of a syphilitic baby. The mother of such an infant is immune to re-infection from her own child.

Eczema of the nipple is a rare condition and is bilateral, and presents features common to eczema elsewhere.

Paget's disease of the nipple (p. 653) must be distinguished from the foregoing.

ABNORMAL DISCHARGES FROM THE NIPPLE

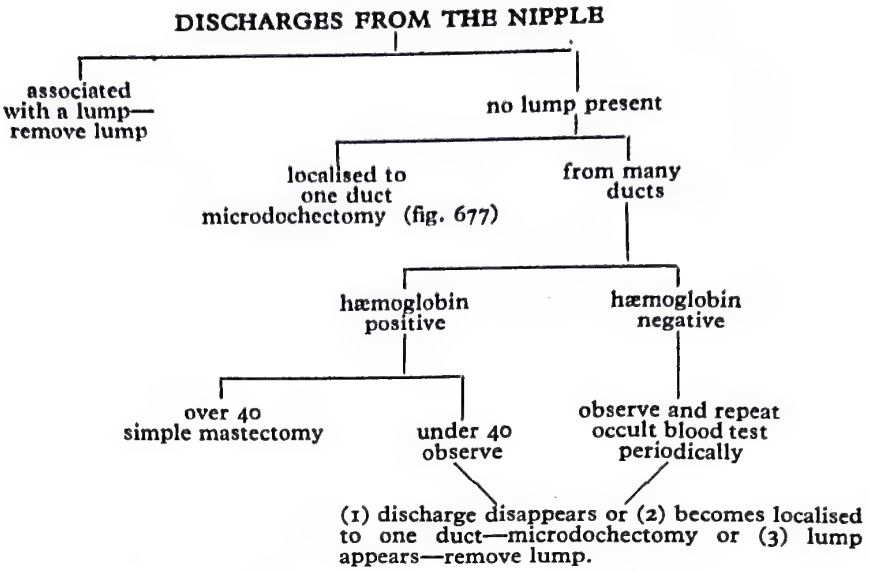
The discharge occurs from one (rarely more) of the lactiferous ducts. The management depends on the presence of a lump, or of occult blood, or whether it is localised to one duct. Mammography is usually unhelpful except to identify a grossly distended duct or a circumscribed tumour. All such cases must be kept under regular observation.

A clear serous discharge is associated usually with a retention cyst, consequent upon fibroadenosis, but may signify an underlying carcinoma.

A blood-stained discharge is pathognomonic of duct papilloma or duct carcinoma. The former condition is more common than the latter.

A black or green discharge may be due to altered blood from the foregoing, but is much more frequently an accompaniment of ductal changes

[1] In some maternity hospitals the nipple is cleansed before and after suckling by wiping it with a sponge removed from 70 per cent. alcohol solution kept in a jar labelled with the patient's name.



Scheme for management of discharges from the nipple.
(After Sir Hedley Atkins, Past P.R.C.S., London.)

and the secondary retention cysts of fibroadenosis. In cases of extensive dirty green discharge, when the breast is removed it is usually found to be riddled with cysts containing the same material.

Common causes of discharge are *Duct Papilloma* (p. 646), *Mammillary Fistula* (p. 641), and *Duct Ectasia.*

Duct Ectasia.[1]—A primary dilatation of the major ducts of the breasts which is commonly associated with discharge from the nipple in middle aged women. The ducts become distended with amorphous debris and crystalline material probably lipid in nature and the discharge is of similar composition. The initial presentation is of a worm-like swelling extending radially from the nipple. As the condition progresses there is an associated periductal inflammation with lymphocytes and plasma cells at which stage there may be local pain and tenderness and ultimately a hard mass with local skin tethering and nipple retraction (Plasma cell mastitis). The condition is benign but may be mistaken for either cancer or an abscess (Haagensen, Hadfield). Provided a tumour can be excluded the treatment should be conservative but symptomatic relief can be gained by local removal of the duct and affected segment of the breast.

FIG. 690.—Congenital absence of the right breast.

THE BREAST

CONGENITAL ABNORMALITIES

Amazia.—Congenital absence of the breast may occur on one (fig. 690) or both sides. It is sometimes associated with an absence of the sternal portion of the pectoralis major. Amazia, which is rare, is more common in males.

Polymazia.—Accessory breasts have been recorded in the axilla, groin, buttock, and thigh, the most frequent site being the axilla. They have been known to function during lactation (fig. 691).

[1] John Birkett, 1815–1904, surgeon to Guy's Hospital gave an early account of this curious condition in 1850. He was a founder member of the Pathological Society of London.

Cushman D. Haagensen, Contemporary. Surgeon, Columbia University College of Physicians and Surgeons, New York, U.S.A.
Geoffrey John Hadfield, Contemporary. Surgeon, Stoke Mandeville Hospital, Aylesbury, England

DIFFUSE HYPERTROPHY

Diffuse hypertrophy of the breasts occurs sporadically in otherwise healthy girls at puberty and, much less often, during the first pregnancy. The breasts attain enormous dimensions (fig. 692), and may reach below the knees when the patient is sitting. This tremendous overgrowth of the mammary glands is due, apparently, to their extreme sensitivity to œstrogenic hormone. Sometimes the hypertrophy is unilateral.[1] Unilateral hypertrophy may be easily mistaken for a breast which is pushed forward by a large lipoma or other tumour of the retromammary area. If diffuse hypertrophy causes real distress, a plastic procedure in the form of a reduction mammoplasty is indicated.

FIG. 691.—Functioning axillary breast. (*M. Kumar, F.R.C.S., Calicut, S. India.*)

FIG. 692. —Diffuse hypertrophy (virginal).

PENDULOUS BREASTS

Flabby breasts that hang loosely and are frequently, but not necessarily, over-size is a common cosmetic mammary complaint. The cause of the condition is regression from a former fullness, due to (*a*) over-development at adolescence, (*b*) a terminated pregnancy, (*c*) lactation, or (*d*) obesity. For the more extravagant cases, plastic reconstruction of the breasts can be undertaken.

UNDER-DEVELOPMENT OF THE BREASTS

In patients between the ages of twenty and thirty some increase in size can be expected following a two months' course of an œstrogen preparation.

INJURIES OF THE BREAST

Injuries of the breast were rare until the introduction of the diagonal motor car seat belt but are comparatively unimportant.

Hæmatoma, particularly a resolving hæmatoma, gives rise to a lump which, in the absence of overlying bruising, is difficult, if not impossible, to diagnose correctly until an exploratory incision has been made.

Traumatic fat necrosis may be acute or chronic, and usually occurs in stout, middle-aged women. Following a blow, or even indirect violence (e.g. contraction of the pectoralis major), or the administration of subcutaneous infusion into the breast, a lump, often painless, appears. In the absence of a definite lead, the swelling, which is often attached to the skin, is usually diagnosed as a carcinoma, though mammography will usually provide the diagnosis. A definite history of injury, especially that

[1] In tropical countries this must be distinguished from filarial elephantiasis of the breast.

inflicted by subcutaneous infusion, should bring the condition to the clinician's mind. On incising the lump a chalky white area of necrotic fat is found resembling necrosis seen in cases of subsiding acute pancreatitis.

ACUTE AND SUBACUTE INFLAMMATIONS OF THE BREAST

Mastitis of infants is at least as common in the male as in the female. On the third or fourth day of life, if a breast of an infant is pressed lightly, a drop of colourless fluid can be expressed; a few days later there is often a slight milky secretion, which finally disappears during the third week. This is popularly known as ' witch's milk '. The explanation of this phenomenon is that the hormone which stimulates the mother's breast reacts also upon the mammary tissue of the fœtus. Mastitis of infants is essentially a physiological activity. It may rarely lead to a true mastitis by retrograde infection.

Mastitis of puberty is encountered rather frequently, usually in males. The patient, aged about fourteen, complains of pain and swelling in the breast. In 80 per cent. the condition is unilateral but the opposite breast may be affected later. The breast is enlarged, tender and slightly indurated. Suppuration never occurs. The tenderness subsides in fourteen days or so, but induration often persists for several weeks. In some instances enlarged tender breasts may persist in males for a prolonged period even up to years. In such circumstances it may be justifiable to recommend local mastectomy.

Mastitis of mumps is usually unilateral, and more common in females.

Mastitis from local irritation, which is commonly subacute and seldom suppurates, may be produced from a too tight elastic brassière. The condition is by no means rare in men (p. 662).

Mastitis from milk engorgement is liable to occur about weaning time ; and sometimes in the early days of lactation when one of the lactiferous ducts becomes blocked with epithelial debris. In the latter instance a sector only of the breast becomes indurated and tender.

Treatment.—Unless the engorgement can be relieved with a breast pump, or by the sucking of the infant (stagnant milk being such a good medium for bacterial growth), bacterial infection is liable to supervene. Antibiotic treatment as detailed below, if commenced early, will abort the infection in most instances. The advisability of weaning the infant and inhibiting secretion of milk (see later) should receive consideration.

Bacterial mastitis, which is by far the most common variety of mastitis, nearly always commences acutely. Although often referred to as mastitis of lactation, it is incorrect to assume that acute mastitis in women is necessarily lactational. Of a hundred consecutive cases of breast abscess, thirty-two occurred in women who were not lactating (De Jode); probably some were due to infection of a hæmatoma. In almost every case the infecting organism is a staphylococcus, and in a high percentage it is penicillin-resistant. In cases where the infection is acquired in hospital no less than 90 per cent. of the infecting staphylococci are insensitive to penicillin. There are two varieties of this condition: Intramammary, and subareolar mastitis.

Louis Rene Julien De Jode, Contemporary. Surgeon, Whipps Cross Hospital, Leytonstone, London.

Intramammary mastitis (80 per cent.) frequently progresses to suppuration. In lactational cases the sufferer is often in the *first* month of her *first* lactation, or, less frequently, is suckling an infant six or more months old, when the incisor teeth are developing.

Ætiology.—In maternity wards, staphylococcal infections of the breast sometimes assume almost epidemic proportions, due, no doubt, to a staphylococcal carrier among the nursing staff. Usually the intermediary is the infant; after the second day of life 50 per cent. of infants harbour staphylococci in the nasopharynx.

'Cleansing the baby's mouth' with a swab is also an ætiological factor. The delicate buccal mucosa is excoriated by the process; it becomes infected, and organisms in the infant's saliva are inoculated on to the mother's nipple.

There seems little doubt that in the great majority of cases the precursor of intramammary mastitis is failure of secretion to escape because one (rarely more) of the lactiferous ducts becomes blocked with epithelial debris—a hypothesis that is strenghtened by the fact that, whether they are lactating or not, intramammary mastitis and abscess of the breast are relatively frequent in women with a retracted nipple. While stasis in some part of the lactiferous tree is a major factor in the production of this condition, undoubtedly the older hypothesis—ascending infection from a sore or an infected cracked nipple—must not be spurned. Once within the ampulla of the duct, staphylococci cause clotting of milk. Within the clot organisms multiply rapidly.

Clinical Features.—The affected breast, or more usually mainly one part of it, presents the classical signs of acute inflammation, and what is aptly called 'the cellulitic stage' of a breast abscess has been reached.

Treatment during the Cellulitic Stage.—The patient must be confined to bed. A broad spectrum antibiotic such as tetracycline 250 mg four times a day for seven days should be started immediately. Support to the breast with a firm many-tailed bandage and local heat will help to relieve the pain, and permit examination of the inflamed breast daily, which is essential.

To wean or not to wean is a question of great importance. Except when the patient has been suckling the child for over nine months, undoubtedly it is better not to wean. Feeding is continued from the uninfected breast, and the infected breast is emptied after each feed by manual expression, carried out by the patient herself; this is more effective than a breast pump, which does not always clear obstructed ducts. The milk expressed from the inflamed breast is boiled for five minutes before being given to the child in a feeding bottle. In patients with bilateral acute mastitis the baby can be fed entirely on the milk obtained by expression and boiled; this is not detrimental to the baby.

In cases where the child has already been breast-fed too long, or the mother finds manual expression too painful, weaning is advisable. Stilbœstrol 10 mg three times a day or as a single dose, is given after the breasts have been emptied and this usually inhibits lactation completely.

Formation of an 'Antibioma'.—It is absolutely essential that an antibiotic should *not* be given if pus is already present. If an antibiotic is given, the pus in the abscess frequently becomes sterile and a large brawny œdematous swelling remains in the breast and takes many weeks toresolve. Some times there is excessive fibrosis and this, with the absence of tenderness, has caused the diagnosis to be revised in favour of a carcinoma. It is better to explore the mass with a wide-bore aspirating needle than to cause an 'antibioma' with its attendant pain, chronicity, and ill health. Most 'antibiomas' are due to late, inadequate, and ineffective antibiotics.

Indications for Operation.—The breast should be incised when, after emptying, an area of tense induration is felt and/or when œdema of the overlying skin is found. In contrast to the majority of localised infections, fluctuation is a late sign and incision must not be delayed until it appears. Usually the area of induration is sector-shaped, and in early cases about one-quarter of the breast is involved (fig. 693); in many later cases the area is more extensive (fig. 694).

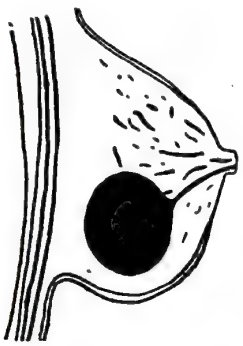


FIG. 693.—Intramammary breast abscess.

Drainage of an Intramammary Abscess.—The usual incision is sited in a radial direction over the affected segment. One which follows the cutaneo-areolar margin has a better cosmetic value and should permit access to the affected area. The best cosmetic result, however, follows the most adequate drainage rather than a particular incision. The incision passes through the skin and the superficial fascia. A long hæmostat is then inserted into the abscess cavity. Every part of the abscess is palpated against the point of the hæmostat, and its jaws are opened. All loculi and 'lactoceles' that can be felt are entered. Finally, the hæmostat having been withdrawn, a finger is introduced and any remaining septa are disrupted. Unless the abscess cavity is situated at the very highest sector of the breast a counter-incision should be made at the most dependent part of the breast and a drainage tube inserted. In this, almost more than any part in the body, *dependent* drainage is essential. Dressings are carried out aseptically on the second day, when the tube is removed, and subsequently every other day. Antibiotic therapy is unnecessary with adequate drainage but if started should be continued for the full course.

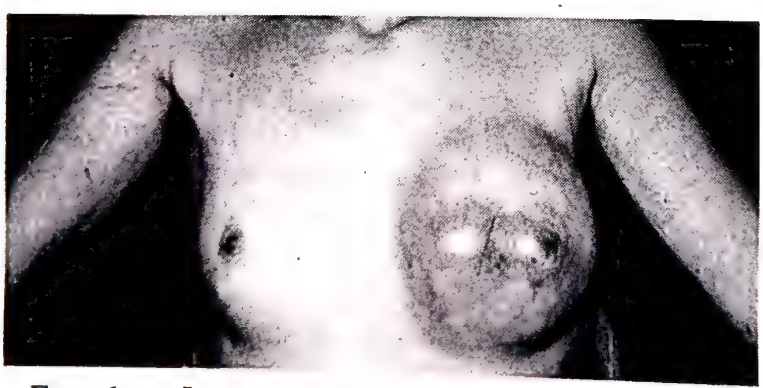

FIG. 694.—Intramammary breast abscess. The abscess should always be drained before it becomes subcutaneous. (*T. A. Bouchier-Hayes, F.R.C.S.I., Dublin.*)

FIG. 695.—Incision exactly at the areolar margin.

Subareolar mastitis (20 per cent.) is really not a true mastitis but results from an infected (sebaceous) gland of Montgomery, or from a furuncle on or near the areola. The inflammation develops insidiously, usually without constitutional symptoms. When the patient presents early, there is often an area of induration no larger than a pea. No matter how small, if a lump can be felt, pus is present (fig. 696), and the abscess should be drained without delay. Spontaneous rupture, if allowed to occur, does not cure the condition; it merely results in recrudescence or chronicity.

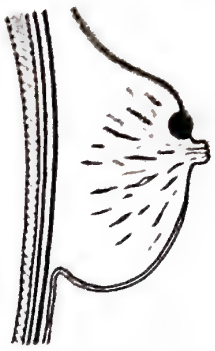

FIG. 696.—Subareolar abscess.

Chronic intramammary abscess which follows inadequate drainage or injudicious antibiotic treatment is often a very difficult condition to diagnose: when encapsulated within a thick wall of fibrous tissue, the condition cannot be distinguished from carcinoma without the histological evidence from a biopsy.

FIG. 697. — Milk-fistula originating in a chronic subareolar abscess.

Chronic Subareolar Abscess (leading to a *milk-fistula* (syn. *Mammillary fistula*)).—A recurrent subacute or a chronic abscess may occur apart from lactation in women of the child-bearing age. The condition is a frequent complication of long-standing retraction of the nipple the infection being restricted to a single obstructed duct system. The abscess ruptures and subsides, only to repeat the cycle over and over again at intervals of a few months when it forms a chronic milk-fistula (fig. 697) which continues to discharge, and flares up when the fistula closes. A non-infective inflammation such as duct ectasia (p. 636) may also result in fistula formation.

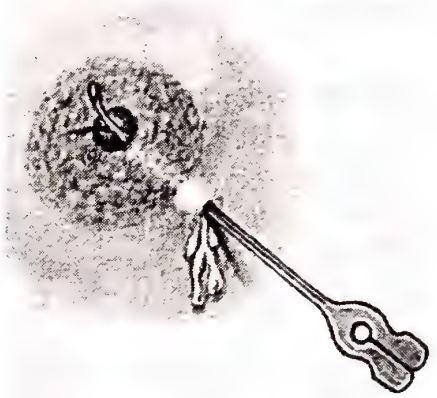

FIG. 698.—Slitting up a chronic subareolar abscess. In this case the patient has a retracted nipple of long standing. (*After H. T. Caswell and A. W. E. Burnett.*)

Treatment.—Antibiotic therapy followed by incision and drainage is useless. The fistula must be treated in the same way as a fistula-in-ano, i.e. the track is laid open and saucerised (fig. 698). The next step is to excise thoroughly the fibrous walls of the abscess. This should be followed by packing and delayed closure.

Tuberculosis of the breast, which is comparatively rare among Western races but more common in Asia and some other parts of the world, is, as a rule, associated with active pulmonary tuberculosis, or secondary to tuberculous cervical adenitis.[1]

[1] In 1829 Sir Astley Cooper, Surgeon to Guy's Hospital, London, described scrofulous swellings in the bosoms of young women, most of whom suffered from tuberculous cervical adenitis.

FIG. 699.—Tuberculosis of the breast with secondary suppurating axillary lymph nodes. *(Professor A. K. Toufeeq, Lahore, Pakistan.)*

Tuberculosis of the breast (fig. 699) occurs more often in women who have borne one or more children and usually takes the form of multiple chronic abscesses with multiple sinuses and a typical bluish attenuated appearance to the surrounding skin. The diagnosis rests on bacteriological and histological examination. Treatment with antituberculous chemotherapy should be given. Healing is usual though often delayed, and mastectomy should be restricted to patients with persistent residual infection.

Actinomycosis of the breast is rarer still, except among peasant women who work in the fields of Europe. The lesions present the essential characteristics of faciocervical actinomycosis (p. 34). If healing does not occur as a result of the systemic treatment of actinomycosis recommended on p. 34, the affected breast should be amputated.

Syphilis of the Breast.—A primary chancre of the nipple has been referred to on p. 635. Secondary lesions of syphilis in the form of mucous patches are sometimes found in the submammary fold. In the second stage also both breasts may become swollen and painful, the condition being known as diffuse syphilitic mastitis. Gumma of the breast is very rare, and almost impossible to diagnose unless there is other evidence of syphilis.

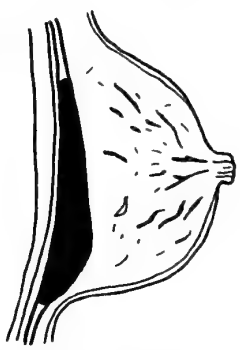

FIG. 700.—Retromammary abscess.

Retromammary Abscess (fig. 700).—Here the pus is situated in the cellular tissues behind the breast, and in the great majority of cases the abscess has no connection with the breast proper. Usually a retromammary abscess originates from a tuberculous rib, infected hæmatoma, or possibly from a chronic empyema necessitatis (p. 695), and treatment must be directed to the relief of these conditions. A submammary incision allows the breast to be retracted as necessary from the field of operation.

FIG. 701.—Mondor's disease, under the right breast.

MONDOR'S DISEASE

Mondor's disease is thrombophlebitis of the superficial veins of the breast and anterior chest wall (fig. 701) though it has also been encountered in the arm.

In the absence of injury or infection, the cause of the thrombophlebitis—like that of spontaneous thrombophlebitis in other sites—is obscure. The essential characteristic physical sign is an indurated subcutaneous thrombophlebitic cord about 3 mm. in diameter, of varying length, situated in the subcutis of the breast. Usually it is attached to the skin, and of a consistency that has been likened to that of the vas deferens. When the skin over the breast is stretched by raising the arm, a narrow, shallow subcutaneous groove alongside the cord becomes apparent. The great importance of the condition is that those unfamiliar with Mondor's disease are likely to diagnose the condition as one of lymphatic permeation from an occult carcinoma of the breast. The only treatment required is restricted arm movements, and in any case the condition subsides within a few months without recurrence, complications, or deformity.

Henri Mondor, 1885–1962. Surgeon, des Hôpitaux, Paris.

FIBROADENOSIS[1]

Ætiology.—Fibroadenosis is an aberration of those physiological changes that occur in mammary tissue at puberty (evolution) and at the menopause (involution). Although it is called an ' aberration ' it may be nothing more than a variation on the normal theme of cyclic proliferation and regression. Some women, however, worry about the lumps or the pain which it sometimes causes and thus it has become a disease ' entity '. Many women are affected without being aware of it.

Pathology.—When sectioned with a knife the affected areas in the breast are white or yellow and of india-rubber consistency, but they never present the grey tones and hard gritty texture of carcinoma. Microscopically the disease consists essentially of five features which vary in extent and degree in any one breast—these are:

(1) *Cyst Formation.*—These cysts are often long standing and vary very much in size. They contain dark mucoid material.

(2) *Adenosis.*—As shown by budding of acini and an overall increase in glandular tissue.

(3) *Fibrosis.*—The interstitial tissues are swollen and there is round-celled infiltration. Fat and elastic tissue disappears and is replaced by dense white fibrous trabeculæ. This fibrous tissue compresses the ducts and leads to cyst formation.

(4) *Epitheliosis.*—Hyperplasia of epithelium in the lining of the acini may occur.

(5) *Papillomatosis.*—The epithelial hyperplasia may be so extensive that it results in papillomatous overgrowth within the ducts and small cysts.

After decades of discussion there is still no agreement between surgeons and pathologists as to whether fibroadenosis is a premalignant condition. The majority are of the opinion that it is not, while others are equally emphatic that the epithelial hyperplasia when florid is undoubtedly premalignant. Both fibroadenosis and carcinoma of the breast are common conditions; by co-incidence, they can coexist, which in point of fact occurs in 3 per cent. of cases of fibroadenosis.

Clinical Features.—Premenstrual pain and tenderness, usually bilateral and often associated with fine nodularity of the breast, occurs frequently. In some young women the discomfort may be disabling in its severity and may be so prolonged as to lose its cyclic pattern. There are minimal abnormal changes in the breast tissue of these patients and the symptoms are self-limiting requiring no active treatment. Pregnancy and lactation nearly always produce permanent relief. The contraceptive pill will also produce a reduction in symptoms in most women although in others, previously asymptomatic, the pill may stimulate discomfort. True fibroadenosis, though it may occur at any age after puberty, is most prevalent between the ages of forty and fifty-five. Spinsters, childless married women, and multiparous

[1] Many alternative terms have been applied to this condition. Fibrocystic Disease, Mammary Dysplasia and Chronic Mastitis are in common use, the choice depending on the opinion of the individual surgeon as to the nature of the disease.

women who have not suckled their children are the usual sufferers. This suggests that the condition is prone to appear in breasts that have been denied their intended function. The patient usually complains of pain in *one* breast, worse before menstruation, or after using the arm. On examination both breasts are inclined to be nodular—the nodules being about the size of rice grains. As a rule it is possible to define the saucer-like edge of the periphery of the breast. When the breast complained of is examined between finger and thumb its texture is unusually firm, more often than not an indefinite lump can be made out, but with the flat of the hand this can be felt only vaguely. The lump is neither adherent to the pectoral fascia nor to the skin. There is no recent retraction of the nipple, but occasionally there is a serous or dark-green discharge therefrom. Fibroadenosis is sometimes more in evidence in one quadrant of the breast than in the remainder. The presence of a palpable cyst or cysts is complementary to the more general clinical findings of fibroadenosis *per se*. Frequently the axillary lymph nodes are slightly enlarged; they are not hard but are often tender.

Treatment.—Reassurance is probably the most important part of treatment. It must be explained that these changes occur at this stage of life, that they are not precancerous and a certain amount of pain is to be expected.

Support for the breast by strapping (fig. 702) or a firm brassiere worn day and night is essential. When the menopause is complete the pain will cease and the lumps disappear. From the surgeon's point of view it is important

FIG. 702.—A method of supporting the breast by adhesive strapping.

FIG. 703.—Submammary excision of the breast completed.

to confirm that the palpable lump is not a carcinoma. Mammography (p. 634) may be helpful but an excision biopsy of the local lesion may be necessary in doubtful cases.

Indications for Surgery in Fibroadenosis.—Apart from excision biopsy, surgery is only indicated when the patient is persistently disabled by intolerable pain, when there is pathological anxiety or when the degree of epitheliosis is such that there is a risk of early malignancy. The advent of synthetic breast prosthetic implants has meant that a subcutaneous mastectomy is no longer associated with the physical and emotional trauma of the standard mastectomy.

Submammary Excision of the Breast (Gaillard Thomas).—The breast, including its axillary tail, is dissected out, leaving the skin and nipple intact (fig. 703).

Theodore Gaillard Thomas, 1831–1903. Professor of Obstetrics, and Diseases of Women and Children, Columbia University College of Physicians and Surgeons, New York, U.S.A.

CLASSIFICATION OF CYSTIC SWELLINGS

Cysts of the breast occur either in the ducts or in the stroma.

Ducts —Fibroadenosis < Solitary. / Multiple.
Intracystic papilliferous carcinoma (p. 653).
Galactocele.

Stroma —Papillary Cystadenoma (p. 647).
Serocystic disease of Brodie (p. 648).
Colloid degeneration of carcinoma (p. 650).
Lymphatic cyst.
Hydatid.

(*a*) *Simple Solitary Mammary Cyst.*—The size of the cyst varies from 6 mm.–5 cm. in diameter, the seat of election being the upper and outer quadrant. Macroscopically the solitary variety (fig. 704) presents as a blue-domed cyst (Bloodgood), the colour being due to its fluid content. Although, clinically, the condition is a solitary cyst, as a rule the breast parenchyma contains a number of tiny satellite cysts. That the swelling is a cyst may sometimes be confirmed by transillumination; aspiration is required to establish the diagnosis.

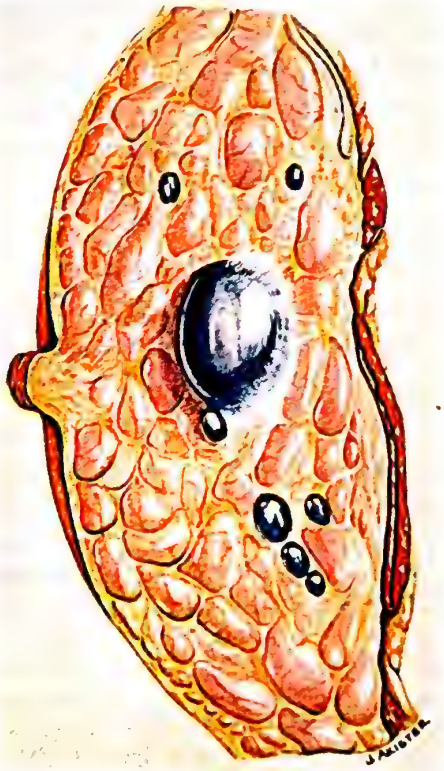

FIG. 704.—The blue-domed cyst of Bloodgood. (*After C. F. Geschickter.*)

(*b*) *Multiple Cysts.*—This is the commonest type; the cysts are usually several in number. Sometimes one sector of the breast is affected alone. If a main duct near the nipple is obstructed, a duct papilloma should be suspected.

Treatment.—*To aspirate or not to aspirate? That is the question!*

Aspiration has its dangers as an intracystic neoplasm may be missed. For this reason many surgeons regard aspiration as unsafe. is It only safe if (1) the cyst does not refill, (2) the fluid withdrawn is not blood stained, (3) there is no residual lump after aspiration (Patey), (4) The cytological examination of the aspirated fluid shows no evidence of malignant cells. If any of these criteria are not fulfilled, biopsy excision must be done, but a preliminary mammogram may be helpful to confirm the diagnosis of cancer or occasionally to support the diagnosis of fibroadenosis. A solitary cyst can be excised through a circumferentially orientated incision over the swelling. Multiple cysts are best dealt with by submammary excision of the breast.

Joseph Colt Bloodgood, 1867–1935. Surgeon, Johns Hopkins Hospital, Baltimore, Maryland, U.S.A.
David Howard Patey, Contemporary. Consulting Surgeon, Middlesex Hospital, London.

Galactocele, which is extremely rare, usually presents as a solitary, subareolar cyst, and always dates from lactation. It contains milk, liquid or inspissated, and in long-standing cases its walls tend to calcify.

Lymphatic cyst is a curiosity, and its pathology is similar to the more common lymphatic cyst of the neck (p. 572).

BENIGN NEOPLASMS OF THE BREAST

- Epithelial
  - Duct papilloma.
  - Pure adenoma (very rare).
- Connective tissue
  - Neurofibroma.
  - Lipoma.
- Mixed
  - Fibroadenoma
    - Intracanalicular
    - Pericanalicular
  - Papillary Cystadenoma.

Duct Papilloma.—The majority of these tumours are single, but bilateral examples are not rare, and occasionally two or more ducts of the same breast are the seat of a papillary growth. The usual single papilloma often has a stalk, and is situated in one of the larger lactiferous ducts.

Clinical Features.—The condition is rare before the age of twenty-five, and usually occurs in women between thirty-five and fifty. In the majority of cases bright red blood or, less often, a dark blood-stained discharge from the nipple is the only symptom. Rarely, the discharge is serous and not blood stained. On examination, a cystic swelling can sometimes be felt beneath the areola; pressure upon it will cause a discharge from the mouth of the affected duct on the nipple. No greater tragedy is enacted than when this eminently curable condition is neglected. The majority of patients are found to have a solitary papilloma which is probably benign but identical symptoms are associated with multiple papillomatosis which is undoubtedly premalignant and after months or years will be transformed into a duct carcinoma.

Treatment.—Amputation of the breast is unnecessary. It is important not to express the blood before operation as it then may be difficult to identify the duct in the theatre.

Microdochectomy (after Hedley Atkins and Brigitte Wolff).—In this operation magnifying binocular glasses have proved most helpful. A fine sewing needle, from which the point has been removed, is inserted into the duct from which the discharge is emerging (fig. 705A). The skin of the nipple is then fixed to the eye of the needle by fine silk stitches. The skin of the incision is then infiltrated with adrenaline in saline (1 ml. of adrenaline $\frac{1}{1000}$ in 80 ml. of saline). Using a pair of fine pointed scissors, a triangular area is cut 1 mm. away from the eye of the needle (fig. 705A). Skin flaps are then reflected and the needle together with the duct is excised to produce a mass of breast tissue about 2·5 cm in diameter. The lesion is nearly always situated within 4–5 cm of the nipple orifice. The whole specimen (fig. 705C), together with the needle and triangular area of skin, is removed intact. After strict hæmostasis, the wound is closed without drainage. A firm pressure bandage is applied for 48 hours.

Nearly all excised specimens are reported upon by the pathologist as "Papilloma. No evidence of malignancy"—a major triumph resulting from a comparatively minor surgical procedure.

Sir Hedley John Barnard Atkins, Contemporary. Emeritus Professor of Surgery, Guy's Hospital, London.
Brigitte Wolff, Contemporary. Formerly Clinical Assistant, Department of Surgery, Guy's Hospital London.

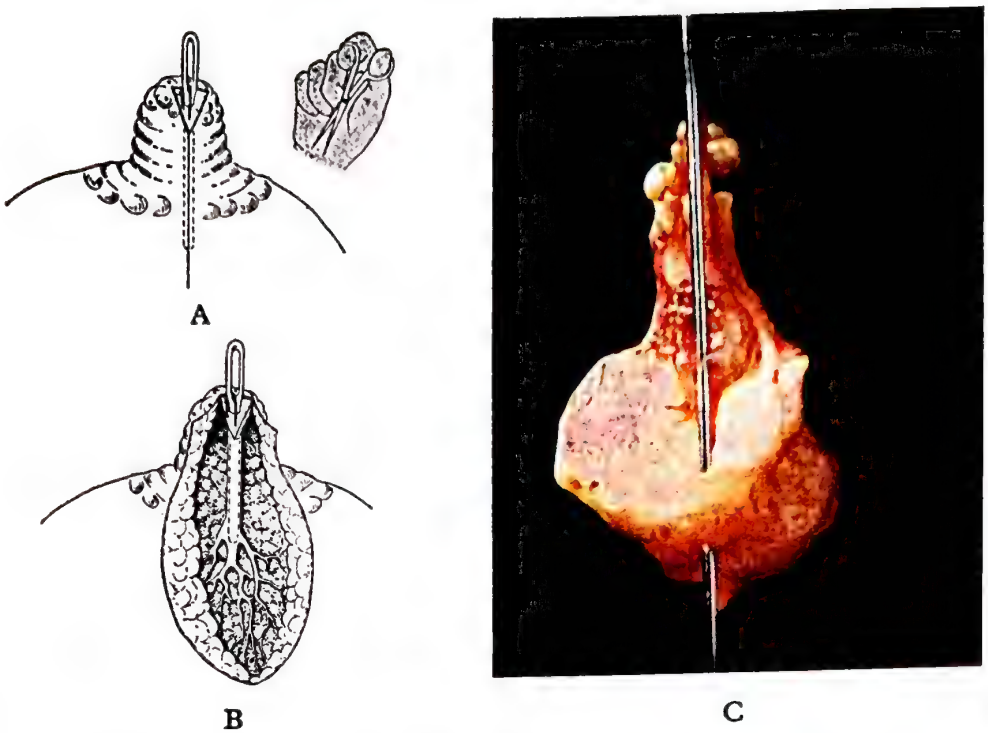

FIG. 705.—A. Blunt needle inserted into duct and stitched in position.
B. Reflection of skin flap to show needle inside duct.
C. Specimen removed intact.
(Atkins and Wolff. From British Journal of Surgery.)

Fibroadenoma of the breast is divided into two varieties, the pericanalicular and intracanalicular. They are benign tumours with epithelial elements set in a fibrous tissue stroma. In the pericanalicular type the epithelial part appears as normal ductules within a background of dense fibrous tissue. In the intracanalicular type the connective tissue stroma is less dense and projects into the duct system whose epithelial cells are flattened and form a single covering layer. A well-developed capsule is always present in both types.

Pericanalicular Fibroadenoma.—As a rule the patient is between fourteen and thirty, the peak being about twenty-one years of age, and she complains of a lump in the breast. Exceptionally, there is more than one of these neoplasms present. On examination the lump is smooth, hard, and so freely movable that it has been termed a ' breast mouse '.

Treatment is enucleation of the tumour through an incision which should be submammary; this is accomplished easily, because this neoplasm is entirely encapsulated.

Intracanalicular fibroadenoma, like the foregoing, is a definitely localised tumour. Much rarer than the hard variety, they occur in women about the age of thirty-five or forty. They are occasionally bilateral and usually lie deeply in the breast. Cystic and sarcomatous changes sometimes supervene.

Treatment.—As an intracanalicular fibroadenoma usually lies at some depth from the surface, it is best removed through an ipsilateral submammary incision (fig. 706).

Papillary cystadenoma is a swelling composed of cysts in which papillomatosis is so extensive that the cysts are almost filled and feel solid. It may cause a bloodstained discharge from the nipple. The condition is entirely innocent and local excision is all that is necessary.

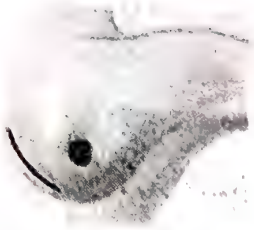

FIG. 706.—Incision for removing a soft fibroadenoma in the medial half of the breast.

MASSIVE SWELLINGS OF THE BREAST

These are:

1. Diffuse hypertrophy, which is usually bilateral (p. 637).

2. *Giant fibroadenoma* of breast in women (about 35 to 40, but occasionally in teenagers) may cause unilateral hypertrophy. This is usually retromammary, difficult to palpate, and can be removed by a submammary incision.

3. *Serocystic disease of Brodie* (*syn.* Cystosarcoma Phylloides)[1].—This may occur at any time from 40 years onwards. It is really a giant fibroadenoma which rapidly attains such a large size that the overlying skin necroses and the tumour fungates through. It is not malignant even though the term cystosarcoma implies this, but there is an undoubted association between this tumour and both sarcomatous degeneration and breast carcinoma. The surface of the tumour is unevenly bosselated with areas of softening and even fluctuation in the larger convexities. The overlying skin is thin and tense, and large veins can be seen coursing beneath the integument. As a rule the tumour is adherent neither to the skin nor to deeper structures. On occasions there is a serous discharge from the nipple. The axillary lymph nodes are not enlarged, except secondarily to infection.

Treatment.—Local excision of the encapsulated tumour is all that is necessary but in very large tumours this usually does infer a simple mastectomy.

When the Diagnosis of Carcinoma is in Doubt.—There will always be cases where the clinician cannot be sure whether a particular lump in the breast is a patch of fibroadenosis or an early carcinoma. In doubtful cases

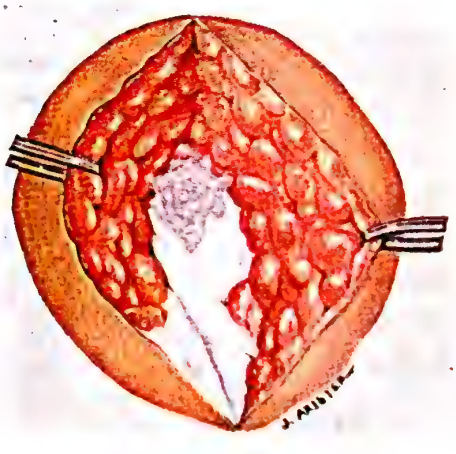

FIG. 707.—Macroscopic examination of a doubtful lump in the breast. In the lower part of the specimen the dead-white appearance of fibroadenosis is evident. In the upper quarter of this area there is a small carcinoma which cuts like an unripe pear, is greyish-white in colour and the surface of which is concave.

it is essential to advocate operation without delay. The first step must be to excise that part of the breast containing the lump. In many cases a naked eye inspection will indicate the nature of the mass (fig. 707) but where possible the diagnosis should be confirmed by immediate histological examination by

[1] Phylloides—from the Greek *Φυλλωδηϛ* = leaf-like. There are branching projections of the tumour tissue into the cystic cavities of this neoplasm. It is not a sarcoma.

Sir Benjamin Collins Brodie, 1783–1862. Surgeon, St. George's Hospital, London. Described this disease in 1840.

frozen section techniques. In the absence of this facility it is wise for the surgeon to close the incision and await a formal histological report.

Drill Biopsy.—A restricted biopsy using a high-speed drill, an aspiration or a biopsy needle may give valuable information if positive but inaccuracies occur in the interpretation of the very small specimen. It is also possible for the biopsy needle to miss a small tumour deeply set within the breast.

Mammography can help in diagnosis. Soft tissue X-rays of the breast will show an area of microcalcification or spiculation in carcinoma, whereas fibroadenosis is more diffuse and may show denser calcification.

CARCINOMA OF THE BREAST

Breast cancer is the commonest malignant disease of women in England and Wales. It causes 10,000 deaths annually. It is estimated that one in 17 of all female children born will develop the disease during their lifetime. In spite of an immense amount of investigation there is still no known cause and its natural history is obscure. Women between forty-five and fifty-five are its most frequent victims, but many factors are known to influence its frequency.

(*a*) *Racial.*—It occurs commonly in the Western World, England and Wales having the highest incidence. It is a rare tumour in the East.

(*b*) *Genetic.*—It occurs more commonly in women with a family history of breast cancer than in the general population.

(*c*) *Socio-economic.*—The incidence is higher in the lower socio-economic classes IV and V than in the higher I and II.

(*d*) *Dietary.*—In some countries it has been shown that the incidence is lower in areas of overall nutritional deficiencies.

(*e*) *Endocrine.*—It appears to be commoner in nulliparous women than in women who have borne many children and have breast fed. It is also less common in women who have their first child at an early age especially if associated with late menarche and early menopause.

(*f*) *Milk Factor.*—Although an infective agent carried in the milk has been proposed there is as yet no evidence to support this.

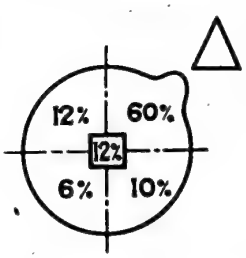

FIG. 708.—The relationship of carcinoma of the breast to the quadrants of the breast. *(Marshall and Higginbotham's statistics.)*

While any portion of the breast may be attacked, the disease commences most frequently in the upper and outer quadrant (fig. 708). Unfortunately, so often the patient states that, although she noticed a lump in her breast while washing herself, she 'took no notice of it' because it was painless. Probably the average time between the patient finding the lump and reporting it is six weeks. Women should be urged to report to their doctors as soon as a lump in the breast is discovered.

Pathological Classification.—Almost all breast cancers arise in duct epithelium.[1] Some are so malignant and rapidly dividing that they transgress barriers readily and are almost everywhere seen to be extraductal and invasive. Such cells are spheroidal

[1] Sir Hedley Atkins, p. 646.
